COLOR ILLUSTRATIONS—VOLUME 31, 1948

Plate 1. Fat emboli are shown in the retinal vessels by the use of Sudan-IV stain. Milo H. Fritz and Michael J. Hogan ..... facing page 527

Plate 2—Figure 1. (A) Large extremely vascular type of pterygium. (B) This shows the head of the pterygium transplanted beneath the bulbar conjunctiva below. (C) Thin, relatively avascular type of pterygium. (D) This eye had been operated on some months before this picture was taken. It shows vascularity and thickening of the bulbar conjunctiva. No X-ray therapy was given. (E) This eye shows a slight amount of injection following surgery and X-ray therapy. Henry L. Hilgartner, R. T. Wilson, and J. D. Wilson ..... facing page 667

Plate 3—Figure 1. Case 1. Drawings of quadrants of iris. Right, the unaffected eye. Left, the affected eye. Shaler Richardson ..... facing page 1223

SERIES 3 · VOLUME 31 · NUMBER 1 · JANUARY, 1948

ORIGINAL ARTICLES

The blood supply of the optic nerve and its clinical significance. The Second Francis I. Proctor Lecture. Derrick Vail 1
A study of the angle of bifurcation of retinal vessels. Clarence W. Wasmund 12
On the mechanism of production of massive preretinal hemorrhage following rupture of a congenital medial-defect intracranial aneurysm. A. J. Miller and J. T. Cuttino 15
The significance of the base pressure in primary glaucoma. Algernon B. Reese 25
Reading difficulty (dyslexia) from the ophthalmic point of view. George E. Park 28
The significance of the intracutaneous test for hypersensitivity to uveal pigment. Samuel D. McPherson, Jr., and Alan C. Woods 35
Functional home exercises in cases of eyestrain. Marianne Eyles 45
The vergence test—an evaluation of the various techniques. Walter H. Fink 49
Intraocular foreign bodies in soldiers. Helenor Campbell Wilder 57
The surgical correction of paresis of the superior oblique. William P. McGuire 65

NOTES, CASES, INSTRUMENTS

A new drainage operation for the relief of glaucoma. Oscar Lavine and Karl H. Langenstrass 78
A case of fixed strabismus. Luis Martínez, Jr. 80
Subretinal hemorrhage simulating sarcoma of the choroid. Joseph Laval 82
Boeck's sarcoid. Morris Kaplan 83
The problem of strabismus in childhood. James W. Smith 85

Penetrating prolonged action

TOPICAL ANESTHESIA IN
OPHTHALMOLOGY and RHINOLARYNGOLOGY

Dependable anesthesia of the mucous membranes is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives *prolonged anesthesia*. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of ½ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

ISOTONIC WITH TEARS

NEO-SYNEPHRINE® OPHTHALMIC 1/8%

FOR CONJUNCTIVAL DECONGESTION

The mild but definite vasoconstriction provided by Neo-Synephrine hydrochloride Ophthalmic 1/8% solution occurs without initial sting, since the efficient vasoconstriction is in a specially formulated vehicle that is isotonic with tears.

One or two drops repeated three or four times a day usually suffice for the relief of congestive conjunctivitis due to physical and chemical irritants; itching and smarting associated with eyestrain, and excessive tearing resulting from allergic states.

Neo-Synephrine hydrochloride Ophthalmic 1/8% solution is available in 14.8 cc. (½ fl. oz.) bottles.

OTHER OPHTHALMIC FORMS FOR OFFICE USE:

Neo-Synephrine hydrochloride Emulsion 1% and 10%
Neo-Synephrine hydrochloride Solution 1%, 2.5% and 10%

NEO-SYNEPHRINE, trademark reg. U. S. & Canada, brand of phenylephrine

EFFECTIVE *mucosal anesthesia*
OF THE EYE...

Topically applied to mucous membranes, Pontocaine hydrochloride produces anesthesia which is more powerful and more persistent than that of cocaine.

Conjunctival anesthesia is of long duration, and diminishes gradually. Frequent repetition of dosage is therefore unnecessary. In addition, Pontocaine hydrochloride is usually well tolerated.

PONTOCAINE® HYDROCHLORIDE

ISOTONIC WITH TEARS

NEO-SYNEPHRINE®
OPHTHALMIC 1/8%

FOR CONJUNCTIVAL DECONGESTION

The mild but definite vasoconstriction provided by Neo-Synephrine hydrochloride Ophthalmic 1/8% solution occurs without initial sting, since the efficient vasoconstriction is in a specially formulated vehicle that is isotonic with tears.

One or two drops repeated three or four times a day usually suffice for the relief of congestive conjunctivitis due to physical and chemical irritants; itching and smarting associated with eyestrain, and excessive tearing resulting from allergic states.

Neo-Synephrine hydrochloride Ophthalmic 1/8% solution is available in 14.8 cc. (½ fl. oz.) bottles.

OTHER OPHTHALMIC FORMS FOR OFFICE USE:

Neo-Synephrine hydrochloride Emulsion 1% and 10%
Neo-Synephrine hydrochloride Solution 1%, 2.5% and 10%

NEO-SYNEPHRINE, trademark reg. U. S. & Canada, brand of phenylephrine

EFFECTIVE *mucosal anesthesia*
OF THE EYE...

Topically applied to mucous membranes, Pontocaine hydrochloride produces anesthesia which is more powerful and more persistent than that of cocaine.

Conjunctival anesthesia is of long duration, and diminishes gradually. Frequent repetition of dosage is therefore unnecessary. In addition, Pontocaine hydrochloride is usually well tolerated.

THE BLOOD SUPPLY OF THE OPTIC NERVE AND ITS CLINICAL SIGNIFICANCE

THE SECOND FRANCIS I. PROCTOR LECTURE*

DERRICK VAIL, M.D.
Chicago, Illinois

The finer details of the blood supply of the optic nerve are not adequately covered in the textbooks or even in the reference books of ophthalmology. The larger vessels and the general anatomic relationships are discussed to be sure, but there is scant mention of their important terminals or loops. Since it is these latter that have ultimately to do with the nutrition of the optic-nerve tissue, they warrant more study in order to obtain the information we need in the interpretation of clinical findings. Schwalbe in 1887, Kuhnt in 1879, Leber in 1903, and Magitot in 1908, concerned themselves with the problem and by injection experiments demonstrated many factors that were confirmed by later observers. These in turn have added and refined our information so that a reasonably clear picture develops. It is the purpose of this paper to review the anatomy of the optic nerve and its blood supply and to touch on a few of the lesions with which ophthalmologists are concerned.

GROSS ANATOMY OF OPTIC NERVE AND CHIASM

It is necessary for a better understanding to consider briefly the gross anatomy of the optic nerve and chiasm. Schaeffer and deSchweinitz, in classic articles, have shown that there is a considerable variation in the anatomic relationship between the optic chiasm and the diaphragma sella, the sella turcica, the circle of Willis, the internal carotid arteries, the cavernous sinus, and the third ventricle. The length of the intracranial portion of the optic nerves have also been shown to vary considerably and, in association, the intracranial portion of the ophthalmic artery likewise shows varying lengths in different specimens. However, in spite of all of these variations in approximately 75 percent of individuals, the relationship of the optic chiasm to the adjacent structures is reasonably constant. The variations must be borne in mind for they may explain anomalous and puzzling clinical findings; for example, bizarre field defects in pituitary disease or bizarre pressure effects on the chiasm from calcified or aneurysmic lesions in the adjacent vessels of the circle of Willis.

According to Wolff, "the optic nerve, ensheathed in pia, runs as a flattened band from the antero-lateral angle of the somewhat quadrilateral chiasm forwards and outwards to the optic foramen. About half way along this course it receives a covering of arachnoid.

"Becoming more oval and acquiring a dural covering it traverses this foramen or canal and enters the orbit. As a rounded cord, it now runs forwards and slightly outwards and downwards in a somewhat sinuous manner (to allow for ocular move-

* Presented before the University of California Medical School, September 18, 1947.

ments) and is attached to the back of the eyeball, just above and at a 3-mm. internal to its posterior pole.

"It total length is 5 cm.; the intracranial portion being about 1 cm., the intracanalicular portion 6 mm., the intraorbital 3 cm., and the intraocular 0.7 mm.

RELATIONS

"(a) Intracranial portion. The nerve lies at first on the diaphragma sellae, which covers the pituitary body, then on the anterior portion of the cavernous sinus. Above it is the anterior perforated substance, the medial root of the olfactory tract, and the anterior cerebral artery, which crosses it from without inwards. The internal carotid artery is at first below, then lateral. The ophthalmic artery usually comes off the internal carotid under the middle of the optic nerve, but since its course here is antero-posterior, and that of the nerve outwards as well as forwards, it may appear at the inner border of the nerve before it eventually passes laterally. At any rate, in this first portion of its course it is nearer the inner border than the outer. The nearer the origin of the artery is to the optic foramen, the nearer the inner side of the nerve is placed, and vice versa.

"(b) Canalicular portion. The nerve is surrounded by its membranes, dura arachnoid and pia, but it should be carefully noted that above, these are firmly united to each other, to the periosteum and to the nerve. This forms a point of fixation of the nerve, which otherwise might easily be pushed backwards and forwards in and out of the cranium and thus liable to injury (Schwalbe). This fixation of the nerve also accounts for the fact that, in the optic canal, the cranial subarachnoid space only communicates with that around the optic nerve below.

"The ophthalmic artery crosses below the nerve in the dural sheath to the lateral side. It leaves the dura at or near the anterior end of the canal.

"Medially, the optic nerve is in relationship with the sphenoidal air sinus or a posterior ethmoidal air cell, from which it may be separated by a thin plate of bone only. Sometimes the sphenoidal sinus or posterior air cell may invade the roots of the lesser wing of the sphenoid, or even the wing itself. The nerve is then surrounded by air cells."

Onodi, in 1910, presented a monograph on the subject of "The Optic Nerve and the Accessory Sinuses of the Nose." In it he showed a number of beautiful and instructive specimens in which the optic nerve either lay bare in the sphenoid sinus, or in the posterior ethmoidal cells, or in very close proximity to these structures, separated therefrom, often by a very thin, bony wall. His work is perhaps forgotten for the most part, but bears careful study. The influence of sphenoiditis or inflammation of the posterior ethmoidal cells upon the optic nerve in the production of retrobulbar optic neuritis is pretty well discounted today. Undoubtedly, however, certain cases of this disease can only be thus explained.

Herzog, carrying this work further, showed that where the nerve is separated from the sinuses by a bony wall there is great variation in the thickness and substance of this wall. Some of the specimens showed a heavy thick bone with few lacunae; others were thin and cancellous with lacunae that connected directly with the mucous membrane of the sinuses on the one hand and the dura of the optic nerve on the other.

To continue with Wolff's description of the optic nerve:

"(c) Orbital portion. At the optic foramen the nerve is surrounded by the origin of the ocular muscles, that of the superior and internal recti being closely adherent to the sheath. It is this connection which gives rise to the pain so characteristic of retrobulbar neuritis.

"Between it and the origin of the external rectus are the two divisions of the III nerve,

the naso-ciliary, the sympathetic, the VI nerve and sometimes the ophthalmic vein or veins. Farther forwards the muscles are separated from the nerve by orbital fat.

"The naso-ciliary, the ophthalmic artery and the superior ophthalmic vein cross the nerve superiorly from without inwards. The ciliary ganglion lies to the outer side of the nerve between it and the external rectus. The long and short ciliary nerves and arteries gradually surround the nerve as it passes to the back of the eyeball."

Circulation of spinal fluid to optic nerve

The central retinal artery, which comes off the ophthalmic near the optic foramen, runs forward in or outside of the dural sheath of the nerve. The artery will be discussed later in more detail. Before doing so, it is necessary to look into the relation of the basal cisterns of the brain and investigate the circulation of the spinal fluid to the optic nerve in all of its parts.

According to Locke and Haffziger, the cisterna basalis and the cisterna magna cerebellomedullaris are to be considered as the main pathway of the cerebrospinal fluid. The smaller spaces are channels leading from the main stream. The basal cistern is made up of pars pontis, pars interpeduncularis, and pars chiasmatis. The pars chiasmatis is the portion of the cisterna basalis located farthest forward. It extends forward a short distance and posteriorly to fill in the space between the diverging limbs of the chiasm. The pars chiasmatis also extends about the chiasm, and infundibulum, as well as continuing along the optic nerves toward the globes. It may partially envelop the pituitary body. It is the deepest portion of the cisterna basalis, an important point relating to gravity and its bearing on inflammatory stasis, as well as from a therapeutic point of view.

The superior surface of the sphenoidal sinus is marked by a groove in which lies the chiasm and origin of the optic nerves. Often very thin, it corresponds topographically with the cisterna chiasmatis. Still thinner is the bony lamella making up the roof of the posterior ethmoidal cells. It is perforated by multiple openings, assuring numerous communications between the nasal fossae and the anterior meningeal spaces.

Cerebrospinal fluid is contained not in the subarachnoid space probably, but between two layers of the arachnoid, one of which is adherent to the dura and the other to the pia. It is the various enlargements of the space between the two layers of the arachnoid that form the different cisterns. Adhesions between these two layers are responsible for the collection and stasis of cerebrospinal fluid and lead the formation of subarachnoid cysts and inflammatory bands of tissue (Vail). This condition is known as adhesive arachnoiditis and occurs any place in the central nervous system.

Weed and others have shown that cerebrospinal fluid penetrates into the most minute structure of the spinal cord and brain along the perivascular spaces. So that wherever vessels go, they are surrounded by collarettes of spinal fluid. This probably applies to the chiasm and optic nerve and one can readily see that cerebrospinal fluid may accompany the septal network of capillaries in the optic nerve particularly.

However, Behr believes that there is a separation between the intervaginal space and the perivascular connective tissue of the central vessels where they enter the optic nerve and that this separation is a complete one. Thus the lacunar system of the axial-nerve part is separated from the intravaginal space. There is no possibility that cerebrospinal fluid could enter the axial-nerve part or the perivascular spaces of the intraneural vessels. Thus free fluid in the nerve tissue itself moves absolutely separately from the free fluid in the septal tissue. Hemorrhages and edema are able to spread along the septa in the nerve stem, but they do not enter the nerve parenchyma as

long as physiologic borders (pial) remain intact.

Mortensen and Sullivan have shown by means of ingenious experiments that spinal fluid passes both into the venous channels and into the cervical lymph nodes, as originally demonstrated by Key and Retzius, in 1876. Thorium dioxide, injected into the subarachnoid space of animals, passes rather readily into both the superficial and deep lymph nodes, which are visible by X ray. Batson confirmed the work of Mortensen and Sullivan, tracing the passage of the opaque mass from the subarachnoid space along the olfactory nerves to the nasal mucosa and then by way of lymph vessels along the pharynx to the upper deep cervical nodes. LeGros Clark (cited by Batson) has demonstrated that a flow in the reverse direction is possible. It has long been known that a free vascular connection exists between the nasal mucosa and the intracranial contents.

Therefore, it appears entirely probable that the protection to nerve structure by bone is only of structural significance, and bone presents no barrier to hematogenous or lymphatogenous infections, toxins, or influences.

Magitot (1908), by injection experiments, was led to believe that the intracranial and intracanalicular portions of the optic nerve have a separate blood supply from that of the intraorbital portion. The orbital portion of the nerve is supplied by branches of the ophthalmic artery, while the intracranial and intracanalicular portions are supplied by meningeal twigs arising from branches of the internal carotid, anterior cerebral, and anterior communicating arteries. Thus while the central retinal artery, which is derived from the ophthalmic, sends small nutrient vessels from the center of the nerve to the periphery, on the other hand the nutrient vessels of the canalicular and intracranial portions of the nerve are from the periphery to the center. These nutrient twigs are end-arteries. This explains the ease, if Magitot is correct in his premise, with which the papillomacular bundle, very delicate and highly differentiated, can be affected by endogenous toxins or infections. The basal cisterns thus become a common meeting ground between nerve parenchyma and blood, on the one hand, and the nasal sinuses, lymphatic systems of the sinuses, and the skull, on the other.

Vascular supply of the optic nerve

Arterial

Our understanding of the vascular nutrition of the optic nerve, although still somewhat confused, has been greatly clarified by the experimental work of Beauvieux and Ristitch (1924) and particularly of Eugene Wolff (1939) and Behr (1935). These authors have shown some discrepancies in their findings, but not enough to interfere with a reasonable interpretation.

The intracranial portion of the optic nerve is supplied chiefly by minute branches, inferiorly, from the internal carotid, sometimes the ophthalmic; superiorly, from the anterior cerebral and anterior communicating arteries. That there can exist much variation in individual cases, is evident from the work of Schaeffer and deSchweinitz. These minute vessels penetrate the pia, pass into the nerve tissue, and form the septal network of the nerve. In doing so the pial sheath is invaginated and forms the connective-tissue covering of the septal capillaries. The fibrous tubes making up the septa are not absolutely closed, according to Behr, but show spaces or small openings communicating with other bundles. The septa are separated from the nerve bundles by glial fibers. Metabolism is regulated principally or exclusively by the bordering glial membranes and the fibers connecting them. Nutriment and metabolites coming from the vessels pass first the perivascular cerebrospinal space, then through the connective-tissue covering. Fluid is collected in this mesodermal connective tissue, and what is

needed from this fluid for the nutrition of the ectodermal nervous tissue passes through the bordering glial membrane. Behr makes the point that, by this collection of free-tissue lymph fluid, a uniform uninterrupted nutrition of the nerve is maintained without quantitative imbalance.

The septa (blood vessels) of the intracranial part can be clearly differentiated between the peripheral and axial portions. In the latter, in which the papillomacular bundle is situated, the septa are thinner and more scarce (the "end-arteries" of Magitot) than in other places, and the individual optic-nerve bundles thus are larger. The nutrition of the papillomacular bundle is therefore less abundant in the intracranial part of the optic nerve than elsewhere. This anatomic finding is probably sufficient to explain the vulnerability of the papillomacular bundle.

The intracanalicular portion of the optic nerve, approximately 6 mm. long, is supplied by pial vessels arising from the internal carotid, and anastomoses with septal vessels from the orbital and intracranial portions of the nerve. Here the septal network is relatively poor. Behr also points out that in the optic canal, there are strong bridges between the optic nerve and the bone, formed by radial connections between pial sheath and dura-periosteum. These bridges are dangerous in skull fractures, injuring the nerve more often than direct injury by bone splinters.

The orbital portion is supplied by two groups of vessels derived from the ophthalmic artery. (a) Those that pierce the dura behind the entrance of the central vessels, and (b) those that anteriorly join the pial network at the site of the entry of the central vessels. Occasionally, there is found a recurrent branch of the central vessel (Wolff, Igersheimer, Abbie) which may extend backward as far as the optic foramen. Apparently, this is a rare finding.

The upper and lateral portions of the periphery of the nerve is supplied by minute branches from the ophthalmic artery, which freely anastomose with each other; with the posterior ciliary arteries at the circle of Zinn; and with the recurrent or collateral arteries that arise from the central artery as it enters the dural sheath. These latter supply chiefly the inferior periphery of the nerve.

As they pierce the dura from different directions, they traverse the subarachnoid space either at right angles or obliquely and, shrouded in meningeal tissue, form the septa.

The axial or central part of the nerve is supplied by branches from the central collateral artery (Wolff) and occasionally, as mentioned before, by a posterior axial branch from the central artery, fine branches of which anastomose with the pial network of vessels.

According to Wolff "the central artery of the retina, about 0.28 mm. in diameter, comes off the ophthalmic artery close to the optic foramen, usually in company with one or other branches, most commonly the medial ciliary artery. It runs a wavy course forward to some 10 to 15 mm. behind the globe. From this position on the under aspect of the nerve until it passes into the retina, the artery makes five bends. The first bend is found where the artery turns upwards at the right and angles, or nearly so, to pierce the dura and arachnoid, from both of which membranes it receives a covering. Having reached the subarachnoid space clothed by the above membranes, it bends forwards and also to one or the other side. After a very short course, for the artery is always cut here transversely in sections, it again bends upwards at nearly a right angle, passes through or rather invaginates the pia to reach the center of the nerve. The entering vessel is clothed by the whole thickness of the pia, and at first some arachnoid trabeculae as well, and thus takes with it the contained (pial) vessels. The fourth bend is formed where the artery passes forward in the center of the nerve. The fifth bend

is made by the terminal branches as they leave the parent vessel at the nerve head to pass into the retina.

"At about the point where the central artery pierces the dura it gives off one or more branches, which diminishes its diameter by about one third. Some of these immediately enter the pia, dividing into branches which go forwards, backwards, and circularly, and joining the pial network, send branches into the nerve. Others pass into the nerve with the central artery, running parallel with it. Although extremely well described by Kuhnt in 1879, these vessels have often been forgotten in subsequent works, and this has led to a great deal of confusion." (To emphasize the fact that they do exist Wolff suggests the name of central collateral arteries.)

"One of these vessels, larger than the rest, can be traced to the lamina cribrosa. These collateral vessels send branches into the nerve and hence get narrower as they pass anteriorly. At the point where the central artery bends forwards at the center of the nerve a branch of the collateral vessels, not of the central artery itself (Magitot) passes backwards, towards the optic foramen.

"While the collateral arteries get finer as they are traced forwards, the central artery remains the same size from its point of penetration to its bifurcation. This is due to the fact that in this portion of its course the central artery gives off no branches, or at least none of any consequence, hence in its intraneural course, takes no part in the nutrition of the nerve (Kuhnt, Behr)."

Origin of central artery

Beauvieux and Ristitch found eight variations in the origin of the central artery.

1. It springs from a trunk common to the long internal ciliary artery on its superior surface (1 in 20).

2. It arises from a trunk common to the external ciliary artery, turns around the external edge of the nerve to penetrate its superior surface (2 in 20).

3. Same as above, except the vessel penetrates the inferior surface (3 in 20).

4. It arises from a trunk that is common to external and internal long ciliary arteries and reaches the inferior surface of the nerve (1 in 20).

5. It arises from a trunk common to the long internal ciliary artery on the external or lateral edge of the nerve. It then turns around the latter and disappears in its inferior surface (5 in 20).

6. It arises from a trunk common to the short posterior ciliary artery, turns around the nerve and enters into its inferior surface (1 in 20).

7. It arises directly from the ophthalmic, external margin, after the lacrimal artery and penetrates into the nerve, sometimes in its superior surface (1 in 20) and, sometimes in its inferior surface (5 in 20).

8. It appears as the first branch of the ophthalmic and enters the nerve in its inferior surface (1 in 20).

These authors are at variance with Wolff in the conclusion that no communication exists between the central arteries and the vessels of the pia of other origin, which contribute to the vascularization of the orbital portion of the nerve, nor do they believe that there is any communication of the central artery branches and those coming from the anterior cerebrals.

The injections by Beauvieux and Ristitch of the central artery alone, have shown that the region of the lamina cribrosa is supplied by twigs from the arterial circle of Zinn (short posterior ciliary arteries). The circle of Zinn together with twigs from the central artery, supply the papilla of the optic nerve. Branches are also sent to the retina, even the fully developed cilioretinal artery. There are apparently no anastomoses between the hyaloid and sclerochoroidal systems.

Central retinal vein

The central retinal vein has numerous anastomoses with the capillaries near the papilla, the lamina cribrosa, and the choroidal system. Beauvieux and Ristitch showed that coloring matter injected into the central artery can be seen to fill the peripapillary choroidal veins, then into the vortex veins, and also into the scleral veins which contribute to form the short posterior ciliary veins. The central vein leaves the optic nerve either obliquely or parallel and then at right angles, usually proximal to the entry of the artery. From thence it becomes the venous network in the orbital fat which empties in the cavernous sinus, the superior ophthalmic vein, the inferior ophthalmic vein, or several combinations. The central vein contributes also to the plexus surrounding the optic nerve and ophthalmic artery.

According to Cone and MacMillan, the posterior central vein of the optic nerve (Kuhnt) is found in the center of the optic nerve during its course through the optic canal. It arises by confluence from numerous venules which collect blood from the orbital portion of the nerve, and it is accompanied by a strand of connective tissue which is the continuation of the pia. It leaves the stem on its lower aspect where the ophthalmic artery is found in the dural sheath. The vein then proceeds around the external margin of the nerve and empties into the cavernous sinus (Greef 1900). The finding is constant and its lumen is nearly the same size as the anterior central vein. Greef says that, according to Berlin, injury of the vessel is responsible for the hemorrhage present at times in fracture of the optic canal.

The posterior central vein of Kuhnt seems to have been neglected and almost forgotten. It may play an important role not only in injury to the nerve in the optic foramen but, by sudden compression in spontaneous subarachnoid hemorrhage, it may lead to profound and remote results in the retina.

Elschnig (1893) was the first to show that a rich anastomoses existed between the arteries arising from the external carotid and the ophthalmic artery. He conducted experiments on a cadaver and showed that after the occlusion of the internal carotid artery intracranially, water and water soluble dyes injected into the common carotid artery would, by retrograde flow appear in the distal segment of the ophthalmic artery. Walsh and King verified this important observation in a series of ingenious experiments and conclusively showed that a large collateral circulation exists between the external carotid artery and the ophthalmic artery of the same side and that there is sufficient cross circulation so that the ophthalmic artery of the opposite side may be filled from the external carotid artery.

Clinical significance

A good understanding of the nutrition of the optic nerve helps us to interpret the clinical manifestations encountered when the nutrition is interfered with. There are, of course, many gaps in our knowledge and many errors of interpretation.

The demyelinating diseases, of which multiple sclerosis is the most common, are poorly understood. There is some glimmer of hope in the recent studies of Putnam and his co-workers. These investigators bring strong evidence to bear upon the premise that thrombosis of venules are essential links in the chain of causation of multiple sclerosis and encephalomyelitides. The premise is based upon the following evidence: (1) Experimental. (2) Human cases—similar lesions in human material following thrombosis of veins of certain size or compression of a pial vein by a tumor. (3) Thrombi, usually in venules and veins, have been observed in a large proportion of cases of acute encephalomyelitis and

in the more acute lesions of multiple sclerosis by various authors over the past half century. (4) Exogenous factors—infection, pregnancy, trauma, and chilling increases the coagulability of the blood to produce thrombophlebitis. These factors correspond closely with those that appear to precipitate the onset or exacerbations of multiple sclerosis. (5) The clothing mechanism of the blood is abnormally labile in cases of multiple sclerosis. Obstructive changes (Rucker) have been observed in the retinal vessels, some of which might be interpreted as thrombotic. Abnormalities can be observed in the capillaries of the nail bed in a majority of cases.

Sheinker studied 20 cases of multiple sclerosis. In all cases the early stage of plaque formation showed positive correlation between the lesion and vascular changes that are probably thrombotic.

There is also some evidence that a tendency to thrombosis may in some measure be allergic and Foster-Kennedy has described cases of acute retrobulbar optic neuritis which were definitely allergic. Putnam and his co-workers treated 43 patients, who had multiple sclerosis, with dicouramin. The results are promising. The dramatic response to blood letting or draining of the sinuses, especially the sphenoid, that is seen in some cases of retrobulbar optic neuritis suggests that the circulation in the optic nerve has a lot to do with the condition. It is also logical to assume from the description of this circulation that has been given, that the intracranial portion of the optic nerve is the primary locus of the disease. Rønne has described a number of cases of acute retrobulbar optic neuritis where the lesion was located in the chiasm; and careful field studies by other observers including myself have supported his findings.

Similar arguments can be directed toward the pathogenesis of other forms of neuritis and the toxic amblyopias. That is to say, a suppression of function of the papillomacular bundle, more commonly in the intracranial portion, due to interference with its blood supply.

The papilledema that is seen on rare occasions in cases where only a focal infection can be found is presumably on a thrombotic basis. The removal of the focus and the establishment of collateral circulation results in improvement (Frost).

Verhoeff and Simpson report a remarkable case of tubercle in the central vein associated with periphlebitis retinalis in the other eye. Other tubercles were found in the vaginal space, in the arachnoid, pia, and in the episcleral tissue, 1.8 mm. outside of the subvaginal space. Their patient had a hemorrhagic glaucoma, the cause of which was not determined until histologic examination. The Mantoux test was negative.

Goldstein and Wexler described a case of bilateral atrophy of the optic nerve due to periarteritis nodosa. Histologic examination showed an affected postciliary artery entering the dura of the optic nerve and proceeding into the region of the lamina and anterior segment of the nerve. The optic disc contained many inflammatory round cells and glial tissue. The infiltration extended behind the lamina and the nerve fibers were atrophic. In Von Herrenschwand's case the periarterial nodes occurred particularly when the ciliary artery altered its direction, such as at its entrance into the sclera, its course through the lamina cribrosa, and on its course from the sclera toward the ciliary body.

The optic atrophy of tabes undoubtedly is associated with a nutritional disturbance of the nerve fibers due to the syphilitic involvement of the blood vessels, as Moore and Woods have so ably argued. Its relationship to syphilitic arachnoiditis has not yet, however, been entirely disapproved. It is entirely possible that the pial network of vessels of the optic nerve, especially in its intracranial portion, may be the first site of the lesion, thus explaining the peripheral

contraction of fields of vision in tabes. Stargardt found, in 10 cases of syphilitic optic atrophy, earliest change in the chiasm and intracranial portion of the optic nerve. There was evidence of inflammation in the pial investment and some gliosis of the superficial parts of the nerves. He noted that the myelin sheaths became degenerated before the axis cylinders. Behr, in discussing the careful study of nine cases of optic atrophy due to syphilis, noted that the primary change was an inflammatory process in the connective-tissue system of the intracranial portion of the nerve and of the blood vessels in relation to this. The myelin sheaths were affected before the axis cylinders. Greenfield and Epstein corroborated Stargardt's observations fully and remarked that the superficial fibers in the optic nerve were first affected, that the myelin was more affected than the nerve fibers, and finally that inflammatory changes in the meninges were much more evident in the intracranial than in the intraorbital portion of the optic nerves.

Gradle (1917), in discussing glaucomatous cupping and atrophy of the optic nerve in cases where the intraocular pressure was never elevated, regarded it as a special disease that began as an optic neuritis with formation of the cavernous changes in the optic nerve described by Schnabel. Loewenstein described vascular changes (thrombosis) in the optic nerve which led to cavernous degeneration, calcified drusen, and sclerotic plaques. He and Garrow also described further examples of this condition which they termed spongy degeneration and cavitation of the optic nerve. Knapp, Elwyn, and others believed that their cases showing the clinical picture of glaucoma without ocular hypertension were secondary to compression by calcified carotid arteries upon the optic nerve. Recently Rintelen, in a classic article on the arteriosclerotic atrophy of the optic nerves, described the histologic findings in 6 out of 35 cases. The atrophic conditions in the nerve were localized chiefly in the anterior third of the nerve, in the part that contains the central vessels. He also found in one case an area that he called "red malacia." Arteriosclerosis of the central artery has little effect on the nerve. The damage is due to the sclerosis of the small nutrient vessels. Subsequent to this local malnutrition, cicatriced areas occur with disappearance of the nerve fibers and secondary glial proliferation. He believed that the arteriosclerotic malacia of the optic nerve is of much more importance than the calcification of the carotid arteries. He distinguishes three forms of arteriosclerotic atrophy of the optic nerve: (1) A benign, slowly progressive, diffuse atrophy, especially limited to the periphery of the nerve. This occurs in the aged and is clinically marked by a moderately cupped and pale optic disc. (2) A malignant, rapidly progressing atrophy which often shows exacerbations, occurring mostly in young patients with arteriosclerosis or hypertension. This form is caused by the malacious areas in the anterior part of the nerve and may have the clinical aspect of a glaucoma without ocular hypertension. (3) A clinically less important atrophy of the optic nerve caused by a direct compression of the nerve by calcified carotid arteries.

It is entirely probable that vascular disease of the nerve as previously described may account for the progress of cupping, atrophy, and field changes that frequently continue after the ocular hypertension has been quite controlled in true glaucoma, especially in the aged.

Drusen bodies in the papilla are hyalin formations. They are formed locally and not directly from surrounding tissue. The first anatomic signs of drusen formations are found in the smallest vessels in front of the lamina cribrosa. Before hyalin is present, the walls of these vessels become thickened. Drusen bodies are found else-

where in the optic nerve and may, by pressure or interference with the nutrient vessels, disturb the function of the nerve fibers. Tuberose sclerosis is closely allied to this process.

The retinal and preretinal hemorrhages found in cases of subarachnoid hemorrhage have created much speculation as to their origin and mode of production. The evidence is pretty conclusive that there is no direct extension of blood through the optic disc from the distended hemorrhagic vaginal sheath. Ballantyne, whose recent studies have thrown further light upon this condition, believes that, while it may be a physical possibility for blood to pass through the optic foramen, it does so only in exceptional cases. He as well as Bucklers and Greear and others think that the sudden rise of intracranial pressure produces a venous stasis which in turn leads to hemorrhages throughout the orbital and ocular structures. Hemorrhage occurs in the subdural and subarachnoid spaces, and the blood in the latter situation, by putting pressure and tension on the central retinal vein, accounts for the retinal and vitreous hemorrhages.

It must be considered also that the pressure upon the posterior part of the globe by the distended subarachnoid space compresses the veins that so freely anastomose around the optic nerve at its insertion into the globe. The role of the posterior central vein of the optic nerve in the production of these retinal hemorrhages has not been studied, so far as is known.

It has been pointed out that there is a rich anastomoses between the arteries arising from the external carotid and the ophthalmic arteries. This explains the number of cases of retained vision where the ophthalmic artery intracranially has been obliterated surgically in the treatment of vascular aneurysms of the circle of Willis (Dandy, Adson).

The cases of blindness and optic atrophy occurring rather infrequently in head injuries require some comment. There is no question but that there is complete degeneration of the axis cylinders both above and below the lesion in severe cases. Most all authors agree that the primary site of injury to the optic nerve lies in the intracanalicular portion and sometimes in the intracranial portion of the nerve, owing to their immobility, and this position of the lesion corresponds with the appearance of pallor of the disc from 14 to 21 days after the injury. The damage to the nerve may be the result of (a) subvaginal hemorrhage within the optic foramen, with pressure on or tearing of the nutrient vessels of the optic nerve, (b) intraneural hemorrhage, (c) fracture, with perhaps tearing of the nervous tissue, (4) later by callus formation within the optic foramen, following a fracture through the anterior clinoid (Turner, Lillie and Adson, Rodger). The role of the posterior central vein in this condition has been mentioned (Berlin), and it must take an active part in the associated hemorrhages from the nutrient and septal hemorrhages that undoubtedly occur at the time of the injury.

These clinical conditions are but a few of the important lesions affecting the optic nerve that a knowledge of the minute details of the nutrition of the optic nerve helps to interpret. Further studies are necessary and it is hoped that this paper will serve as a stimulus to those studies, particularly experimental ones.

A STUDY OF THE ANGLE OF BIFURCATION OF RETINAL VESSELS*

CLARENCE W. WASMUND, M.D.†
Brooklyn, New York

It is often stated that in sclerosis of the retinal vessels the arterial branches diverge from the stem vessel at an acute angle. Lurje[1] mentions that in sclerotic states in which hypertension is present the arteries are usually straight and branch acutely.

Friedenwald[2] (using the evidence presented by Hertel and by Coats that the neural portion of the central artery shows more sclerotic changes than the retinal portions) states that the straightness of the retinal arteries and their tendency to branch at acute angles must be due to longitudinal shrinkage in the central vessel behind the disc, which draws the branches of the first and second order onto the disc.

To add credence to this hypothesis, he examined the fundi of two groups of elderly arteriosclerotic patients—one group in whom the retinal arteries were straight and narrow and one group in whom they were straight and tortuous—counting the number of major branches which crossed the disc margin. The group in whom the retinal arteries were straight and narrow showed an average of 5 to 6 major branches crossing the disc margin while the group in whom the retinal arteries were straight and tortuous showed an average of slightly better than four. This appears to be the only evidence in the literature to substantiate this oft-quoted statement.

Friedenwald, however, believes that, in the condition which he designates arteriolar sclerosis, the angle of bifurcation is more obtuse. In his Doyne Memorial Lecture he stated: "The larger retinal arteries in early cases (of arteriolar sclerosis) are full and tortuous and often show a widening of their reflex band associated with a coppery appearance of blood column. . . . In late stages of this condition the larger arteries also show marked lesions, such as beading, increased visibility of their walls, and even diffuse constriction of caliber. A point of distinction between these cases in their late stages and those of the group next to be described (arteriosclerosis with hypertension) is that the larger arteries in arteriolar sclerosis usually remain tortuous and branch at right angles even when they have become greatly narrowed, while in the next group they are generally quite straight and branch at acute angles." However, no evidence is presented to support this concept.

PLAN OF STUDY

In order to assemble some specific data on this subject, a plan of study was drawn up. The angles were measured from photographs of normal and arteriosclerotic fundi

* From the Department of Ophthalmology, Long Island College of Medicine and the Long Island College Hospital.
† Resident in Ophthalmology, Long Island College Hospital.

for comparison. Bedell's *Atlas of Fundus Photographs*,[5] was used since it was thought that the results would be less prejudiced than if studies on a selected series of pictures were made. Those photographs were selected in which the branches of the retinal artery were most clearly in focus. Because of the lack of detail in these reproductions, it was found impossible to measure accurately the angle by direct application of a protractor. Therefore, each photograph was enlarged by means of a reflection projector on a screen of white paper. The arterial pattern was traced on this paper. In addition to enlarging the photographs from 3.5 cm. to 23 cm., this procedure proved advantageous in that it transferred the photograph to white paper where trigonometric calculations could more readily be made.

Calculation of angles

In calculating the angles at the first, second, and third bifurcations of the central arteries, straight lines were drawn from the junction of the branches and stem, following the centers of the vessels. In this way tortuosity of the two arterial limbs distal to the bifurcation did little to influence the fairly accurate construction of the angle. Each line was extended to exactly 5 cm.; the ends were joined by another line, creating an isosceles triangle. A perpendicular was dropped from the vertex of the angle to this line which necessarily bisected the angle.

Using elementary trigonometry, either half of the bisected angle was readily calculated; that figure, multiplied by two, revealed the size of the angle in question. In this way, 70 angles of normal fundi and 23 angles of arteriosclerotic fundi were measured. Contrary to expectations, the averages showed a normal average angle of 70 degrees and an arteriosclerotic average angle of 82 degrees.*

In other words, in this small series, and by the methods employed, the arteriosclerotic vessels showed a more obtuse angle than did the normal vessel angles. This result was quite contrary to the generally accepted statements found in the literature already referred to with the possible exception of that made by Friedenwald. Individual variation in the size of the angles in different fundi was found to be very great in both normal and arteriosclerotic fundi, ranging from a low of 37 degrees to a high of 106 degrees in normal fundi, and from a low of 45 degrees to a high of 108 degrees in arteriosclerotic fundi.

Comments

Interesting is the fact that in those few cases where several bifurcations were measured from the same fundus, individual variations were not nearly so marked. Of 18 normal fundi in which several angles were measured in each, in 9 the angles differed by less than 10 degrees and in 15 by less than 20 degrees; of the 6 arteriosclerotic fundi so measured, in 2 the angles differed by less than 10 degrees and in 5 by less than 20 degrees.

Although every precaution was taken to standardize the technique there were many instances in which the construction lines following the long axis through the center of the vessels offered a number of choices; thus, others repeating the study might arrive at somewhat different averages. However, since this error occurs equally in measuring both normal and arteriosclerotic fundi, it seems reasonable to assume that others might find a similar ratio between the two

* The standard deviation of the measurements for the bifurcation angles of 70 normal retinal arteries is 14.2; for the 23 angles of bifurcation of sclerotic arteries the standard deviation is 14.5. The standard errors are, therefore, 1.7 and 3.0, respectively. For normal arteries the angle of bifurcation may be given as 69.8 degrees $\pm$1.7 degrees; for the sclerotic arteries, 81.5 degrees $\pm$3.0 degrees. The standard error of the difference is 3.5, and the ratio of the difference of the means to the standard error of the difference is 3.3, indicating a significant difference between the two groups.

groups of fundi. In several cases, the outline of the retinal vessels was difficult to visualize; perhaps in this way error might have been introduced.

Discussion

As mentioned earlier in this paper, Friedenwald stated that longitudinal shrinkage of the central artery behind the disc was responsible for the acute angles reputedly found in retinal arteriosclerosis. It seems equally convenient to explain the more obtuse angles found in this series by the converse condition; namely, a longitudinal stretching of the central artery.

Thoma[3] believed that the first change in arteriosclerosis was a loss of the normal elasticity and contractability in the walls of the arteries; consequently the arteries become lengthened. Since no increase occurs in the size of the eye, the elongated arteries must adapt themselves to the environment by becoming tortuous.

Duke-Elder[4] also believes that the elongation of the arteries causes an increased degree of tortuosity but ascribes the elongation to the hypertrophic thickening of the vessel walls. He states that if the thickness of the walls is increased, the length of the vessel must also increase, for it appears unlikely that the additional tissue would be deposited in the vessel wall in one plane only.

Perhaps this arterial lengthening, which is thought to be the cause of tortuosity, is the cause of the more obtuse angles that this short series of measurements seems to indicate are present in arteriosclerosis. In order to determine whether this longitudinal stretching does occur, an attempt was made to measure the length of the central artery, on the fundus photographs, from its point of emergence from the disc to its first bifurcation. However, because most of the vessels in the disc area were out of focus and therefore poorly defined, no accurate measurements could be made.

One might more reasonably postulate a shrinkage of the retina itself with retraction toward the nervehead. This would tend to widen the angle of the relatively stiff vessel tree as the branches would be flexed away from the more resistant trunk vessel. Moreover, the branches are anchored to the retina by their capillaries; whereas, we know that there is a capillary free zone about the arterial trunks. Retraction toward the periphery would not be expected because we know that the retinal periphery in arteriosclerotic subjects shows degeneration, cyst formation, and other signs of atrophy and thinning.

It is evident that while the results are quite contrary to the generally accepted statements, they appear to be in accord with Friedenwald's observations on arteriolar sclerosis. However, since Bedell deals only with arteriosclerotic fundi in his *Atlas,* we are able only to report on this condition. Whether perhaps a few or many of Bedell's cases are in reality cases of arteriolar sclerosis as defined by Friedenwald is an open question; certainly one cannot tell from the brief descriptions or from the photographs. We are able, therefore, only to say that in this study of arteriosclerotic fundi, as selected by Bedell, it was found that the arterial branches came off more obtusely than did the arterial branches of normal fundi of a larger series.

The fact that in normal fundi the angles vary from 37 to 106 degrees, and in arteriosclerotic fundi from 45 to 108 degrees precludes the possibility of using the size of the angle of bifurcation as an aid in diagnosis. However, if serial funduscopic photographs were taken of individual cases over a period of years, perhaps then the measurement of the angle of bifurcation by the method described in this study might prove a reliable index of the progress of sclerosis.

Summary

Using Bedell's funduscopic photos the angle of bifurcation of 70 normal retinal

arteries and of 23 arteriosclerotic retinal arteries was measured. The average angle in the normal fundi was found to be 70 degrees and in the arteriosclerotic fundi 82 degrees; this appears to be quite contrary to the generally accepted statements found in the literature. A brief discussion of the possible mechanisms responsible for the more obtuse angles in arteriosclerosis is presented.

Acknowledgement is made to Dr. John N. Evans for his encouragement and guidance in the preparation of this paper.

ON THE MECHANISM OF PRODUCTION OF MASSIVE PRERETINAL HEMORRHAGE FOLLOWING RUPTURE OF A CONGENITAL MEDIAL-DEFECT INTRACRANIAL ANEURYSM*

A. J. Miller, M.D., and J. T. Cuttino, M.D.
Durham, North Carolina

Two possible explanations have been offered for the preretinal hemorrhages commonly associated with ruptured congenital medial-defect aneurysms of the cerebral arteries. In one of these, the older, it is postulated that blood passes by direct extension from the subarachnoid space along the optic nerve through the lamina cribosa to infiltrate the retina[1, 2] (fig. 1). In the other, a more recent and generally accepted explanation, extravasated blood is thought to pass along the perineural or intervaginal space of the optic nerve and to constrict the central vein of the retina as it leaves the nerve, [3, 19-21] thus producing marked engorgement and eventually rupture of the preretinal veins (fig. 2). We have recently had the opportunity to make a detailed study of a case of preretinal hemorrhage of the type in question. In reviewing the anatomy of the eye especially with reference to the vascular arrangement, we have been impressed by certain venous relationships which appear to serve as an entirely satisfactory and quite probable basis for a third possible explanation of the intraocular hemorrhage (fig. 3).

Case report

History. The patient, a 38-year-old white housewife, was in good health until the early morning of the day of death, at which time she complained of sudden, severe pain in the frontal region of the head. This was followed by vomiting and convulsions. She was hospitalized 2½ hours after onset of the pain. There was no history of trauma or of similiar episodes. Her mother was said to have died of a "stroke" two years previously.

Examination. The patient was semiconscious, uncoöperative, and responded

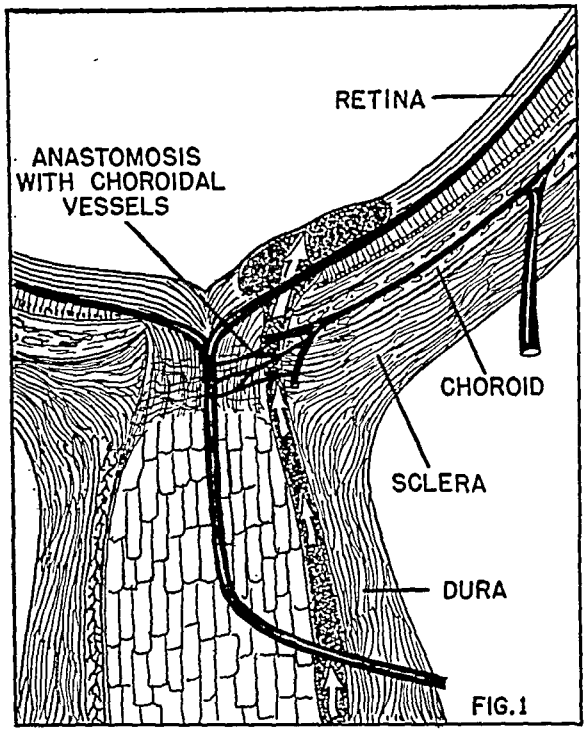

Fig. 1 (Miller and Cuttino). Diagram of mechanism of production of preretinal hemorrhage, as postulated by Symonds. According to this hypothesis, blood in the intervaginal space was thought to be of sufficient pressure to traverse the lamina cribrosa and appear in the retina.

poorly to questions. Blood pressure was 125/80 mm. Hg, pulse 60, respirations 24 per minute, and temperature 36.6°C. The skin was cold and clammy. She moved her right arm about aimlessly, but did not move her left arm. Repeated extensor spasms followed episodes of hyperventilation.

Eye Findings. A slow lateral nystagmus of the right eye was present. The right pupil was larger than the left, and both were fixed. There was a fixed left lateral gaze. Funduscopic examination showed marked protrusion of the right optic disc with a large flame-shaped hemorrhage virtually obliterating the temporal half of the right fundus. The left eye was normal. Right facial paralysis and ptosis of the right eyelid were questionable. The reflexes on the left side of the body were slightly reduced with a positive Hoffman's sign on the right.

Laboratory findings. The pertinent laboratory findings were as follows: Hgb. 8.3 gm.; W.B.C., 31,450, R.B.C., 3,480,000; platelets, normal; spinal fluid grossly bloody, contained 1,300,000 R.B.C. and 120 W.B.C. The initial cerebrospinal-fluid pressure was 570 mm. and the final pressure, 230 mm. of water.

Course of disease. Shortly after admission an extreme extensor rigidity similiar to that of the decerebrate animal followed one of the convulsions. The pupillary reflex returned, and reëxamination revealed that bilateral Hoffman and Babinski signs, ankle clonus, and equal but hyperactive reflexes had developed. Blood pressure was now 170/110 mm. Hg. The patient grew progressively weaker and became comatose. Secretions collected in the upper respiratory tract, requiring frequent aspiration. The pulse rose to 152 per minute and the temperature to 39°C. Terminally the respiration movements became slow and deep. The patient died 12 hours after onset of the severe frontal headache.

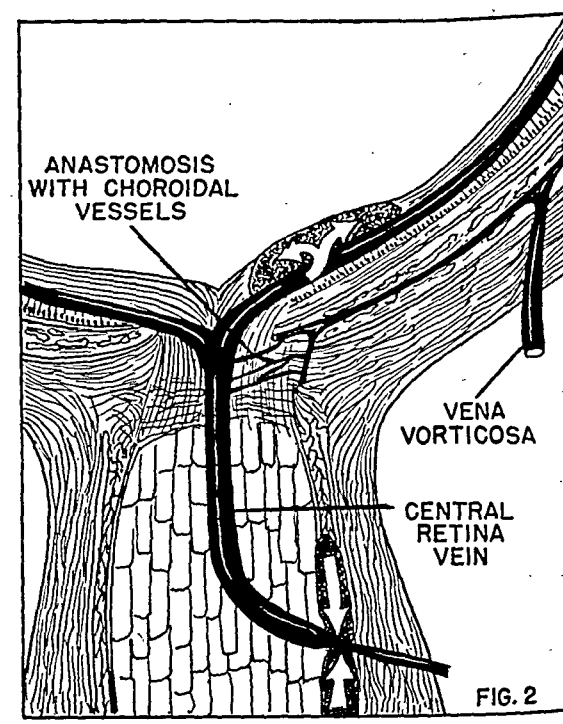

Fig. 2 (Miller and Cuttino). Diagram of mechanism of production of preretinal hemorrhage, proposed by Paton and Holmes. Here the hemorrhage results from stasis produced by compression of the central retinal vein as it leaves the optic nerve.

Autopsy findings. When the cranial cavity was opened at autopsy, the dura was under increased tension. Attached to its right under surface was a meningioma, 8 mm. in diameter. Over the convexity of the brain was a diffuse subarachnoid hemorrhage. The inferior surface of the brain likewise was covered by hemorrhage; this was especially prominent in the vicinity of the right internal carotid artery and on the inferior surface

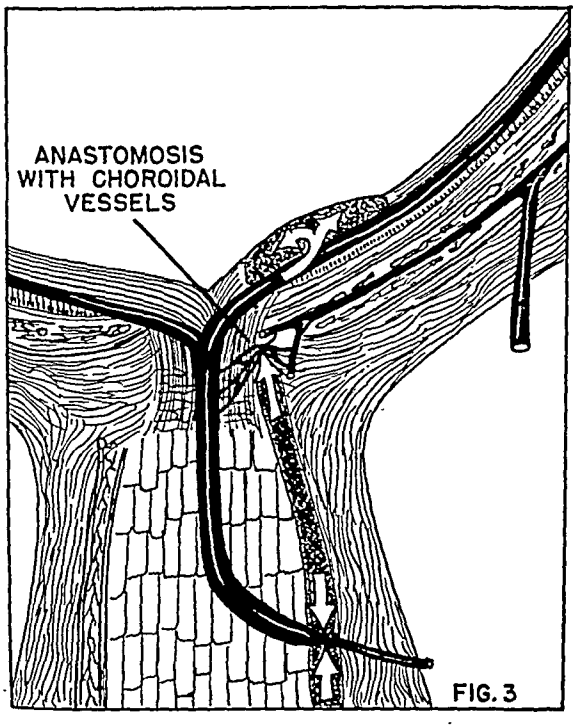

Fig. 3 (Miller and Cuttino). Diagram of the mechanism of production of preretinal hemorrhage, as outlined in Figure 2, but with the modification of compression of the choroidal anastomosis, as suggested in the text.

of the right frontal lobe. The right internal carotid artery was dilated throughout its intracranial course. At the common site of origin of the anterior cerebral, middle cerebral, and posterior communicating arteries was a saccular aneurysm, 1 cm. in diameter, with an anterolaterally situated rupture in its thin wall. Corneal sections of the brain revealed a 2-cm. deep penetration of the temporal lobe, directly opposite the aneurysm, by hemorrhage.

Nervous-system dissection. The cranial

Fig. 4 (Miller and Cuttino). Right eye on section showing preretinal hemorrhage and hemorrhage about the optic nerve. The hemorrhage about the optic nerve is not continuous with the hemorrhage of the retina.

nerves were not remarkable except for the right optic nerve. This was surrounded by blood as it entered the optic foramen. There was also clearly defined hemorrhage in the central portion of the nerve. As demon-

Fig. 5 (Miller and Cuttino). Right eye showing preretinal hemorrhage confined within the retina and the relationship of the intervaginal hemorrhage to the lamina cribrosa. Hematoxylin and eosin (×17).

strated by serial cross sections at 2-cm. intervals, the latter was confined to the intracranial segment of the nerve. Throughout its orbital course the nerve was surrounded by blood, which lay in the intervaginal space. Hemisection of the right eye showed hemorrhage in the nasal half of the retina, which did not connect with that in the intervaginal space of the nerve (fig. 4). The left eye showed nothing unusual. Further dissection of the central nervous system was noncontributory.

The somatic organs showed an early pneumonia, left ovarian cyst, and right ventricular dilatation.

Microscopic findings. In microscopic preparations the aneurysm was found to be a fibrous connective-tissue sac whose thin walls contained neither muscle nor elastic tissue. Interrupted serial sections of the optic nerve and eye were prepared. The hemorrhage in the center of the optic nerve was thus shown to be small and confined to the intracranial segment of the nerve. The hemorrhage in the subarachnoid and subdural spaces was traced uninterruptedly throughout the course of the nerve to an abrupt termination at the lamina cribrosa (fig. 5). There was no connection between the hemorrhage in the intervaginal space of the optic nerve and that in the retina. The central retinal artery and vein were not constricted as they left the optic nerve, nor were they dilated in their intraneural course. The optic nerve was edematous. Sections of the eye showed moderate papilledema and numerous dilated preretinal veins. The intraocular blood noted grossly was confined by the internal limiting membrane to the retina; there was no extension into the vitreous chamber (fig. 6). One of the dilated preretinal veins located in the nerve fiber and ganglionic cell layers and in juxtaposition to the hemorrhage was clearly ruptured at a point where its wall had become necrotic (figs. 6 and 7). The vessel was obviously the origin of the preretinal hemorrhage. The central artery and vein were

somewhat dilated in the region of the optic disc. No dilatation of the choroidal vessels was observed.

Other microscopic sections confirmed the findings of pneumonia and the left cystic ovary.

Anatomic diagnosis. The following anatomic diagnosis summarizes the findings in the case: Ruptured congenital medial-defect aneurysm of the right internal carotid artery at its termination; massive subarachnoid hemorrhage, with hemorrhage in the optic nerve at its point of entry into the intraorbital space of the right eye; hemorrhage along the course of the right optic nerve in the subarachnoid and subdural spaces; rupture of a preretinal vein with associated preretinal hemorrhage in the right eye; right ventricular dilatation of the heart; anemia; hemorrhage, acute congestion, and early pneumonia of both lungs; left ovarian cyst; recent corpus luteum; abdominal adhesions; meningioma.

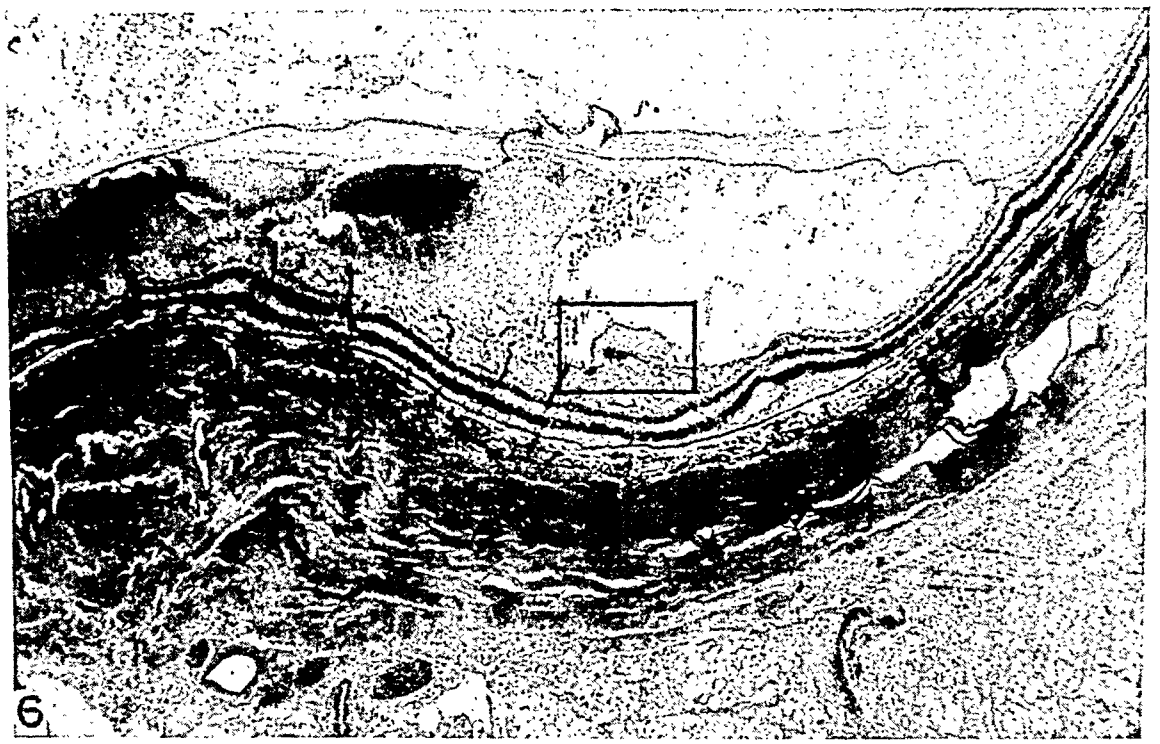

Fig. 6 (Miller and Cuttino). Preretinal hemorrhage at the site of rupture of the preretinal vein. The confinement of this hemorrhage by the internal limiting membrane of the retina is well shown. Hematoxylin and eosin (×35).

The dynamics of preretinal hemorrhage

To acquire a satisfactory understanding of the possible mechanisms responsible for preretinal hemorrhages a detailed knowledge of the vascular supply of the eyeball and optic nerve is essential. The ophthalmic artery, in supplying the eyeball, has two components; namely, the central artery of the retina, which supplies part of the optic nerve and all of the retina, and the ciliary artery, which supplies the remainder of the eyeball.[4, 5] Shortly after its entry into the proximal part of the optic nerve the central artery of the retina gives off a recurrent branch. In its intraneural course it supplies branches to the choroid at the level of the lamina cribrosa. These branches enter numerous capillary plexuses, through which they eventually anastomose with branches of the anterior ciliary artery in the region of the ciliary process. The central artery then continues to the optic disc, where it divides

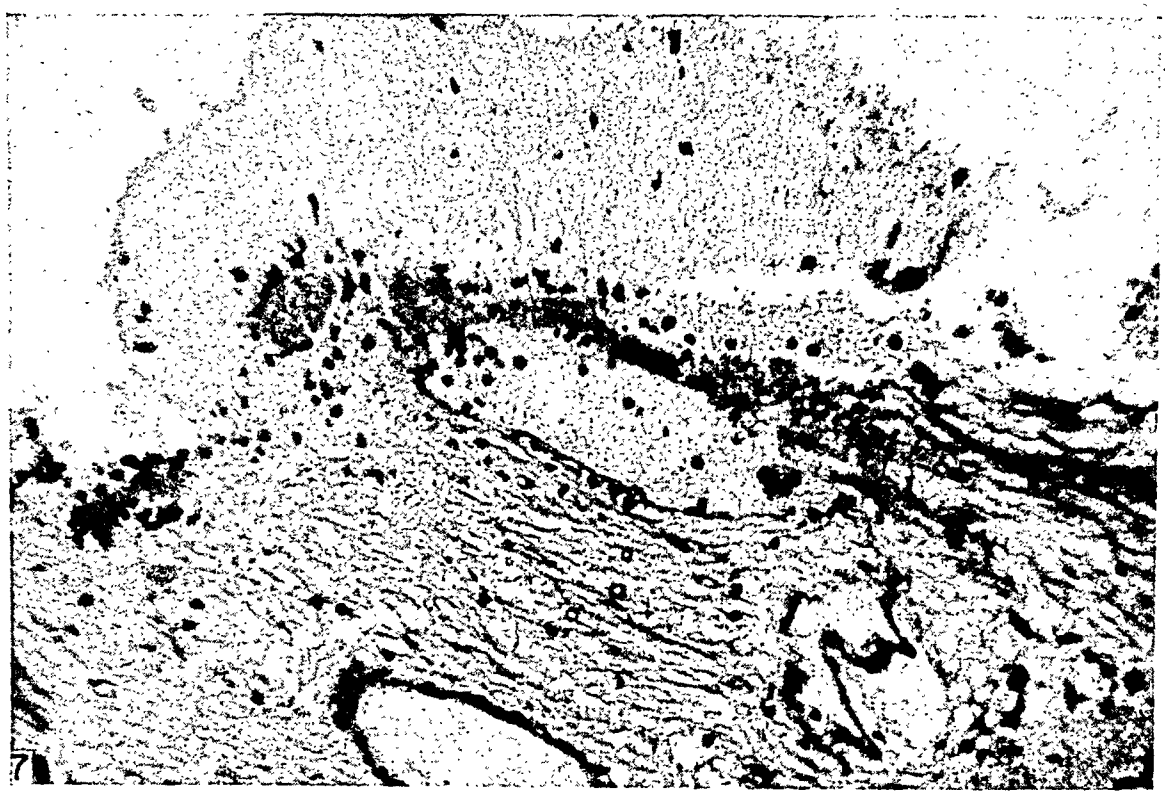

Fig. 7 (Miller and Cuttino). High-power view of the ruptured preretinal vein, as shown in bracketed zone of Figure 6. Half of this vessel wall shows necrosis and is the origin of the hemorrhage. Hematoxylin and eosin (×250).

into two branches, directed upward and downward, respectively. Each of these two primary branches divides into nasal and temporal secondary branches. Divisions of the latter follow a dichotomous pattern.[26] The vascular network into which the central artery ultimately breaks up in the retina has no connection with any other artery in the eyeball.[5, 26] Thus, it is generally agreed that the terminal branches of the central artery are end-arteries, analogous to the subpial arteries of the brain. These terminal branches lie against the inner layers of the retina; namely, the plexiform and ganglion-cell layers, from which position they extend outward to the inner nuclear layer.[27] The outer layers of the retina are nourished by the transudation of fluid from the choroid vessels.[5, 26]

The venous drainage of the retina parallels the arterial supply; there are no anastomotic connections of the veins in the retina with either those of the choroid and sclera or those of the ciliary body. These retinal veins all drain into the central vein at the optic disc. The latter, as it passes through the lamina cribrosa, has a limited anastomosis with the choroidal veins;[5, 26] except for this anastomosis, the central vein is considered an end-vein. The central artery and vein lie parallel and adjacent to each other in the center of the optic nerve for a distance of 5 to 20 mm. behind the eyeball.[8, 9] At this point the vein usually takes a position at right angles to the artery and reaches the periphery of the nerve nearer the eyeball than the point of entry of the artery into the nerve. Most commonly it runs for a variable distance in the subarachnoid space before transversing the intervaginal space and piercing the dura. The central artery, on the other hand, leaves the dura, crosses the intervaginal and subarachnoid spaces immediately and enters the nerve. Upon reaching the center of the nerve, it turns anteriorly, forming a 90° angle, and

takes its position adjacent to the vein. The central vein, thus, usually has a longer course in the subarachnoid space of the nerve than has the artery. The vein then proceeds proximally into the orbit to drain most commonly into the cavernous sinus.[5, 10] However, on at least one side anastomosis with the ophthalmic veins is present, thus making it possible for blood to drain either into the angular and facial veins or downward through the inferior orbital fissure into the pterygoid plexus.

The theories advanced to explain preretinal hemorrhages, like those utilized in the pathogenesis of papilledema, depend heavily upon the demonstration of the free communication between the subarachnoid and subdural spaces of the cranial cavity and the corresponding intervaginal or perineural spaces of the optic nerve through the optic foramen.[11] This anatomic relationship has been proved to exist by injection experiments in which various dyes were used[16, 28] and by study of the distribution of blood following spontaneous subarachnoid hemorrhage due to ruptured intracranial aneurysms;[1-3, 13-14, 19, 21,29] the extravasated blood has been traced from the cerebral subarachnoid space as far forward as the lamina cribrosa.

The earliest description of intraocular hemorrhage associated with spontaneous subarachnoid hemorrhage was contributed by Litten in 1881.[12] Symonds[1, 2] quoted a case, reported by Hale-White in 1895, in which the intracranial subarachnoid hemorrhage, extending into the intervaginal space of the optic nerve, had torn its way forward under the retina in both eyes. Symonds himself felt that there was sufficient pressure in the optic-nerve sheaths to force the passage of blood through the lamina cribrosa (fig. 1). Doubler and Marlow[13] described a similar case. Paton[14] thought that in a small percentage of cases retinal hemorrhages were due to direct leakage of blood from the optic nerve sheath through the lymphatic space at the site of the lamina cribrosa and along the central vessels into the optic disc and retinal tissues. He based his opinion on his failure to demonstrate dilated retinal vessels on ophthalmoscopic examination. In none of the more recent reports has continuity of the intervaginal hemorrhage with either the substance of the optic nerve or the retina been demonstrated.

Among the theoretical explanations proposed for papilledema, those based upon venous obstruction are of chief interest in conjunction with the pathogenesis of preretinal hemorrhages. Before the demonstration of the collateral circulation of the central vein in the orbit with the facial veins and the pterygoid plexus, it was thought that stasis of the ophthalmic vein resulting from obstruction of the cavernous sinus by thrombosis or compression from without was the cause of papilledema.[6, 11] Swift, however, has reconsidered this possibility recently in his discussion of anomalous and poorly developed anastomoses of the transverse sinus[15] and doubts this explanation.

According to Greear,[3] Uhthoff, in 1901, was the first to question the observation of direct hemorrhage from the intervaginal space of the optic nerve into the retina. Cushing and Bordley[16] were able to produce papilledema, as well as swelling of the intervaginal space, experimentally in dogs either by introducing fluid under tension into the intracranial subdural space or by simple digital compression exerted against dura exposed by a trephine opening. Their production of venous congestion by constriction of neck veins in the absence of fluid under tension in the perineural space failed to result in papilledema. Wolff and Davies[17] could not substantiate these results and pointed out that in dogs the central vessels do not cross the intervaginal space.

Paton and Holmes[7] in their study of the pathogenesis of papilledema concluded that it resulted from increased intravenous pressure which developed following compression of the intervaginal portion of the central vein. This compression was due to trans-

mitted increased intracranial pressure. In association with the increased pressure within the sheath of the optic nerve there was obstruction of the lymph drainage from the optic disc. Fry's[8, 9] studies on the anatomy of the central vessels supported their interpretation, as did the observation of Wallfoors (quoted by Lauber[18]), who demonstrated the continuity of the intracranial and intervaginal spaces by ligating the optic nerve proximal to the exit of the central retinal vein and thus preventing the development of papilledema when the intracranial pressure was increased.

Riddoch and Goulden[19] in interpreting their cases of intracranial aneurysm suggested that preretinal hemorrhages, as well as papilledema, could be explained on the basis of compression of the central retinal vein by the hemorrhage in the intervaginal space (fig. 2). The result of this compression was, according to these observers, an increase in the intraocular venous pressure, venous dilatation, and eventual rupture of the preretinal veins. They cited as variable factors the suddenness of rupture of the aneurysm, the distance of the aneurysm from the optic nerve, and the presence or absence of arachnoidal adhesions in the cisterna basalis. These variations tend to alter the degree of intervaginal tension and thus influence the production of preretinal hemorrhage. MacDonald[20] pointed out that the dura about the optic nerve in the orbit is the only portion of dura unsupported by a bony wall and therefore readily distensible. Drews and Minckler[21] affirmed the part played by increased pressure within the intervaginal space and suggested double angulation and axial elongation of the central retinal vein in its intervaginal course resulting from distension of the optic dura as additional factors responsible for the rise in central retinal venous pressure.

As a corollary, Igersheimer[22] has noted the absence of papilledema in a case with coëxistent glaucoma and intracranial neoplasm, the inference being that, in preexisting increased intraocular pressure, papilledema does not develop with increased intracranial pressure. Conversely, marked papilledema and retinal extravasation may develop under conditions of normal intracranial pressure when there is decreased intraocular tension.

Recently Ballantyne[23] has described hemorrhages occurring not only in the intervaginal space, but also in the optic nerve, the dural sheath, Tenon's capsule, the optic chiasm, the pial sheath in the sclera near the porus opticus, and in the orbital fat and muscle. He thought that the sudden rise in intracranial pressure at the moment of rupture of an intracranial aneurysm was followed by excessive venous stasis resulting from compression of the dural sinuses. Rupture of the distended veins in these scattered areas was, he thought, the result of "loci minori resistentiae." Because of the lack of continuity of the hemorrhages, he was not satisfied with the suggestion that the preretinal hemorrhage results from venous pressure due to simple extension of blood from the cerebral subarachnoid space into that of the optic nerve. It is the general consensus at the present time,[6, 11] however, that preretinal hemorrhages associated with extravasation of blood into the intervaginal space of the optic nerve, as well as those associated with papilledema, can be explained on the basis of obstruction of the central retinal vein as it passes through the intervaginal spaces of the nerve.

In our own case, described above, rupture of a congenital medial defect aneurysm of the right internal carotid artery has been demonstrated. Its histologic features are in accord with those described by Forbus.[30] Its location was such that blood could be traced into the subarachnoid space, through the optic foramen, and continuously along the intervaginal space of the optic nerve, terminating abruptly at the lamina cribrosa. In the eye an independent hemorrhage was found associated with a ruptured preretinal vein just beneath the internal

limiting membrane in the retina. Our interpretation of these findings is in general agreement with the consensus of opinion regarding the mechanism of production of preretinal hemorrhages; that is, that the hemorrhage is due to increased venous pressure. We think, however, that the *choroidal anastomosis* of the central vein at the lamina cribrosa, as well as the vein at its point of emergence from the nerve into the intervaginal space, is obstructed. Following rupture of the aneurysm the blood, under a high pressure simulating the systemic arterial pressure, is transmitted directly against the lamina cribrosa. The tissues of the lamina cribrosa are then compressed upon the *anastomosis* of the central retinal vein with the choroidal veins. The resulting sudden obstruction of the vein at its point of emergence from the nerve *and its choroidal anastomosis* is followed by rapid elevation of the preretinal intravenous pressure and rupture of a preretinal vein (fig. 3).

In support of this interpretation it should be recalled that the retina is supplied by end vessels and that their first anastomotic connections are with the choroidal vessels at the lamina cribrosa. Assuming the prevalent theory of obstruction of the central vein at its exit from the nerve to be correct, the result in that case would be a gradual compensatory distention of the choroidal anastomosis, and there would be no rupture of the distended preretinal veins. On the other hand, if the obstruction of the central vein occurred at its point of emergence from the nerve *and also at the choroidal anastomoses,* as suggested in our case, there would be no avenue of return for venous blood from the retina. The result would be an abruptly and markedly increased preretinal intravenous tension and almost immediate rupture of one or more preretinal veins. It might be added that the failure to demonstrate blood histologically in the intervaginal space would not be contrary to this view because pressure could be transmitted through spinal fluid trapped in perineural spaces.

Our interpretation is analogous to a theory postulated by Manz,[24] who thought that swelling of the optic disc results from compression of the lamina cribrosa by an increased cerebrospinal fluid pressure in the intervaginal space. It has further been shown in animals that ligation of the optic nerve distal to the exit of the central vessels from the nerve results in papilledema and swelling of the nerve distal to the point of ligation.[6] These findings were absent when the ligation was made proximal to the exit of the central vessels. They were particularly pronounced, however, when the ligation included only the vein. No mention is made of the simultaneous occurrence of preretinal hemorrhage in the experiments.

Summary

1. An instance of preretinal hemorrhage following massive subarachnoid hemorrhage from the rupture of a medial defect aneurysm of the internal carotid artery has been studied with particular reference to the pathogenesis of the ocular lesion.

2. Prevalent theories relating to the mechanism of production of preretinal hemorrhage accompanying subarachnoid hemorrhage have been reviewed and a modification proposed.

3. It is suggested that preretinal hemorrhages accompanying subarachnoid hemorrhage from ruptured medial defect aneurysms of the superficial cerebral arteries are the result of sudden increase in preretinal intravenous pressure which arises from compression of the choroidal anastomosis of the central vein of the retina at the level of the lamina cribrosa, together with compression of the central vein at its intervaginal portion, by extension of the subarachnoid hemorrhage into the intervaginal space about the optic nerve.

THE SIGNIFICANCE OF THE BASE PRESSURE IN PRIMARY GLAUCOMA*

ALGERNON B. REESE, M.D.
New York

The intraocular pressure varies throughout the day and from day to day in the normal as well as in the glaucomatous eye. Apparent variations may be due to the readings of two different tonometers, to a difference in the manner in which two individuals take the pressure readings, to changing muscle tension around the eyeball, to differences in the position of the tonometer foot plate on the cornea, and to the length of time the instrument rests on the cornea before the reading is made. Real variations may depend on whether or not miotics have been used, frequency of their use, and differences in strength, and the time elapsed since last used prior to the pressure readings. In glaucomatous eyes, variations in pressure no doubt depend on the current emotional state of the patient and the size of the pupil. Most important of all, however, are the real variations contingent on the glaucomatous state.

PEAK AND BASE PRESSURES

In glaucomatous eyes, the height to which the pressure rises is referred to in this paper as the "peak pressure" and the depth to which the pressure descends as the "base pressure." These terms represent merely the upper and lower limits of the excursions of the pressure taken from time to time. Any sustained elevation of the base pressure indicates permanent damage to the filtration angle. The difference between the base pressure and the peak pressure represents the transitory, functional factor in the glaucomatous state. The more advanced the glaucoma the more nearly the base pressure approaches the peak pressure, so that in absolute glaucoma they tend to merge.

The peak and base pressures are in a way comparable to the systolic and diastolic blood pressures. In both instances the lower pressure represents a rest period. A high diastolic pressure means less rest for the heart, and a sustained elevated base pressure means continuous damage to the eye with more rapidly developing field changes. A glaucomatous eye with a normal base pressure may for years show no field changes and no cupping of the disc but these changes may appear and progress rapidly when the base pressure is elevated. A further analogy to the heart can be made: in absolute glaucoma the base pressure tends to approach the peak pressure, and in a decompensated heart, the diastolic pressure approaches the systolic pressure.

STUDY PRESSURE TREND

For the purpose of this study the tension curves kept as a routine procedure in the office have been employed. This means that the intervals between pressure readings varied in length from a day to three or more months. Because of real and apparent variations already mentioned, frequent readings over a short period are not desirable. A long-range perspective, giving the general trend, is necessary. It is not so valuable to know that the pressure is 30 mm. Hg one week and 25 mm. Hg the next week as it is to know whether or not the reading of 25 mm. Hg is a sustained low or mean low, and whether or not it has risen to a mean 25 mm. Hg from a mean 15 mm. Hg. It is of more interest to compare the base pressure now with what it was a few months ago or even one year ago than to compare the current pressure with that of one week

* Read at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947.

ago or even one month ago. Perhaps a more accurate comparison can be made between pressures taken at the same time of day. This is usually done, for patients generally pay visits to the office at about the same time. For our purposes, however, these small diurnal variations as well as the variations consequent to the changing emotional state, physical condition, treatment with miotics, and time elapsed since last medication can be disregarded in the long-range, over-all estimate of the pressure trend.

Classification of primary glaucoma

Fundamentally, I think the classification of primary glaucoma into shallow-angle and deep-angle glaucoma is sound.

A. Shallow-angle type

Shallow-angle or iris-block glaucoma is caused by some transitory dynamic factor back of the iris which pushes the root of the iris forward, blocking the angle. If this functional dynamic factor subsides or abates, the angle opens and the pressure returns to normal. If this blocking occurs often enough and over sufficiently protracted periods, the angle fails to open adequately because peripheral synechias form and the pressure is constantly elevated; that is, the base pressure has risen above normal. The functional episodes continue, so that the peak pressure soars, but in the interludes the pressure never returns to normal. Therefore, the height to which the base pressure rises represents the degree of permanent, irrevocable damage done the angle.

A common belief is that the functional factor is in the ciliary body in the nature of a vascular crisis. This produces edema of the ciliary body and processes which in turn push the iris root forward. There is not much histologic evidence to support this. In eyes approaching the absolute glaucomatous state when the base pressure nears the peak pressure, there may be evidence of increased vitreous pressure. This is frequently demonstrated on the operating table. If such eyes are palpated with an instrument such as a spatula, they will be quite hard even with the anterior chamber open. It seems possible, therefore, that transitory rises in vitreous pressure push the iris-lens diaphragm forward and block the angle.

B. Deep-angle type

The primary glaucoma, characterized by an angle which is of normal depth or deeper than normal, is thought to be due to trabecular obstruction. Not a great deal is known about the exact nature of the obstruction. Microscopic sections indicate that in some instances a cuticular product is laid down by the endothelium lining the interstices of the trabeculae, and in others there is a sclerosis of the trabeculae. The important point here for our discussion is that the changes leading to the glaucoma are commonly believed to be organic with no functional element. Were this true, the intraocular pressure should rise gradually with only small excursions due to variable factors not inherent in the glaucomatous state as previously discussed. Judging from a study of tension curves on this type of glaucoma, one can see that there may be excursions of pressure but never to the point of acute deep-angle glaucoma. This apparent variable functional element in this type of glaucoma is not readily explainable. It is true in general, however, that this type of glaucoma does show a more or less steady rise in the pressure, and that the apparent functional factor indicated by the excursion of pressure is an inconspicuous feature. Therefore, in this type of glaucoma we do not have the same occasion to speak of peak and base pressure as we do in the shallow-angle type. The pressure at any given time tends to represent the permanent organic damage to the angle.

In all glaucomas, primary as well as secondary, peripheral synechias eventually form. There is no exception to this, regardless of the causes of the glaucoma. Granting this, there is no escape from the fact that

prolonged increased intraocular pressure per se promotes the formation of peripheral synechias. Thus a vicious circle is formed by which "x," the unknown quantity initiating the glaucoma, causes an increase in the pressure which in turn promotes peripheral synechias which in turn produce increased pressure. This vicious circle, if continued, eventually causes complete annular peripheral synechia whereby the peak and base pressures merge and absolute glaucoma is reached.

Type of operation indicated

In determining the type of operation indicated, particularly in shallow-angle glaucoma where the functional feature is prominent, how high the pressure goes (peak) is not so important as how low it is capable of going (base). The higher the base pressure, the greater the drainage load the operation must carry. Sometimes it is impossible without several observations to determine the base pressure and therefore the operation indicated. For instance, if the intraocular pressure is found to be 35 mm. Hg even with miotics, it is important to know if this is peak, base, or average. If this is base pressure, then an operation capable of carrying a greater drainage load must be done than if the base pressure were 25 mm. Hg. Patients with glaucoma are too often sent to a consultant with instructions not to use miotic drops for 12 or more hours prior to the visit. If an opinion must be based on one visit, I should prefer to have the patient come with drops used routinely, since this gives a better idea of the base pressure. A pressure of 45 mm. Hg without drops is not as informative as a pressure of 20 mm. Hg with drops.

The difference between an acute glaucoma and an acute exacerbation of a chronic glaucoma is that in the former the base pressure is normal and in the latter it is elevated. This may be a difficult differential diagnosis to make but it is exceedingly important in determining the type of operation indicated.

A general working rule I employ for chronic primary glaucoma is:

A. Shallow-angle glaucoma

1. Low or normal base pressure—iridencleisis operation.
2. Rising base pressure to high normal, or up to approximately 30 mm. Hg—iridencleisis with sclerectomy or Lagrange type of operation.
3. Base pressure over 30 mm. Hg—trephining operation.

B. Deep-angle glaucoma

1. Base pressure of 30 to 35 mm. Hg—iridencleisis or cyclodialysis operation.
2. Base pressure of 35 to 40 mm. Hg—iridencleisis with sclerectomy or cyclodialysis operation.
3. Base pressure of over 40 mm. Hg—trephining operation.

READING DIFFICULTY (DYSLEXIA) FROM THE OPHTHALMIC POINT OF VIEW*

GEORGE E. PARK, M.D.
Chicago, Illinois

Reading difficulty, or dyslexia, is the result of the dysfunction of the various factors that are concerned in learning. Although the most prominent characteristic of dyslexia is an inability to read, the components of the problem are so diverse that any remedial program must be based on a thorough investigation of each individual reading failure. Not until the facts disclosed by the individual investigation are completely correlated and analyzed should any attempt either at diagnosis or prognosis be made.

Too often in the past, research studies in this field have been made to prove some preconceived idea that eventually influenced the research worker to interpret his findings and mold them into prejudiced patterns. The approach in previous investigations has depended largely on the particular field—psychology, education, ophthalmology, and so forth—in which the investigator was interested. An ophthalmic research worker would, for example, select a group of poor readers and attempt to correlate the ocular defects with the reading difficulties.

It is the purpose of this paper to present certain broad aspects of the problem of dyslexia, to outline the influence of certain physical factors involved in reading difficulties, to present some of the psychophysiologic elements, and to discuss the ocular findings in 133 cases of dyslexia under treatment.

BROAD ASPECTS OF DYSLEXIA

Patients with reading difficulty should not be neglected for fear that the difficulty might defy diagnosis and correction. Based on our results, it can be said that in otherwise normal children, dyslexia can be helped almost without exception. Although some patients, because of abnormal mental ability, do not show the expected improvement, most patients make gains that are both rapid and permanent. The most outstanding improvements in our experience have been a two years' gain in reading skill in two months; a five years' gain in 10 months; and a six years' gain in one year.

Since it would be unreasonable to expect a single individual, no matter how expert in his own field, to investigate and analyze reading failure on a sufficiently broad basis, it has been found necessary to coördinate the work among a group of experts. A staff capable of carrying on this work should include a skilled educational psychologist; teachers having special aptitude, interest, and experience in remedial instruction; a psychologist versed in psychometry and proficient in the art of interviewing and advising; a psychiatrist who understands the emotional development of the child as well as child-parent relationships; an internist; an otolaryngologist; an ophthalmologist; a social worker; and a voice teacher. This staff of experts must be willing to work together and to listen to each other's opinions.

---

* From the Department of Ophthalmology, Northwestern University Medical School, and the Dyslexia Memorial Institute. Read before the Chicago Ophthalmological Society, March 17, 1947.

The author wishes to acknowledge the untiring work of the following present and former members of the staff of the Dyslexia Memorial Institute: Dr. Daniel P. MacMillan, Dr. James H. Appleman, Prof. Alfred Schmieding, Dr. Albert H. Andrews, Dr. Frederick Hiller, Dr. George Shambaugh, Dr. Frank Wojniak, Dr. Truman O. Anderson, Dr. Clara Burri, Violet Lannert, Marguerite Ullmann, Marjorie Hunter, Dorothy Taraba, and the members of the Dyslexia Guild.

Before a course of treatment is prescribed, the patient's environment, physical status, emotional reactions, learning achievements, and work habits should be completely investigated. After each member of the staff has examined the patient, a conference should be held to report the findings and to establish the remedial program. It is advisable, even necessary, to consult with the patient's parents, siblings, and teachers in order to make recommendations and the reasons for them. Consulting with all persons concerned makes for better understanding. The patient, himself, should be given a clear explanation of the follow-up procedures.

Such a complex program can be facilitated if a central location can be provided to carry out the entire schedule. If a child should need not only medical care, including that of the eyes and ears, but also psychologic, educational, and psychiatric guidance, and voice training as well, the time consumed and the expenses incurred in getting treatments at different locations would make the prognosis less satisfactory.

Physical factors influencing dyslexia

Since vision is so dependent upon sufficient and proper lighting, one must determine what qualities and intensities of light are desirable for different reading situations. Much information is available concerning the optimum requirements for proper physical factors, which are controllable and necessary for comfortable reading.

Patterson and Tinker,[1, 2] and Luckiesch and Moss[3, 4] have investigated and reported extensively much valuable detail and information on the hygiene of reading. It has been estimated that the critical level for reading was between 3 and 4 foot-candles, but, as a margin of safety, reading should not be done with less than 5 foot-candles of light. School rooms should not have less than 10 foot-candles, and sight-saving classes should have 20 to 25 foot-candles. The critical level of light intensity for reading newspapers should be 7 foot-candles, but for a margin of safety, an intensity of 15 to 20 foot-candles is recommended. The critical level was defined as the intensity beyond which no improvement in reading performance occurred as the illumination intensity increased.

Maximum readability occurs when optimal physical conditions are supplied, with the printed material set in 10- to 12-point black type on a 2-point lead, in line lengths of 3 to 3½ inches, on white paper without gloss finish. Under these conditions, the light should not be less than 10 foot-candles. This light intensity should be increased even to 50 foot-candles for prolonged tasks of reading difficult material or for proofreading. Glares should be avoided at all times.

Pyscho-physiologic aspects

As a rule, the more intelligent a person is and the more perceptual experiences he has encountered, the more quickly he learns from abstractions and symbols. Since printed letters and words are abstract symbols, it is necessary to have visual perceptual experiences in order to understand their meanings when arranged in phrases and sentences.

If we accept the customary concept that reading is a simple reaction to visual stimuli, we would have to conclude that the visual process is the dominate factor in dyslexia. However, in order to analyze and interpret reading achievements and failures, it is necessary to consider the central perceptual and conceptual processes as well as the entire peripheral ocular mechanism in all its complexity.

There are many individuals with normal or superior intelligence who, although they are unable to understand printed signs and symbols, are able to learn through oral instruction.

Such a complex achievement as reading involves many variables, and it would be unreasonable to assume that any function can be altered from normal development

without influencing the entire psychophysiologic mechanism. The degree to which normal or abnormal functions influence the process as a whole depends upon the ability of the person to adjust himself to the psychophysiologic needs or contingencies or stimuli that are present at any particular time. The degree of this homeostatic[5] stability and adaptation depends on the relative degree of normality of all the diverse functions that are involved in the reading processes.

According to conservative estimates, about 15 percent of the school population has some degree of dyslexia. This varies considerably with the standard of the school and the opportunities of the home. The social-economic status of the family seems to have no significant influence on the development of dyslexia. In the series of cases presented in this study, the average age of the patient was 12 years and 2 months. Boys having reading difficulties outnumbered girls, 4 to 1. The average intelligence quotient in the patients herein studied was 107.6, with the highest, full-scale I.Q. at 147.

Reading readiness in general is a further consideration. The child's readiness for reading requires broad interests. He must have a certain degree of emotional and social maturity, a normal expectancy in language development, and a sufficient number of perceptual and informational experiences.

Wilson[6] found that letter-perception abilities are more closely related to beginning reading progress than any of the other abilities studied. Since so much depends upon accurate visual perception, it is essential to determine at what age a child's eyes are sufficiently mature for him to learn to read. It is no more reasonable to assume that every child will have fully matured visual development when he enters school at the age of six years than to say that all children are equally developed in other maturational processes. Park and Burri[7] have shown that a larger percentage of children at the prereading age and in the first and second grades have more incompletely matured visual mechanisms than children in the next higher grades.

If this slow development of "eye readiness" should persist, it would become a definite deterrent to reading readiness and eventually, because the criticisms of teachers and parents would arouse anxiety in the child, it might lead to nervousness, irritability, resentments, and behavior problems. Under these circumstances, it is advisable to postpone, or at least to modify the entire reading program until such immature maturational processes have been corrected.

Ocular study of dyslexia

Many reports have been made and many conclusions reached relative to the etiologic importance of ophthalmic findings in reading difficulties, some with finality, others with less certainty.

The following data were catalogued after an analysis was made of the ophthalmic factors in this study of 133 cases of dyslexia. The results and conclusions are presented with the preface that all data should be interpreted as being only a part of the complex problem and that the whole makeup of the child must be considered.

Visual examination

In this series, 75 percent of the patients had normal vision; 20 percent had subnormal vision in both eyes; and 5 percent had subnormal vision in one eye only. At the initial examination an additional 8 percent seemed to have subnormal vision, but these examinees attained normal vision easily at a subsequent examination. Perhaps, their lack of interest and attention in any task concerned with reading was carried over to the examination.

Only 19 percent showed sufficient ametropia to require refraction. There were twice as many hyperopic as myopic cases. Glasses were removed from six of our pa-

tients, five of whom were wearing spectacles because they had been prescribed empirically as an aid in reading. Three of these patients had a high degree of exophoria which was aggravated by the convex lenses. An inaccurate refraction influences reading adversely and is worse than ametropia itself, for the patient then has to compensate for an artificial ametropia.

The incidence of subnormal vision cannot be ignored as a factor in dyslexia but it is relatively rare. No doubt, to attain clear vision, ametropia with its accompanying excessive demand upon the ocular neuromuscular mechanism results in fatigue and would be a very definite factor in some cases. For as Dearborn[8] mentions, the fatigue would thus lessen the incentive to learn, causing avoidance or neglect of reading.

Oculomotor functions

Ninety-three percent of the cases in this series had normal motility during fixations into the various fields of action of the extraocular muscles both monocularly and binocularly.

Since fusion ability was present in practically all cases of dyslexia (97 percent), fusion per se is not a dominating influence. It is the ability to maintain fusion without undue effort and fatigue which determines the proper oculomotor function. Although fusion and stereopsis are acquired oculocerebral processes, 22 percent of our cases showed extremely weak stereopsis or none at all. Of these, only 4 percent were due to tropias. The remaining 18 percent learned stereopsis properly after training. The question naturally arises whether or not weak stereopsis is another manifestation of the dyslexia enigma.

Ocular dominance

The number of investigations dealing with the controversial question of dominance, handedness, eyedness, have been considerably smaller during the last 5 years than the preceding 10 years. Although the results are still somewhat conflicting, the evidence points to the conclusion that handedness is not significantly related to reading ability but that mixed eye-hand dominance is probably present in some cases of reading disability.

In checking for ocular dominance, 80 percent of our cases showed no preference; 8 percent had a tendency to alternate; 2 percent had a tendency to alternate but recovered quickly; 3 percent showed a tendency to suppress one eye; and 7 percent suppressed one eye completely. By using the stereoscope with dissimilar cards that stimulate fusion only slightly, the probability of introducing an extraneous factor in determining the dominance is eliminated. For, as soon as an extraneous act such as pointing and sighting is used, one eye or the other, through expediency, will be chosen as the dominant one, even though both eyes are maintaining fixation and fusion of the image of the object observed. Apparently not more than 13 percent of dyslexia cases show any tendency to fixate alternately or to suppress one image, unless this suppression is due to a strabismus.

Incidence of phorias

Phorias have more significance, for 55 percent of the patients were orthophoric. The remaining 45 percent were heterophoric, and half of them were exophoric for near (reading distance). This condition with its potential of temporary diplopia can be a definite hindrance to the proper functioning of the eyes, causing a predisposition to fatigue and eventual lack of interest in reading or doing other tasks close at hand. The Maddox rod and red light were used to measure phorias. The various types of phorias present and their relative incidences were:

Orthophoria, 55 percent; esophoria for distance and near, 5 percent; esophoria for distance only, 2 percent; esophoria for near, 4 percent; exophoria for distance and near, 4 percent; exophoria for distance only,

2 percent; exophoria for near, 22 percent; esophoria for distance and exophoria for near, 2 percent; hyperphoria, 4 percent; tropia, 4 percent. From 4 degrees esophoria to 4 degrees exophoria was considered as orthophoria; less than 2 degrees was normal for hyperphoria.

Measurement of ductions

During the measurements of ductions, care was taken with each individual to obtain accurate reports as to the point at which the image separated and diplopia appeared and the point of recovery—where the two images fused again. In scoring for ductions, the standards were quite flexible. A variation from the established normal of approximately 10 percent was allowed as "normal." The phorometer was used to make these measurements which are analyzed in Table 1.

TABLE 1

An analysis of ductions

	Diplopia Considered Normal	Recovery from Diplopia Considered Normal	Percentage of Entire Series (133 Cases)		
			Lower Ability	"Normal"	More than Normal Ability
			Percent	Percent	Percent
Distance					
Adduction	18*		17	66	17
Adduction		10*	28	55	17
Abduction	8†		20	74	6
Abduction		5†	25	70	5
Near					
Adduction	24*		15	60	25
Adduction		13*	22	61	17
Abduction	14†		10	63	27
Abduction		6†	15	57	28

* Prism base out.
† Prism base in.

Even with a relatively low prism strength considered as normal in measuring the diplopia and recovery points, it is evident that weak fusion amplitude is definitely associated with dyslexia, especially weak recovery ability from diplopia. With a low duction reserve in the presence of convergence insufficiency or accompanying accommodative or convergence spasm, there is a tendency toward undue fatigue that prevents the eyes from efficiently making the fusional responses and adjustments so necessary in getting and maintaining single and clear binocular vision. If this is not accomplished efficiently, there is a constant tendency for the two images to fail to remain on the fovea and, as a result, there is blurring of the images or even potential temporary diplopia. An unusual amount of nervous energy is required to adjust the foveal positions constantly in order to achieve and keep a single image. This may be evidenced by some general physical and emotional disturbance and can happen even though the vision may be normal or may have been improved to normal by refraction. Thus, in studying the correlation of the eyes to dyslexia the entire peripheral ocular mechanism must be considered.

Orthoptic treatments were recommended in 69 (52 percent) of our cases showing abnormal ductions or marked muscular imbalances. Eleven of these were orthophoric, 5 had tropias (3 of which were of such magnitude it was impossible to measure their ductions), and the remainder were heterophoric.

Observations were made by motion pictures* of the eyes while reading. This included rate of reading, average fixations calculated per 100 words, span of recognition, number of regressions per 100 words, saccadic movements, whether rhythmic or arrhythmic, whether eyes are synchronized, and so forth. The results are indicated in Table 2.

TABLE 2

ANALYSIS OF OCULAR MOVEMENTS IN READING

Grade level used to photograph eye movements	1	2	3	4	5 to 7	High School and College
Reading ability from psychologic report (average)	2.12	2.8	2.8	4.1	5.9	10.3
Rate per minute						
Norms*	55	90	115	168	200	310
Dyslexia	83	66	97	95	161	250
Fixations per 100 words						
Norms*	190	150	137	115	100	70
Dyslexia	164	181	162	181	119	96
Regressions per 100 words						
Norms*	40	32	30	25	17	13
Dyslexia	19	43	29	35	23	12
Span of recognition Norms	.52	.66	.73	.87	1.0	1.4
Span of recognition Dyslexia	.61	.55	.61	.55	.84	1.0

* Taylor, E. A.: Controlled Reading. The University of Chicago Press, 1937.

There were several patients for whom no reading graphs were made for they lacked the ability to read even first-grade material.

The excellent showing made by the group that was photographed while reading first-grade material is attributed to the circumstance that even though their average reading ability was on the 2.12 grade level, they refused to try any reading on that level. In the over-all picture of the peripheral ocular function while reading on the other grade levels, the dyslexia cases are inferior to the "norms."

Exercises were given to 15 percent of our cases to stimulate rhythmic saccadic movements, to increase the span of recognition, to overcome regressions, and to regulate the ocular speed in reading.

It would be erroneous to take the peripheral ocular mechanism habits as the standard and the visual acuity as the determinant of cerebral action or of perceptual processes. It is also inconclusive to take mental processes as the sole factor influencing the modus operandi of peripheral ocular performance. Since the roles are probably interchangeable, it would be difficult to determine which acts as the originator and which as the compensator. All available faculties plus the desire to achieve the universal concept are probably integrated in the processes of learning.

* Four types of eyes—emmetropic, hyperopic, myopic, and aphakic—were also photographed.[9] Conditions under which these patients read were identical, except for their refractive corrections. The results showed that the excursion of the eyes in reading a line was influenced by the power of lenses used in myopia and aphakia. The excursions of emmetropic eyes and hyperopic eyes (with +11D. to +13D. lenses) averaged 6.5 to 7 mm. The excursions of aphakic eyes reading under similar conditions (with +13D. lenses) were increased even to 10.5 or 11 mm. The myopic eyes moved approximately 5 to 5.5 mm. This occurs in individuals who have had no difficulty in reading and helps explain the marked difficulty which some aphakic patients have in adjusting to lenses, especially while reading.

Conclusions and Summary

1. Dyslexia is an entity.

2. The incidence of dyslexia is sufficiently high to require attention.

3. The correction of this condition can be best attained after a complete examination and appraisal of the child and his problem from every viewpoint, including physical, emotional, and pedagogic.

4. A somewhat detailed analysis is made of the ophthalmic findings that were coincidental with other symptoms in a series of 133 cases of dyslexia.

5. Ametropia must be considered as a factor in some cases of dyslexia.

6. Refraction should correct the ametropia but the empirical prescribing of glasses to help a child overcome reading disabilities is not advisable.

7. Abnormal motility is rare in dyslexia cases—probably as rare as in an unselected group.

8. Fusion is present in practically all cases, so fusion per se seems not to be a dominant factor.

9. The incidence of the lack of stereopsis is rather high.

10. Phorias are significant, especially exophoria for reading distance.

11. Weak ductions, slow recovery ability after diplopia, heterophoria, convergence insufficiency or accommodative or convergence spasm are associated with half of our cases.

12. Orthoptic treatments were recommended in 52 percent of our cases.

13. Exercises were given in 15 percent of our series to stimulate rhythmic saccadic movements, to increase span of recognition, to overcome regressions, and to regulate the ocular speed in reading.

14. It is erroneous to take the peripheral ocular mechanisms as determinants of perceptual and conceptual processes.

15. Conversely, it is illogical to take the cerebral processes as determinants of the ocular functions.

16. The roles of originators and compensators are probably interchangeable when an abnormality is present. Otherwise, there is perfect homeostasis between these sensory and motor functions.

THE SIGNIFICANCE OF THE INTRACUTANEOUS TEST FOR HYPERSENSITIVITY TO UVEAL PIGMENT*

SAMUEL D. MCPHERSON, JR., M.D., AND ALAN C. WOODS, M.D.
Baltimore, Maryland

The intracutaneous test for hypersensitivity to uveal pigment is the direct outgrowth of Elschnig's old anaphylactic theory of sympathetic ophthalmia.[1] The test was first used clinically by one of us (A. C. W.) in 1921.[2] At first it was read on a clinical basis, based on erythema and induration at the end of 30 minutes, 24 hours, and 48 hours. In 1934 Friedenwald studied the histologic changes accompanying a positive test.[3] He showed that two weeks after the injection of the pigment into the skin of a hypersensitive individual, there occurred in the skin a remarkable and typical histologic picture, characterized by phagocytosis of the injected pigment, infiltration of the dermis with lymphocytes, giant cells, and epithelioid cells, the latter usually occurring in nodules. The picture in the skin was startlingly similar to the picture of sympathetic ophthalmia in the eye.

Since the publication of Friedenwald's paper, chief reliance has been placed on the histologic reading of the excised skin. This test has been used extensively in the Wilmer Institute since 1934. It is the purpose of this report to summarize our experiences with this test, to discuss its occurrence in various ocular conditions, and to attempt an evaluation of its significance, its diagnostic and its prognostic import.

TECHNIQUE

A. PREPARATION OF PIGMENT

The uveal pigment is prepared from fresh beef eyes obtained from the slaughter house. Under sterile precautions, the eyes are clipped clean of the surrounding orbital tissue. They are then dipped for a few seconds in boiling water and further cleansed. The corneas are then removed, a sagittal section made in the eye, the vitreous, lens, and retina removed. The uveal tract is then dissected out intact and clipped free at the optic nerve. The uveal tracts of all the eyes thus dissected are ground up in a sterile mortar with glass, sand, and salt solution. The pigment is thus extracted from the uveas and the pigment-containing solution poured off and fresh salt solution added until the supernatant fluid becomes pigment free. The pigment-containing salt solution is then diluted so the end dilution is 5 cc. of solution to each uveal tract. This gives almost a 0.5-percent (wet weight) concentration of pigment, together with the soluble protein extracted from the uveal tract. Tricresol is then added to 0.5 percent. The mixture is then agitated several hours in a shaking machine with glass beads. It is then incubated for 48 hours, and its sterility tested. Thereafter it is decanted under sterile conditions and stored in treatment bottles for use.

B. TECHNIQUE OF TEST

An injection of 0.1 cc. of the pigment solution is made intracutaneously in the forearm. As controls, 0.1 cc. of salt solution, containing 0.5-percent tricresol, and preferably 0.5-percent beef serum, is injected as a control. The test is read at 30 minutes, at 24 hours, and at 48 hours clinically. It is then left for 14 days at the end of which time the pigment-containing skin is excised and prepared for microscopic study.

C. RESULTS

The tests are reported here on the microscopic reading only. They are read as positive, doubtful positive, negative, nonspecific

* From the Wilmer Ophthalmological Institute of The Johns Hopkins University and Hospital.

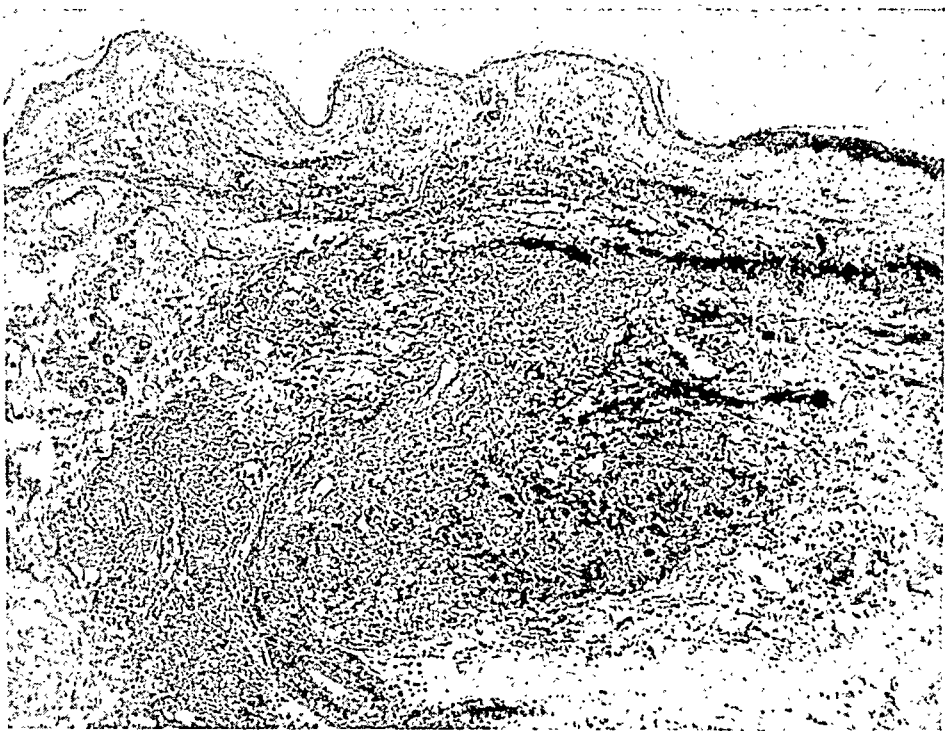

Fig. 1 (McPherson and Woods). Positive reaction.

reaction, or infected. The following are the criteria for the various readings:

Positive Test. All of the pigment is phagocytosed by the epithelioid and giant cells. The area of the section is densely infiltrated with lymphocytes, epithelioids, and giant cells, which are evenly dispersed throughout the section and (fig. 1) in some places form nodules—giant cells circumscribed by epithelioid cells.

Fig. 2 (McPherson and Woods). Doubtful-positive reaction.

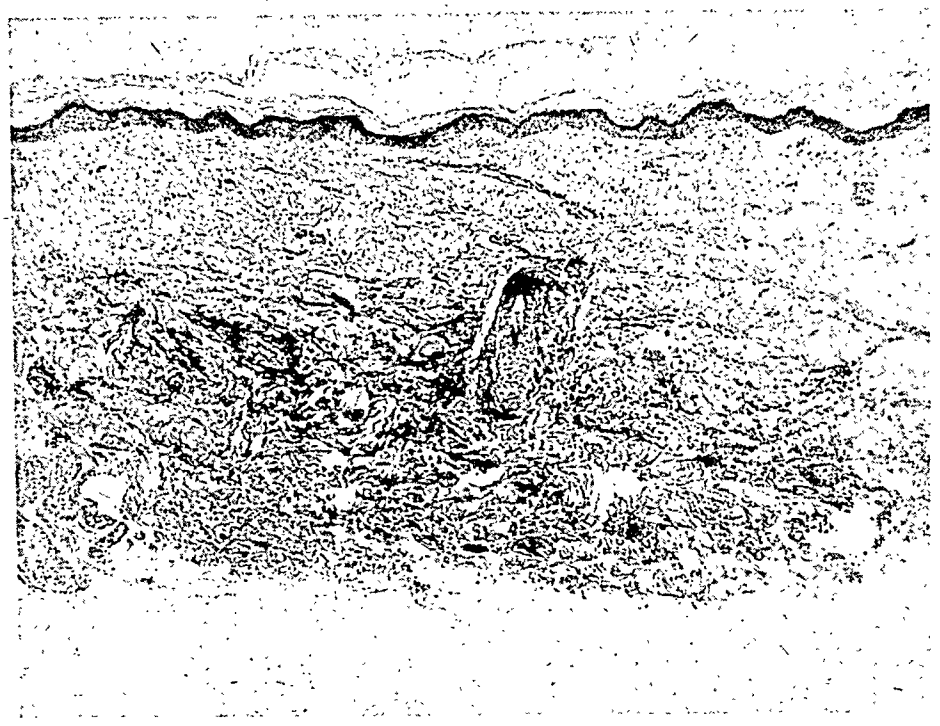

Fig. 3 (McPherson and Woods). Negative reaction.

Doubtful Positive. A portion only of the pigment is phagocytosed by the epithelioid and giant cells, the remainder being inertly distributed throughout the dermis. The cellular reaction of lymphocytes, epithelioid and giant cells is less intense than in the positive reactions, and is spotty in its distribution. There is no typical nodule formation (fig. 2).

Negative Reaction. All the pigment lies inertly distributed in the dermis, usually in large clumps. There is no phagocytosis and

Fig. 4 (McPherson and Woods). Nonspecific reaction.

no cellular reaction other than an occasional lymphocyte (fig. 3).

Nonspecific Reaction. The greater portion of the pigment lies inertly distributed in the dermis. There is a moderate cellular reaction chiefly of lymphocytes and wandering mononuclear cells. There may be an occasional epithelioid cell containing a little phagocytosed pigment, but such cells are extremely scanty (fig. 4).

Infected. The pigment is largely unphagocytosed in the dermis. The entire section is infiltrated with polymorphonuclear leukocytes, which occasionally phagocytose some of the pigment. There is often severe necrosis (fig. 5).

Fig. 5 (McPherson and Woods). Infected.

Material

The material on which this study is based is (1) 30 cases of sympathetic ophthalmia; (2) 139 cases of intraocular operations or injuries involving the uveal tract, in some cases healing uneventfully, in others complicated by a postoperative or posttraumatic uveitis; and (3) 43 cases of endogenous uveal disease from constitutional causes without a history of injury. In many of the patients there were repeated tests available for study. The following are the results in these three groups.

Results

I. Sympathetic ophthalmia

There are 30 individual cases in this group. In 22 of these, the diagnosis was histologically proven by examination of the exciting eye. In eight patients the diagnosis was unproven, the reasons being either that the exciting eye had never been enucleated and there was no reason for enucleation in the stage in which the patient was first seen, or the eye had been enucleated elsewhere and the sections were unobtainable for study. However, in none of these cases did there appear any reasonable doubt of the diagnosis. Therefore, both the 22 histologically proven and the 8 clinically diagnosed cases are grouped together.

The results of the pigment tests in these

25 positives and doubtful positives = (18 positives—7 doubtful) = 83 %.
5 negatives—tested = 4 tested in first 3 mos. and never retested. 1 tested 18 mos. after onset—still active.

30 patients are given in Table 1. Eighteen of these 30 cases, or 60 percent, gave straight positive reaction, while seven, or 23 percent, gave doubtful, or weakly positive reactions. Of these 25 strongly or weakly positive reactions, 10 occurred in the first month of the disease, while four patients tested in the first month were negative. Two patients were examined for the first time in the second month of the disease, both being positive. Four patients were tested for the first time in the fourth month of their disease, and all four tests were positive. The remaining four straight positive reactions were found in patients tested for the first time anywhere from the fourth month to the second year after the onset of the disease. One patient who gave a negative result on the first examination in the third month of the disease became positive in the fourth month. Of the five negative tests, four were done in the first three months of the disease, and the patients were not tested thereafter. The one remaining negative patient was first tested at the end of 18 months after the onset of symptoms.

This evidence would indicate that the tendency, if not the rule, is that the test becomes positive by the fourth month after the onset of symptoms, and in the majority of cases, becomes positive within the first month. If this is true, as it appears to be, the fact that the test was negative in f[illegible] patients must be explained by the ti[illegible]

which the test was done. Thus in four of the five negative patients the tests were done in the first three months. Had they been repeated later, positive results might have been obtained. The fifth case was tested 18 months after the onset of the disease, when the sensitivity may have faded, there being several cases in the positive group which were positive in the early stages of the disease and became negative by the end of the first year.

On the strength of this evidence—that 25, or 83 percent, of the cases gave strongly or weakly positive reactions to pigment while the five negative cases occurred in stages where collateral evidence indicates a negative test might well occur—it seems a reasonable deduction that hypersensitivity to uveal pigment is a fairly regular concomitant of sympathetic ophthalmia.

II. Pigment hypersensitivity in injuries and operations involving the uveal tract

If it is granted that hypersensitivity to uveal pigment is part of the disease picture of sympathetic ophthalmia, the immediate question is whether or not a hypersensitivity to pigment occurring after an operation or trauma to the uveal tract, but without clinical evidence of sympathetic ophthalmia, should be regarded as an indication or harbinger of impending sympathetic disease. This question can be answered only by an over-all study of the results of pigment tests in patients with injuries or operations involving the uveal tract, and a comparison of the results of these pigment tests with the subsequent clinical course of the patients.

There are a total of 139 cases of various penetrating wounds of the eye involving the uveal tract and intraocular operations involving the uveal tract in which, for one reason or another, tests for pigment hypersensitivity were done. None of these patients had or later developed sympathetic ophthalmia. This material falls into two groups.

TABLE 2

Pigment reactions in traumatism of uveal tract, posttraumatic or postoperative complications

Type of Case	No.	Positive ++++	Doubtful Positive ++	Negative	Non-specific	Infected
Penetrating wounds of Uveal Tract—Enucleation of Injured Eye	37	3	3	29	1	1
Recurrent Postoperative Uveitis	37	7	7	18	1	4
Postoperative Infection or Hemorrhage	20	3	2	15	0	0
Totals	94 or 100%	13 or 14%	12 or 13%	62 or 66%	2 or 2%	5 or 5%

Group A. Patients who ultimately lost their eyes as a result of the injury or operation, or who suffered postoperative uveitis, infection, or hemorrhage. There were a total of 94 patients in this group. *Group B.* Patients in whom the course after injury or operation was uneventful and who healed without complication. There were a total of 45 patients in this group.

Group A. The results of the test for pigment hypersensitivity in this group are shown in Table 2. In 13 patients, or 14 percent, the tests were strongly positive. In 12, or 13 percent, the tests were doubtful positive. In 62, or 66 percent, the tests were entirely negative. In seven patients the test was either nonspecific or infected.

Group B. The results of the test for pigment hypersensitivity in this group are shown in Table 3. No positive tests were found. Seven, or 16 percent, showed doubtful positive reactions. The remaining 38, or 84 percent, were entirely negative.

TABLE 3

PIGMENT REACTIONS IN TRAUMATISM OF UVEAL TRACT—UNEVENTFUL RECOVERY

Type of Case	No.	Positive	Doubtful Positive	Negative	Non-specific	Infected
Penetrating Wounds of Eye—Uneventful Recovery	38	0	3	35	0	0
Operations on Uveal Tract—Uneventful Recovery	7	0	4	3	0	0
Totals	45	0	7 or 16%	38 or 84%	0	0

Comparing these two groups it is at once evident that the occurrence of a strongly positive pigment test after an injury or operation involving the uveal tract is a harbinger or a warning of a stormy postoperative course, but it is not an indication that sympathetic ophthalmia will develop.

Doubtfully positive and negative tests are manifestly of no prognostic significance, occurring in much the same proportion in postoperative or posttraumatic cases, regardless of whether there are posttraumatic or postoperative complications or uneventful healing.

III. PIGMENT HYPERSENSITIVITY IN ENDOGENOUS UVEAL DISEASE

There are 42 patients in this category on whom pigment tests were done and the injected skin studied histologically. These cases fall into two distinct groups. In the first group are 37 cases of endogenous uveal disease from various constitutional causes, and in the second group five cases of the amazing Vogt-Koyanagi syndrome—uveitis with dysacousia, poliosis, vitiligo, and alopecia. The results in these two groups are shown in Table 4.

In the 37 patients with ordinary uveitis from constitutional causes, there were no positive tests. Doubtful positive tests occurred in five patients and negative or nonspecific in 32 patients. The notable finding is the complete absence of positive tests. The doubtful cases are difficult to evaluate. They suggest that occasionally some incomplete immunologic reaction involving pigment may occur. It is interesting that the disease was bilateral in four of these five cases with endogenous uveitis and doubtfully positive tests. The possibility of some tissue reaction in bilateral uveitis might be explored.

In the Vogt-Koyanagi syndrome, the test was positive in three of the five patients tested. The etiology of this disease complex is unknown. All that can be said is that clinically and histologically the ocular picture of the disease resembles sympathetic ophthalmia.

DISCUSSION

In the cases which form the basis for this study, clear-cut positive skin tests for pigment hypersensitivity occurred only in three conditions: (1) in sympathetic ophthalmia; (2) in the prolonged uveitis after injuries or

TABLE 4

PIGMENT TESTS IN ENDOGENOUS UVEAL DISEASE

Type of Cases	No.	Positive	Doubtful Positive	Negative	Non-specific	Infected
Uveitis from Constitutional Causes	37	0	5	30	2	0
Vogt-Koyanagi Syndrome (Uveitis—dysacousia, poliosis, vitiligo, alopecia)	5	3	0	2	0	0

operations involving the uveal tract; (3) in the Vogt-Koyanagi syndrome.

The mechanism of these positive tests can be well understood. It has been clearly shown that uveal pigment possesses organ-specific and lacks species-specific immunologic properties, although it has not been shown whether this is an attribute of the matrix of the pigment-containing cells or of the melanin granules. The relative insolubility of the melanin, with some unpublished experimental work in the Wilmer Institute, suggests the first possibility. Thus theoretically, and indeed experimentally, the pigment (using the term in the sense of pigment-containing cells) can act as an antigen in the homologous animal. When pigment hypersensitivity occurs after an ocular injury or disease, the obvious explanation is that uveal pigment is absorbed from the eye, the cells of the body react to the pigment, and a generalized hypersensitivity ensues. In sympathetic ophthalmia and in the Vogt-Koyanagi syndrome further absorption of pigment from the eye results in a local hypersensitive reaction in the eye manifested by phagocytosis of the pigment; epithelioid, giant cell, and lymphocytic cellular infiltration; and nodule formation. Likewise, a similar reaction occurs when the pigment is introduced artificially in the skin.

In the cases with persistent posttraumatic or postoperative uveitis which show positive skin tests, the mechanism of sensitization is the same; but when the process stops, sympathetic ophthalmia does not occur. The eye shows only the picture of nonspecific endophthalmitis. The obvious explanation for this is that after the establishment of the pigment hypersensitivity by the initial absorption of pigment, there is no further absorption from the eye, and hence no local hypersensitive reaction. When the hypersensitive skin is injected with uveal pigment, it reacts in the classic manner.

Does the occurrence of hypersensitivity to uveal pigment in sympathetic ophthalmia throw any light on the riddle of the etiology of the disease? In consideration (a) of the fact that pigment hypersensitivity may develop after ocular injury and without sympathetic ophthalmia and (b) of the identical histologic picture of pigment hypersensitivity in the skin and sympathetic ophthalmia, in 1935 one of us (A. C. W.) advanced the following hypothesis. Pigment hypersensitivity is not the actual cause of sympathetic ophthalmia, but it is a prerequisite for its development. It sets the stage for the occurrence of the disease, and determines the histologic pattern. Some other unknown factor, possibly specific, but quite possibly nonspecific, initiates the disease. In the light of the findings reported in this paper, and the explanation offered for the occurrence of positive skin tests to pigment without sympathetic ophthalmia—namely, that after hypersensitivity to pigment is established there is no further absorption of pigment and hence no local hypersensitive reaction with the characteristic histologic picture—there are three obviously different ways of viewing the possible relation of pigment hypersensitivity to the pathogenesis of sympathetic ophthalmia.

These are (1) that once local ocular hypersensitivity to pigment has developed, the further or continued absorption of pigment produces a local hypersensitive reaction, clinically and histologically manifested as sympathetic ophthalmia. Thus some factor which favored or produced the continual absorption of pigment would be necessary for the outbreak of the disease. Such a factor might be related to the nature of the trauma, to some local condition, or to some specific or nonspecific infection.

The second explanation is that (2) after pigment hypersensitivity is established, some specific unknown infective agent initiates the disease. The further absorption of pigment is secondary and produces a hypersensitive reaction which determines the histologic picture of the disease, but is not

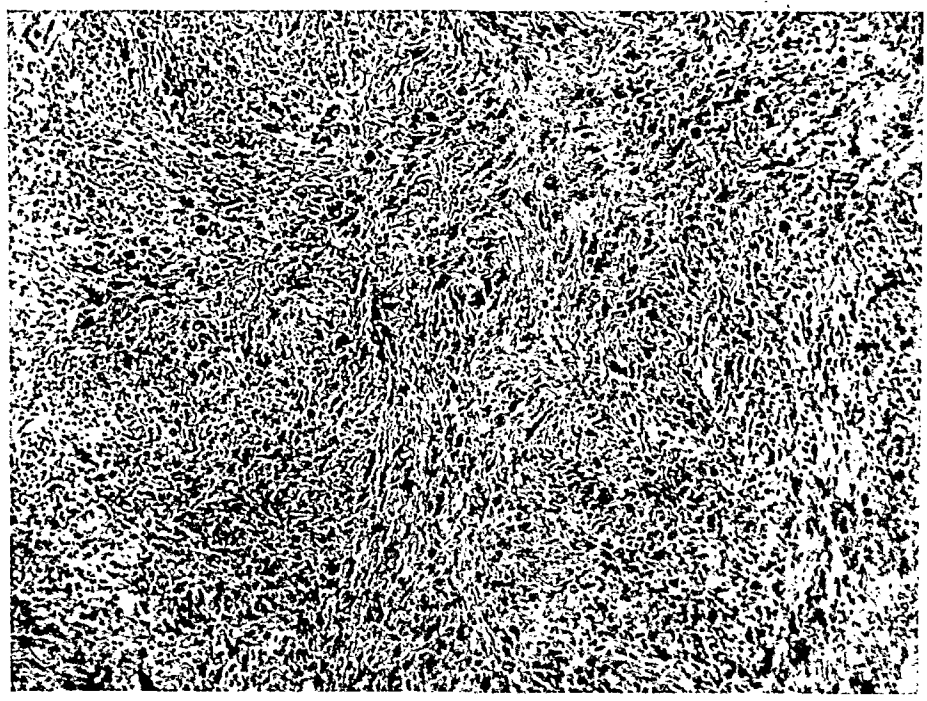

Fig. 6 (McPherson and Woods). Flat section of positive skin test.

per se the actual cause of sympathetic ophthalmia.

The third viewpoint would be (3) that the absorption of pigment after an ocular injury and the subsequent development of pigment hypersensitivity is a chance phenomenon and in no way related to the pathogenesis of sympathetic ophthalmia. However, when one considers the identical histologic picture of a flat section of the positive skin test and a flat section of the choroid in sympathetic ophthalmia (figs. 6 and 7), it does not seem

Fig. 7 (McPherson and Woods). Flat section of the choroid in a case of sympathetic ophthalmia.

probable that the last viewpoint is valid and that the pigment hypersensitivity is without significance. At the least, it would appear that it is the factor responsible for the characteristic and identical histologic picture.

Three of the five patients with Vogt-Koyanagi syndrome gave straight positive reactions and two patients gave negative reactions. It is interesting, although not statistically significant, that the incidence of straight positive reactions (60 percent) in this remarkable disease is almost exactly the same as the incidence of straight positives in sympathetic ophthalmia. The reason for the occurrence of positive reactions to pigment in patients with this disease must obviously be systemic absorption from the melanin-containing cells. That such absorption occurs in the eye is certainly not surprising. The disease is characterized not only by phagocytosis of the pigment of the uveal tract in the eye, but also by vitiligo and poliosis-bleaching and loss of pigment in the skin and in the hair. Here again, as in sympathetic ophthalmia, what precipitates the disease is not known. Both diseases may well be due to the same cause.

The doubtful or weakly positive tests present a problem. They occur with much the same frequency in sympathetic ophthalmia, postoperative and posttraumatic cases with and without a subsequent uveitis, and in uveitis from constitutional causes. When such reactions are encountered in sympathetic ophthalmia, they can easily be regarded as evidence either of a diminishing or developing pigment hypersensitivity, as the case may be. An examination of Table 1 shows that in sympathetic ophthalmia, although skin hypersensitivity may develop within the first month after the onset of ocular symptoms, in some cases it may not develop until the fourth month. Once developed, it may fade and disappear after a year. Thus there must obviously be both a developing and a waning phase, which in sympathetic disease would account for the weak or doubtful reactions. In other conditions in which doubtful positives occur—after injuries or operations with or without a complicating uveitis, and in uveitis from constitutional causes—one must hypothecate some different mechanism, either slight and insufficient absorption of pigment, or some unknown factors affecting either the antigenic activity of the pigment or the reaction capacity of the organism. In any event, the doubtful positive reaction in postoperative and posttraumatic cases and in uveitis from constitutional cause has no diagnostic or prognostic significance, occurring with the same general frequency in all three conditions.

Finally, what clinical significance should be attached to positive, doubtful positive, or negative skin reaction to uveal pigment? From this study, the answer seems fairly clear.

A positive test occurring after an injury or operation involving the uveal tract especially in the presence of a persisting traumatic uveitis should put the ophthalmic surgeon on guard. A positive reaction does not mean that sympathetic ophthalmia is imminent or inevitable. It does mean that it is a possibility. This possibility should be carefully weighed in the decision to enucleate or not to enucleate the injured eye. In general, our feeling is that if all is going well and it is probable that the injured eye will have some useful vision, then a positive pigment test should be disregarded. On the other hand, if the eye appears clinically as a possible sympathogenic eye, or if there is little prospect for the preservation of any useful vision, then enucleation is indicated.

The interpretation of a doubtful positive reaction is more difficult. In outspoken sympathetic ophthalmia, the doubtful or weak positive may be regarded as evidence either of a developing or waning hypersensitivity. In conditions other than frank or suspected sympathetic ophthalmia, the doubtful positive reactions have obviously little diagnostic significance.

Negative or nonspecific reactions give

only slight comfort to the surgeon. A study of Table 1 reveals that in four of the 30 cases of sympathetic ophthalmia tested for skin hypersensitivity in the first three months, the skin test was negative when first done, although in two patients it later became positive. In these patients, the development of hypersensitivity in the skin apparently lagged behind its development in the eye. Thus a negative test after an injury does not preclude the possibility of sympathetic ophthalmia. However, in the presence of a reasonably favorable clinical course, a negative test does make the occurrence of sympathetic ophthalmia very unlikely.

Summing this up, the diagnostic and prognostic significance of the skin sensitivity test is limited. Positive tests are causes for alarm and increased vigilance. Doubtful and negative tests lend slight comfort and indicate in general a better prognosis. However, the margin of error in both positive and negative tests is so great that their interpretation should be made only in the consideration of the clinical course.

FUNCTIONAL HOME EXERCISES IN CASES OF EYESTRAIN

MARIANNE EYLES, M.B.O.S.
Seattle, Washington

The criterion for giving or not giving orthoptic treatment does not depend upon the presence of a demonstrable heterophoria, but upon the presence of an actual asthenopia. If the patient complains of symptoms after refractive correction, orthoptic treatments are indicated, but if there are no symptoms in spite of the presence of heterophoria, such heterophoria being of the inherent type, then treatments are contraindicated. Inherent exophoria may be due to anatomic causes, and the etiology of this condition indicates that, normally, it does not have a related asthenopia.

A developed exophoria of more recent onset shows, on the other hand, that a breakdown has occurred in the functional ability of the eyes to restrain a latent deviation by means of such reflexes as fusion, convergence, and so forth. It is the persistent effort of the subconscious mind to maintain normal binocular vision in the presence of ocular imbalance which causes the development of symptoms. These symptoms may range from slight discomfort to extreme neurogenic fatigue and the production of psychoneuroses. Treatment is therefore directed toward the attainment of a smoothly working dynamic apparatus, so that the individual can deal both physiologically and psychologically with any visual situation in any presentation and still be within the limits of ocular comfort.

In all cases there must be a full range of convergence, but in exophoria and esophoria the latent deviation must also be dealt with by actually varying the accommodation-convergence relationship for any given distance. In exophoria, besides teaching full convergence over the normal range, we endeavor to train excess convergence for a given amount of associated

accommodation; or, in other words, to teach relative relaxation of accommodation while the convergence is exerted to the utmost.

In the case of esophoria, it is still necessary to teach full convergence, since this is a normal function, together with a lessening of the rigid accommodation-convergence link which exists. In this way the esophoric patient is taught to accommodate without overconverging or while relaxing the associated convergence. A full range of divergence must also be present. In both exophoria and esophoria, the patient acquires a foveal suppression habit, especially in the case of latent divergence. Antisuppression treatment is, therefore, always necessary.

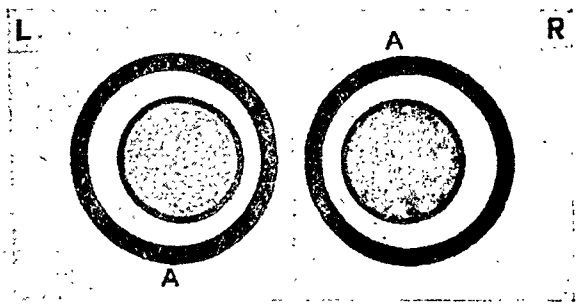

Fig. 1 (Eyles). These figures are printed on separate white cards which are 2 by 3 inches in size. The center circle of the card marked L is colored a medium green; that of the card marked R is a medium red.

It is noted that when the normal ocular functions such as convergence, divergence, good fusion range, and stereoscopic vision are fully restored, there is complete freedom from symptoms even though a heterophoria may still be demonstrated by disassociation tests.

Severe symptoms may be present even when there is orthophoria for distance and near, in which case convergence insufficiency is usually the cause. The convergence reflex was the last to develop phylogenetically, and it is often easily disrupted either under the strain of excessive use or through under use, as in the case of the faulty ocular rigidity (almost a "fixus") which some persons acquire. These persons apparently have a horror of ocular movement, especially disjunctive. The treatment of convergence insufficiency is very satisfying, since symptoms quickly disappear.

Another group of patients, the presbyopic, need some functional adjustment. Their reading addition is conducive to the increase of exophoria and, since accommodation is not normally used, to the lack of convergence incentive.

Orthoptic treatments should prove much more effective than the use of base-in prisms, in correcting these various conditions. Functional anomalies require a dynamic functional cure rather than a physical adjustment which cripples the normal innervational and physiologic processes. Because of this, orthoptic treatments attempt to establish corrective conditioned reflexes, or to reinforce existing conditioned reflexes, on a sound physiologic basis.

Exercises for home use

The following exercises (to be carried out as the doctor recommends) are intended primarily for home use. In them an attempt has been made to formulate a graded series for the elimination of suppression and the development of full convergence, full divergence, controlled convergence-accommodation relationships and stereoscopic appreciation. The patient is given the six cards* (figs. 1 to 3), together with a page of directions. The technical notes which follow the exercises are a useful supplement for the ophthalmologist or orthoptic technician.

---

* Dr. Walter B. Lancaster has helpfully suggested that each pair of pictures may be attached to a piece of cardboard and, when the patient has learned to fuse them, the cardboard can be cut in two and the pictures held one in each hand and then separated laterally.

Two minutes only are to be spent on these exercises at a time. Do them twice daily until you can do them all, then once daily for one week, followed by once every other day for a week.

Exercise 1. Hold the first pair (fig. 1) of cards side by side in your hand at about three quarters of an arm's length, or reading distance. Hold a pencil with the other hand, just in front of the cards and in the center of them. Look at the pencil point as you gradually move it toward your eyes. You will notice four blurred sets of circles in the background instead of two. When the pencil is about halfway between the pictures and your eyes, the two middle sets of circles will join up, making three in all. Hold the pencil still, and notice that the middle picture is a tunnel and has "depth"; that is, you are looking into it. There is an "A" above and below the tunnel. Keep looking at this tunnel and you will be able to remove the pencil without losing the picture. Is the middle of the tunnel red or green, or a mixture of both colors? Make a conscious effort to see both red and green.

Exercise 2. Watch the tunnel obtained as in Exercise 1, and bring the cards toward your eyes, almost touching your nose, then back to arm's length. Try to see the tunnel clearly.

Exercise 3. Watch the tunnel at about three quarters of an arm's length, and part the cards sideways, slowly. The tunnel will become smaller and smaller until the pictures break into four.

Exercise 4. Hold the cards close to your eyes, touching your nose, and you will see a blurred tunnel with its center red and green. Withdraw the cards from the eyes, slowly, watching the tunnel which will become clearer. A red and green picture will appear on either side of the joined picture.

Exercise 5. If you find Exercise 4 difficult, do this one. Hold the cards at three quarters of an arm's length or reading distance and look beyond them. You will notice three sets of circles. Watch the middle tunnel, which is the joined picture.

Exercise 6. In both Exercises 4 and 5, the tunnel, which is the middle joined picture, appears to be inverted; that is, the small circle is nearer to you than the

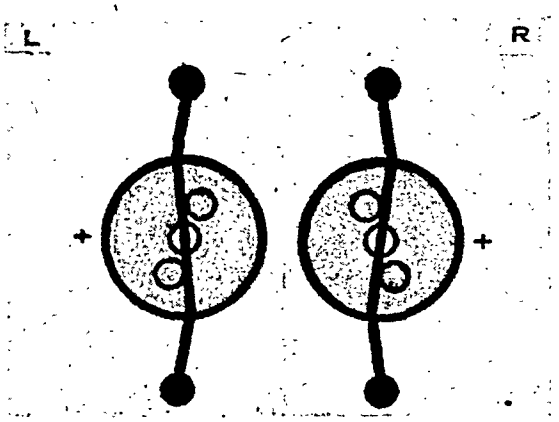

Fig. 2 (Eyles). The card size and figure colors are as described in Figure 1. The three tiny circles are colored as follows: top circle, purple; center circle, white; bottom circle, orange.

larger circle. The center of the circle should be both red and green fused. See it clearly, and bring the cards toward your eyes and back again to arm's length.

Exercise 7. Still watch the tunnel, and part the cards sideways. It is possible to part them about one inch before they break into four.

Exercise 8. Take cards Number 2 (fig. 2). Repeat Exercises 1 to 3. In this case notice that in the middle picture the line from the top ball comes toward you, then turns backward through the circle, and finally returns toward you and the lower ball. There is a small cross on either side of the middle picture.

Exercise 9. Obtain the middle picture as before, and look from the purple ball to the yellow ball and vice versa six times. The yellow ball is nearer to you.

Exercise 10. Do Exercises 4 to 7 with

cards Number 2. The stereopsis is reversed.

Exercise 11. Obtain the middle tunnel as in Exercises 4 and 5. Look from the purple ball to the yellow ball and vice

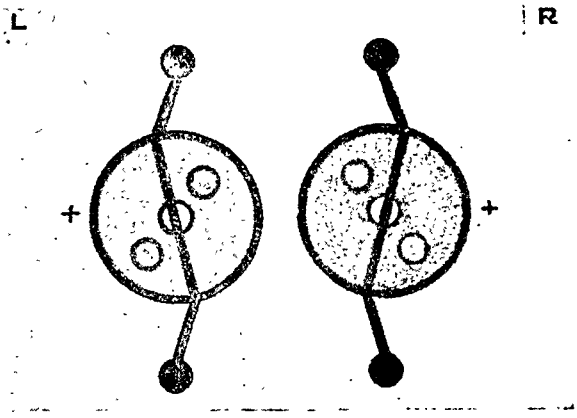

Fig. 3 (Eyles). The size and all colors are as indicated in Figures 1 and 2.

versa. Now the purple ball is nearer.

Exercise 12. Repeat all with cards Number 3 (fig. 3).

Technical notes

Exercise 1. For training convergence and fusion. Antisuppression exercise. If the middle picture appears green, then there is suppression of the left eye, and the right eye is the master eye. If the middle picture appears red, then there is suppression of the right eye, and the left eye is the master eye. If it varies, then there is alternating suppression. When there is suppression of one eye, the patient should concentrate on seeing the suppressed color. This is a good exercise for suppression on convergence.

Exercises 2 and 3. For training convergence, and relaxing accommodation while converging. Especially for treating exophoria and accommodational spasm at near (ciliary spasm), and presbyopia with convergence insufficiency.

Exercises 4, 5, and 6. If the middle picture appears green, there is suppression of the right eye. If the middle picture appears red, there is suppression of the left eye, in divergence.

Exercises 4 to 7. Especially for treating esophoria. Produces accommodation while relaxing convergence. Exercises divergence.

Cards Number 2 and 3. Angles of fusion of the two lines are 5 and 10 degrees. This is a difficult fusion exercise. Looking from the purple to the yellow balls is good convergence exercise while maintaining the static convergent position in Exercise 9 and the divergent position in Exercise 11. In all exercises depth perception is exercised.

Exophoria. Exercises 1, 2, and 3 are necessary to obtain good convergence. Relax the eyes by finishing with Exercise 5.

Esophoria and ciliary spasm. Exercises 1, 2, and 3 to obtain smooth convergence. Concentration upon Exercises 5, 6, and 7 to lessen th esophoria, ceasing Exercises 1, 2, and 3 as soon as possible.

Convergence insufficiency and presbyopic adjustment. Exercises 1, 2, and 3 especially. Relaxing with Exercises 5, 6, and 7 afterward.

Hyperphoria. Fusion of the two cards is obtained by raising one of them a little. Vertical vergences are exercised by gradually lowering the card previously raised, and keeping the tunnel fused.

Conclusion

A fusional reserve well beyond ordinary requirements will be built up by these exercises.

Since the muscle balance often changes quickly after doing them, the ophthalmologist may find it advisable to check the patient's measurements at least once every two weeks.

402 Cobb Building (1).

THE VERGENCE TEST—AN EVALUATION OF THE VARIOUS TECHNIQUES*

WALTER H. FINK, M.D.
Minneapolis, Minnesota

The vergence test constitutes an important phase of a routine refraction. It offers very tangible evidence as to the binocular efficiency.

In spite of the importance of the vergence test in routine refraction, there seems to be a question as to how generally the test is used. There apparently exists, in the minds of many, a question as to the reliability of the test. Moreover, they feel that the information obtained does not justify the expenditure of time. This attitude is seemingly due, in a large degree to the variability in results obtained. Such a reaction is understandable, because we know that a wide variation in readings may exist, not only between the different patients tested, but even in retesting the same patient. Undoubtedly, the test would be used more routinely if the reading would check on repetition; if different patients would respond similarly; and if examiners could depend upon each other's findings. In other words, definite, dependable standards should be established.

UNIFORMITY OF PROCEDURE NEEDED

Granting that various factors enter into the problem, it is evident that one factor which definitely leads to variability in results is the lack of uniformity of procedure. Analysis of available data shows a wide variation in both technique and interpretation of the findings. Such a situation inevitably leads to confusion.

An efficient technique should be evolved which is standardized. In addition, the clinician should have a clear conception as to the interpretation of the results and their relative value in contributing to the analysis of the case being examined. With this standardization of technique, and the resulting greater consistent readings, the clinician would be more willing to spend precious time to do the test.

It is the object of this presentation to attempt to analyze the more common methods of testing vergence in use today, and to attempt to evaluate them. It seems logical that a definite technique could be evolved which would embody all the advantages of the various techniques, and be a step toward securing more constant and dependable results.

The problem may be divided into two phases: first, a consideration of the various steps to be determined in the vergence test; and, second, the technique for determining these steps.

VARIOUS STEPS TO BE DETERMINED

In the first consideration, which has to do with the various steps to be determined, there seems to exist a difference of opinion as to what constitutes a satisfactory procedure. A review of the medical literature shows that very little organized investigation has been carried out on the subject. Judging from the information available, a large percentage of the profession employs the vergence test, but varies its procedure. For example, Pascal[1] and Roper[2] advocate that the blur, break, and recovery points should be determined; whereas, Tait[3] and Burian[4] advocate the determination of only the break and recovery points. As a whole, it appears that most clinicians limit their observation to only the break point.

* Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946. This paper was accompanied by elaborate charts, information concerning which may be obtained from the author.

The majority of the literature available is comprised of the work of physiologists, and this work was instigated chiefly by Sheard[5] and Fry.[6] Their research, which is based upon investigation both in the laboratory and in the clinic, is as a whole in agreement. According to their data, there is evidence to support the fact that an adequate vergence test should include a test for adduction, which embraces the determination of the blur, break, and recovery points for both distance and near. In testing for abduction, the determination of the blur, break, and recovery is made for near, but only the break and recovery for distance. In the case of the supraduction, only the break and recovery are determined. This group of observers maintains that a complete picture of the vergence power is obtainable only when the above routine is followed.

Physiology of the vergence test

Although it is outside the scope of this paper to explain the physiology, and discuss the various interpretations advanced concerning these various steps, it seems advisable to summarize very briefly the consensus held by the majority of the workers in this field. It is thought that the chief contribution of the blur, break, and recovery points give to the analysis of the case is a more detailed picture of the accommodative-convergent relationship. In them, we have a means of analyzing the various phases of this association, bringing to light any abnormal relationships.

Fry[7] states, "In the blur-point test, prism power is gradually increased in an effort to throw the images off corresponding points of the two retinas. The reflex fusional mechanism compensates the effect of the prisms by making the eyes turn as the prism power is increased. As long as the increase in the power of the prism is compensated solely by the operation of the reflex fusional mechanism, the target remains clear. When blurring does occur, it is the limit of fusional convergence, and means that the accommodative mechanism is thrown out of focus by over-accommodation in the base-out test, and under-accommodation in the base-in test. These changes in accommodation assist in maintaining fusion, because every time accommodation increases or decreases, the associated convergence must follow suit.

"Accommodation remains relatively constant from the base-in to the base-out blur point. At the base-out blur point a rapid increase in accommodation occurs, and at the base-in point a rapid decrease. These changes in accommodation continue at the same rate all the way from the blur point to the break point. Positive fusional convergence is used to bring the eyes from the phoria position to the base-out to blur position and from this point on an increase in convergence is associated with it. Negative fusional convergence is required to bring the eyes from the phoria position to the base-in to blur position, and from this point on accommodation must be decreased in order to obtain further divergence of the eyes."

The break point represents the maximum convergence or divergence effort which can be made in order to maintain single vision. It represents the extent of the reserves set aside by the brain to hold the function steadily in force. Addition of prism power from blur to diplopia gives an additional measure of the degree to which accommodation and convergence are associated.

The recovery, or the reversion to fusion, involves the sensitivity of retinal elements in the extra-macular region. It estimates the efficiency and rapidity with which binocular fixation adjustments are made, and it probably has no bearing on the efficiency with which single binocular vision is maintained after being once established for a given fixation. It gives a measure of the "desire" for binocularity.

If the patient takes the attitude of doing all he can to recover fusion, the recovery finding will be much higher than if he had taken a passive attitude and waited for the two images to fuse of their own accord. When such an effort is made to fuse the images, presumably what happens is that a voluntary movement of convergence occurs first, and then as soon as the diplopia is reduced to the point at which the reflex fusional mechanism can operate, this mechanism helps to complete the recovery of fusion.

Fry[8] states, "The movement to recovery fusion is often referred to as a reflex. The application of like stimuli to non-corresponding points of the two retinas is supposed to constitute the adequate stimulus for evoking the reflex. The nearer the two stimuli come to falling on corresponding points, the more effective they are in evoking the reflex, and if the image on one retina falls too far away from the point corresponding to the image on the opposite retina, no response can be obtained. Undoubtedly, the operation of such a reflex mechanism must play a dominant role in the reversion to fusion, but it is necessary to reckon with a certain amount of voluntary control over convergence."

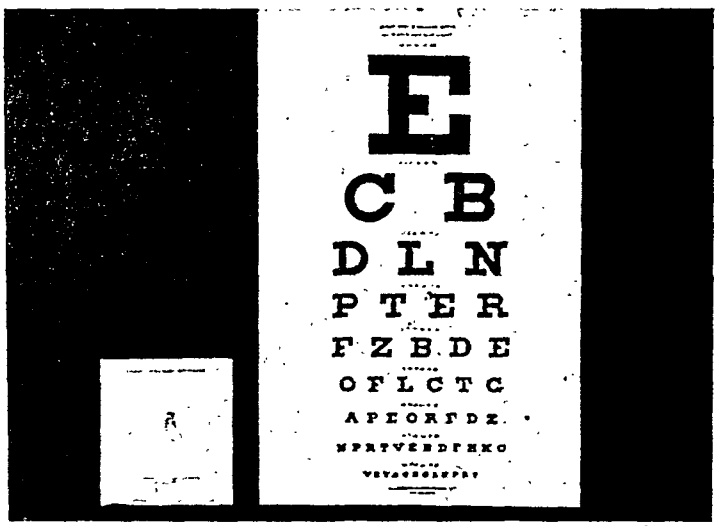
Interpretation of abnormal findings

This very briefly indicates some of the opinions held concerning the physiology of the vergence tests. To elucidate on the interpretation of the various abnormal findings would exceed the scope of this paper. It is noteworthy that experimental data reported attribute practical significance to the various abnormal relationships.

The absence of a normal accommodative-convergence relationship indicated by a high, low, or absence of the blur point, is of diagnostic significance. Likewise, a high or low break point and a high or low recovery point is of value in estimating the binocular efficiency.

Fully cognizant of the many valuable contributions to the subject, it is obvious that the final status of the blur, break, and recovery points has not been fully established. As long as there exists a disparity of opinion concerning their value, the subject is still unsettled and calls for more study.

Fry,[9] who is one of the outstanding contributors, states, "I am very humble about this problem, and if I heeded my scientific inclinations, I would not try to formulate an opinion. But from the point of view of teaching students, it is necessary to formulate some statement of the problem, and the formulation that I have presented is really one which we are accepting tentatively as a basis of clinical procedure until it can be replaced by a more satisfactory formulation of a problem."



A unified effort should be made to establish a definite evaluation of the various phases of the vergence test. If the results are based upon an adequate scientific background, the status of the test will become fully established, and we will know what is of practical value and what is of scientific interest only. A common understanding will be reached in deciding as to what routine should be followed in order to obtain the maximum practical knowledge in doing the vergence test.

Methods of doing vergence test

The other consideration, namely, the method of doing the vergence test, is an important factor in our problem. The literature shows a wide variation in techniques and instrumentation. For example, the use of the prism is typical. Some advocate a rotary prism, others advocate the prism bar; whereas, others advocate a separation of the target used. The most commonly used target is a spot of light; others use various types of targets, such as a single letter, a line of letters, or a complete chart such as the Snellen chart, all of which are constructed to stimulate

macular fusion with more or less disregard for perimacular and peripheral fusion.

It is evident that such variation in method should produce variable readings, and thus make it impossible for two examiners to compare results. It is logical to believe that the various techniques are not equally accurate. Steps, therefore, should be taken to select the most efficient method and to make it a standard. If a standardized technique were adopted, more uniform results could be expected. This, in turn with a knowledge of the interpretation of the findings, would stimulate the examiner to make the vergence test a part of his routine investigation, and consider it as important as testing for astigmatism.

A B

Fig. 1 (Fink). A is a reduced Snellen chart to be used at near point. B is a standard Snellen chart.

Standardization study undertaken

With this in mind, the following investigation was undertaken. One hundred cases were analyzed and the data obtained were used in conjunction with other available data to formulate a method of procedure. Various techniques and instruments were compared, both for the type of prism used, and also the type of target most suited. It was considered desirable to eliminate all factors in instrumentation which would contribute to variation in readings.

Refractive procedure followed

All cases were refracted under cycloplegia, and only the cases with 20/20 vision in each eye and a small refractive error were selected. In addition, only cases showing a small amount of heterophoria, normal accommodation, and PcB. were used. By being selective, a greater possibility of what may be considered normal vergence range could be obtained.

The procedure was as follows: The full refractive error was worn during the examination. Accommodation for each eye was tested. Near point of convergence was likewise checked. Muscle balance was determined by the prism-displacement method. This was checked for both distance and near. Only cases whose muscle balance were within what may be considered normal limits were employed. Cases showing a hyperphoria greater than one prism diopter were discarded. The cases showing one diopter of hyperphoria had it corrected by prisms.

VERGENCE-TEST PROCEDURE

In doing the vergence, the jump method (prism bar) was compared with the results using the rotary prism. Adduction and abduction were measured both for distance and near.

Only the lateral ductions were included in the investigation, because the additional testing of the vertical ductions would prolong the test, producing more fatigue, and would not appreciably influence the conclusions.

In checking the vergence at 20 feet, the following steps were taken: For adduction—the blur, break, and recovery points were determined. For abduction—the break and recovery points were determined. At 15 inches both for adduction and abduction the blur, break, and recovery points were recorded.

The following targets were compared both for distance and near. A standard spot of light was employed both at 20 feet and at 15 inches. A standard Snellen chart was used for the 20-foot determination, whereas, the reduced Snellen chart was used at 15 inches.

A third target, as devised by the author, was used for comparison. This consisted of a line of letters corresponding to the 20/20 line such as used on the Snellen chart. Behind this line of letters was a large "E" one foot in diameter, which was rotated slowly by a small motor. A similar chart was used for the 15-inch test in which small print was used, with a rotating "E" four inches in diameter placed behind it.

The fourth target compared was one in which stereoscopic vision was employed. Polaroid lenses were placed in the phorometer, and the patient was tested at 20 feet by projecting a picture on a screen. This process was repeated at 15 inches. When the patient was tested at 20 feet, the room was in a darkened condition so that objects in the room would not influence results. It is the opinion of some students of this subject that by using stereoscopic vision we simulate ocular experience encountered in daily life where the whole retina is involved. They maintain that binocular action is dependent not only on the macula, but also on perimacula and peripheral areas of the retina, and a true test of the vergence power should be the result of such a stimulation of the entire retina, rather than merely macular.

A B

Fig. 2 (Fink). A is a rotating target to be used at near. B is a rotating target to be used at distance.

The cases examined had preliminary training so that they had a clear understanding of what was expected of them. The element of fatigue was carefully avoided. Some cases were discarded when the coöperation was questionable.

Discussion

An analysis of the data obtained from the study suggests the following conclusions:

It is important to emphasize that fatigue will alter the findings. The test should therefore be carried out with a minimum number of repetitions. When fatigue is evident, rest should be taken.

Proper rotation of the prisms should be employed. Rotating the prism too rapidly is apt to break the fusion quickly, resulting in abnormal duction findings. Likewise, too slow a rotation places undue strain on the muscles involved, and will also alter the findings.

The full correction should be employed, including the correction of the vertical imbalance of one degree or over.

Rotary prisms seem to be superior to the prism bar or separate prism. The gradual increase in using the rotary prism gives a more constant result than the steplike increase as experienced when using the prism bar. The phorometer is the most satisfactory instrument for this.

The test should be done at both 20 feet and 15 inches. The 15-inch test is the more informative.

To obtain the maximum information, it is necessary to test the blur, break, and recovery points. In distance testing with the base-out prism, the three steps should be noted. With the base-in prisms, only the break and recovery points are noted. In testing at 15 inches, the blur, break, and recovery points are noted for both base-out and base-in tests.

In testing for the blur points, great care must be exercised. Considerable difficulty is encountered frequently in the recognition of the blur point, especially when the blur and break occur almost simultaneously. The patient should concentrate on the smallest print he can see, and indicate the point when the print is completely blurred. By using this technique, a more definite reading can be obtained. The blur point can be simulated by inserting a half-diopter sphere before the eyes, which will cause the letters to blur. This will give him a better conception of what to watch for.

The break point is comparatively easy to determine, and is more consistent if the attention is directed to the entire target when the blur point is reached. The patient is instructed to hold the target single as long as possible. When the break occurs, he will be suddenly aware of two widely separated targets and may or may not have been conscious of the process of separation of the images.

The recovery point is variable if a definite technique is not carried out. The patient is instructed to concentrate on the whole target and to try to unite the separated images, thus having convergence take an active part. This convergence, plus the fusion desire, causes the establishment of single vision.

The target producing the most consistent results was the rotating type. It was superior to the others in that the motion produced a more consistent stimulus to the perimacular area, so that when the break point was reached, the patient was immediately conscious of it. Likewise, the recovery-point reading was more consistent because the stimulus was uniform. It should be emphasized that the recovery-point reading is very uncertain and variable unless the patient is fixing on the entire target, which will stimulate both the macula and perimacula. To fix on small letters at this point materially alters the reading.

Next to the rotating target in efficiency was the Snellen chart. The regulation chart was used for distance and the reduced chart for close. From a practical standpoint, this target can be used, although the results were not so consistent as the rotating target. However, it was superior to the spot of light.

The spot of light was the most inefficient. It produced a wide variation in results because it stimulated only the macula, ignoring the perimacular area; reflexes confused the patient; the bright light fatigued the patient; the blur point was practically impossible to determine; the break and recovery points were frequently missed and varied widely. Repeated trials were frequently necessary which added to ocular fatigue.

The stereoscopic target using polaroid seemed to offer even greater possibilities than the other targets. It has the advantage in that it tests the macular area, the perimacular, and also the peripheral area of the retina. It thus simulates what we actually experience in daily life. It gives us a truer picture of our ocular coördination than the more artificial methods. It is possible that with this method the rotary prism should not be used, but rather the vergence power tested by a separation of the two superimposed pictures making up the target. This method, however, is as yet not feasible, but it is very possible that it will ultimately be the method of choice. This change in technique should produce more consistent results, and will give us a truer picture of the efficiency of the binocular apparatus.

The comparison of the polaroid method with the rotary target was favorable. The readings did not agree in amount but the relationship in readings was in fair agreement. The objective is quickly grasped by the patient, and the blur, break, and recovery points recognized with comparative ease. Of the various targets tested, it seems to offer the greatest promise because it simulates more closely conditions in daily life, and is a better stimulus to our desire for stereoscopic vision.

Summary

To formulate a routine to be followed in testing the vergence, the following procedure is suggested. Based on the study of the above cases, it incorporates techniques which seem to produce more consistent results, are more understandable to the average patient, lessen the time factor, produce less fatigue, and give the maximum information obtainable.

1. The test is briefly explained to the patient.
2. Fatigue is avoided. A short interval of rest is valuable if the patient shows signs of fatigue.
3. The room should be quiet, and the period free of interruption.
4. The room is illuminated in a normal manner.
5. The correction is used, and if the hyperphoria is one diopter or over, it should be corrected.
6. The phorometer with rotary prism is preferable.
7. The prism should be rotated at the proper speed.
8. The rotating target or the Snellen chart is used both for distance and near.
9. Distance base-in test: Attention is directed to the whole chart and not to a specific line. Base-in prisms are rotated before the eyes in the manner indicated above. A recording is made of the amount of prism necessary to create diplopia. The rotation of the prisms is then reversed, having the patient make an effort to unite the images and the point recorded as the return fusion occurs.
10. Distance base-out test: A similar method of procedure is used in making this test as was used in the base-in test, with the exception that we employ a line

of small letters representing the patient's highest distance visual ability. The selection of the smallest type the patient can read is of extreme importance, because even a slightly larger fixation object is apt to give a much higher reading.

The patient's attention is directed to this line of small letters; base-out prisms are introduced in increasing amounts; and the point recorded at which the patient reports he can no longer read the letters. This is the distance blur-out point.

Next, direct the patient's attention away from the small blurred letters to the entire target and instruct him to keep it single as long as possible. The base-out prisms are increased in amount and the point recorded at which diplopia occurs. The patient is asked to try to unite the two targets, and the prisms are then rotated in a reverse direction. A record is made of the amount of prism, allowing for refusion of the target.

11. Near-point base-out test: The technique is similar to that used in testing the distance base-out test. The patient's attention is directed to the reading of the smallest type possible on the near-point target. Base-out prisms are slowly increased in amount before the eyes as the patient attempts to maintain the necessary accommodative adjustments for keeping this fine type legible. The point at which the type becomes illegible, or blurs out, is the blur-out point.

After the blur-out point has been reached, the patient's attention is referred to the entire target, and he is instructed to keep it single as long as possible. The increase of base-out prisms is continued until diplopia results. This is the break point. The prismatic power is next reduced and the patient is instructed to fuse the two images. This point is recorded as the recovery point.

12. Near-point base-in test: The technique for this test is identical with that of the foregoing test, with the exception that base-in prisms are used.

13. Vertical ductions: These are tested for the break and recovery points both for distance and near.

This briefly outlines a feasible routine to be used in testing the vergence. Appreciating the fact that such a procedure is time-consuming, and that such an expenditure of time may not be indicated in every refractive case, it will, when the indication arises, serve as a guide to a complete analysis of the vergence power, and give a more complete picture of the accommodation-convergence relationship. Although the above recommendations are based on a comparatively small group of cases, and therefore cannot be considered except as suggestive, they serve at least to point the way to further investigation. It is important to point out that the inclusion of the blur, break, and recovery points in the above routine is tentative. The data obtained concerning them in the series of cases here presented are suggestive. More data are necessary before a final opinion can be formulated concerning their clinical value.

Conclusions

The vergence test is an important part of our daily routine. It is generally admitted that the various techniques used for this test do not give consistent results. An attempt is made to determine which is the most efficient and the most dependable. Certain changes in techniques seem to increase the efficiency of the test. These changes in techniques, according to the data, produce more dependable readings, produce less fatigue of the patient, are more understandable to the patient, save time for the examiner, and give a more correct interpretation of the findings.

INTRAOCULAR FOREIGN BODIES IN SOLDIERS*

HELENOR CAMPBELL WILDER
Washington, D.C.

Retained foreign bodies were found in 731 of 3,882 eyes of soldiers studied at the Army Institute of Pathology during World War II. Although nearly all of these foreign bodies were introduced during combat and training, a few were the result of preinduction injuries, with recent exacerbations of pain and inflammation leading to enucleation. All globes with penetrating wounds were examined by X ray and were searched for foreign bodies. In many instances the particles were so small or so deeply embedded in organizing hemorrhage or inflammatory membrane that they were not recovered from the gross specimens and only became visible on microscopic examination. These could not be subjected to magnet test, but sections containing them were stained with Prussian blue. Those which gave a positive iron reaction were classified as probably magnetic, although the degree of their magnetic quality could not be determined; whereas, those giving no reaction were regarded as nonmagnetic. The Federal Bureau of Investigation assisted in the more specific identification of many of the foreign bodies by spectroanalysis. In many eyes the particles were multiple (figs. 1 and 2), and in a few, both magnetic and nonmagnetic materials were found. The following table demonstrates a preponderance of retained nonmagnetic foreign bodies in eyes of soldiers who, in all but a few instances, had sustained military injuries.

INTRAOCULAR FOREIGN BODIES

Ferrous	273
Nonmagnetic	452
Both	6

Ferrous foreign bodies (figs. 2 and 3), although outnumbered by nonmagnetic ones, formed the largest relatively homogenous group. Some were more strongly magnetic than others, and it is possible that many which were weakly magnetic on direct contact may have been clinically nonmagnetic.[2] Siderosis, with deposits in the cornea (fig. 4), lens (fig. 5), filtration angle, iris, ciliary

epithelium (fig. 6), and retina (figs. 7 and 8), occurred in 27 eyes with retained ferrous particles. In one eye, a rather extensive iron reaction was noted only 23 days after injury, but in this case many ferrous particles provided multiple foci of diffusion. In some instances in which ferrous foreign bodies had been retained for much longer periods, early encapsulation by scar tissue (fig. 9) had prevented dissemination of the metal, and only a local iron reaction was obtained with Prussian blue. In hematoxylin and eosin sections basophilic staining, as well as pigmentation, was frequently ob-

served around the sites of the ferrous material (fig. 10), but rarely around other metals and never to so marked a degree.

The nonmagnetic foreign bodies comprised a variety of materials. Among the metal substances, copper, brass, lead, nickel, and zinc alloy were identified; among the nonmetallic, glass, vegetable matter, eyelashes, rock, shale, and clay predominated.

Copper and brass were most numerous among the nonmagnetic metals. Unfortunately chalcosis could not be demonstrated by special staining, and it was, therefore, impossible to study the intraocular distribution of copper.

Many nonmagnetic foreign bodies were readily identified by gross or microscopic examination more specifically than by magnet test. Copper fragments (fig. 11) could be recognized both in microscopic sections and on gross examination by their characteristic color. Lead (fig. 12), in comparatively large pieces, was sectioned in the celloidin blocks with little damage to the microtome knife. Glass, of course, was easily identified on gross examination, and vegetable matter and eyelashes (fig. 13) on microscopic examination. Nonmagnetic foreign bodies were found not only as primary missiles or in association with magnetic material, but also as material retained after extraction of a magnetic missile or as implants along the path of a primary missile which had passed completely through the eye. Eyelashes were the most common of the secondary foreign bodies. In one instance a fragment of chrome-green paint remained in the choroid, although the piece of metal from the bumper of a jeep which it had camouflaged had been extracted by magnet. Intraocular particles of stone, clay, and vegetable matter frequently were retained after land-mine explosions. In severe head injuries, skin (fig. 14) and bone (fig. 15) were sometimes im-

planted and behaved as inactive foreign bodies, unlike conjunctival epithelium (fig. 16) which finds the interior of the globe a fertile field for growth.

Some of the eyes in this series were removed because of the severity of the initial injury and before secondary pathologic changes had appeared. In these, partial evisceration, disorganization, massive intraocular hemorrhage (fig. 17), and collapse of the globe were the kinds of damage which led to early enucleation. All stages of organ-

izing hemorrhage were present in eyes removed after longer postoperative periods (figs. 18 and 19).

Abscesses were frequently seen around the sites of foreign bodies of various types, almost invariably around vegetable matter (fig. 20). In the vitreous chamber, the subsequent formation of a pyogenic membrane resulted in retinal detachment (fig. 21) and phthisis bulbi (fig. 22). Glaucoma, a less frequent sequela of intraocular foreign body, was present in association with siderosis bulbi. It also occurred occasionally when the missle lodged in the anterior chamber and the inflammatory process was confined to the anterior segment (fig. 23). Foreign-body granulomas appeared around all kinds of foreign bodies, but the formation

of giant cells seemed to be stimulated particularly by eyelashes (fig. 24) and vegetable matter (fig. 25). In some instances large syncitial cells were arranged around implanted hairs in such a way as to suggest proliferated sheath cells. Phagocytized melanin granules were usually present in them, however, confirming the opinion that they were more probably true histiocytic giant cells. The tendency of vegetable matter to stimulate a giant-cell reaction is evidenced in a case in which cotton fibers and carbon particles were introduced into the vitreous chamber by a dynamite explosion. Endophthalmitis developed and the eye

was enucleated six weeks following injury. Incarcerated in an inflammatory cyclitic membrane, the cotton fibers (fig. 26) were all surrounded by giant cells, whereas none appeared around the carbon particles (fig. 27).

Sympathetic uveitis developed in five patients with retained intraocular foreign bodies. In one instance, lead (fig. 28) had been introduced in combat two months before enucleation and in another, wood (figs. 29 and 30) had been introduced in a preinduction injury 36 years before enucleation. In the latter, following the old corneal perforation, the eye retained a small amount

of vision until three months before enucleation, when it became inflamed and blind. Uveitis appeared in the sympathizing eye one month before enucleation. One eye retained a fragment of glass until enucleation 1½ months after injury. One was removed three months following the introduction of an unidentified nonmagnetic foreign body. In the fifth case the time interval between injury and enucleation was not given, but about one week after injury, severe uveitis was reported to have developed in the sympathizing eye. The foreign body was magnetic.

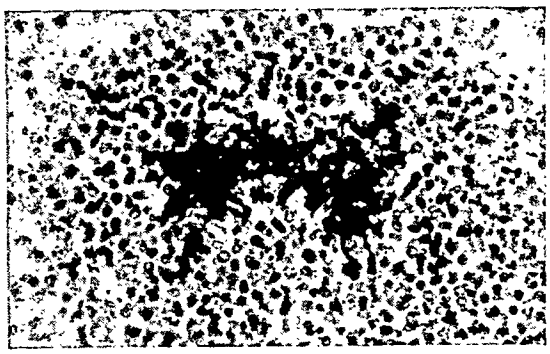

Fig. 32 (Wilder). Colony of unidentified fungi in a vitreous abscess. A minute nonmagnetic foreign body was found in the abscess on gross examination. Enucleation followed penetrating wound sustained in Italy. Duration unknown. A.I.P. Negative 97283.

Fig. 33 (Wilder). Wood fragment prolapsed with retina through corneal wound in purulent panophthalmitis. Enucleation eight days after injury. A.I.P. Negative 97355.

A variety of infections followed introduction of foreign material into the eye. Masses of cocci (fig. 31), bacilli, and unidentified fungi (fig. 32) were sometimes seen in vitreous abscesses. Saprophytic fungi were frequently found in and around wood particles (figs. 33, 34, and 35).

Comment

A wide variety of foreign bodies was found in eyes of soldiers following injuries in training and combat. Of these approximately 37 percent were magnetic, 62 percent

nonmagnetic, and 1 percent mixed. This apparently confirms previous observations[1, 2, 3] that in military injuries nonmagnetic intraocular foreign bodies predominate. They do, undoubtedly, in eyes submitted for pathologic examination, but many instances of successful magnet extraction do not come to the pathologist's attention; and, even in eyes that are enucleated, nonmagnetic foreign bodies are often secondary to ferrous missiles which may have been extracted. The infections and reactions associated with the different types of foreign bodies ran the gamut from staphylococcus infection, resulting in purulent panophthalmitis, to the mild reactive inflammation associated with siderosis bulbi and intraocular hemorrhage without infection. The formation of giant cells was particularly abundant around vegetable matter and eyelashes. Of particular interest were five cases of sympathetic uveitis associated with retained nonmagnetic material in four eyes and with a retained ferrous foreign body in one. Phthisis bulbi was a common end result, and glaucoma was comparatively rare, as in any series of penetrating wounds.

I wish to thank Lawrence P. Ambrogi and Eleanor V. Paul for X-ray studies, careful gross examinations, and magnet tests, as well as for their preparation of sections which always included the foreign body sites.

7th Street and Independence Avenue, S.W. (25).

THE SURGICAL CORRECTION OF PARESIS OF THE SUPERIOR OBLIQUE*

WILLIAM P. McGUIRE, M.D.
Winchester, Virginia

It is well recognized that paresis of the superior oblique is, with the exception of paralysis of the external rectus, the most common paresis of any individual ocular muscle. In the past three quarters of a century, cases of underaction of this muscle have been reported with increasing frequency, but until 1934 when Wheeler[1] reported upon his procedure for the advancement of the tendon, the surgical relief of paresis of the superior oblique was confined to procedures upon its yoke or direct antagonist muscles, with occasionally a recession of the superior rectus, or a resection of the inferior rectus of the same eye. Even since Wheeler's report, the vast majority of attempts at correction of the condition have dealt with the yoke or direct antagonist muscles and, only in rare instances, has the tendon of the superior oblique been operated upon. Whether or not this is due to the deeply ingrained belief of most ophthalmologists that it is dangerous to operate upon the superior oblique, I cannot say, but it is in an attempt to dispel this fear that this study and case reports are presented.

HISTORY

The malposition of the eyes which constitutes strabismus has been recognized from the earliest period of medical history, but not even the anatomy of the muscles concerned in ocular movements was understood with approximate accuracy until studied by Fallopius[2] in the 16th century. In the middle of the 18th century John Taylor[3] claimed to straighten cross-eyes by operation. Sir Charles Bell,[4] in 1823, divided the recti and oblique muscles of the eyes of lower animals and concluded that the former had to do with the voluntary and the latter with the involuntary movements of the eye. In 1827 Anthony White[5] suggested that by cutting the ocular muscles one could correct strabismus but the suggestion was not acted upon until Dieffenbach[6] operated.

Meanwhile, the treatment relied upon for squint was the wearing of a mask with openings through which the eyes could see only when properly directed, as suggested by Paulus Aegineta[7] in the 7th century; or the occlusion of the fixing eye proposed by Erasmus Darwin,[8] in 1778. In 1831 Strohmeyer[9] performed a tenotomy on the tendo achillis and followed up his first partial success by operating on muscles and tendons in all parts of the body. In 1838 Strohmeyer did a "myotomy for strabismus" on a cadaver. The era of operation upon the eye muscles may be said to begin with the announcement of Dieffenbach (1839) that he had obtained a perfect result in a case of convergent strabismus by division of the internal rectus muscle.

ANATOMY

The muscle arises by a short tendon just anterior and medial to the optic foramen, from which it is separated by the medial rectus, in the angle between the zonule of Zinn and the periorbital fascia. The belly of the muscle runs forward along the nasal wall of the orbit, close to the internal rectus but separated from the latter by the nasociliary nerve and ophthalmic artery and crossed by their ethmoidal branches. A few mm. behind the

* Presented as a candidate's thesis for membership in the American Ophthalmological Society, June, 1946.

orbital margin at its upper nasal angle the muscle becomes tendinous and passes through a cartilaginous ring, the pulley or trochlea. This is the physiologic origin of the muscle. The tendon then bends backward, laterally and slightly downward, pierces Tenon's capsule and passes beneath the superior rectus to be inserted into the sclera in the superior posterior lateral quadrant of that structure. The tendon is enveloped by a prolongation of Tenon's capsule from its insertion to the pulley, and is, on the average, 20 mm. in length.

Embryologically Whitnall[10] states that the reflected portion of the muscle, that is, the tendon, from the trochlea to the insertion in the sclera, is fleshy in most mammals, and in the lower vertebrates the whole muscle is represented by the reflected portion only, this arising from the medial angle of the orbit near the origin of the inferior oblique.

The line of insertion of the tendon crosses the vertical meridian of the globe obliquely and is curved with a backward directed convexity. In the anterior part the tendon is narrow and almost rounded but near the insertion it spreads out in a fan-shaped insertion.

The distance from the corneal margin to where the tendon crosses the vertical meridian has been measured by Fuchs[11] who found it to be from 16 to 17.9 mm., and by Weiss[12] who found the anterior edge of the obliquely placed line of the tendon to lie 13.85 mm. from the cornea and 14.66 mm. from the optic nerve, while the posterior end was 18.8 mm. from the cornea and 7.56 mm. from the nerve.

Fortin[13] has stated that the insertion of the superior oblique into the sclera lies just above the macular region and attributes many of the cases of retinal detachment in the macular area to the pull of the tendon of the superior and inferior obliques upon the sclera in this region.

The trochlear or fourth nerve crosses over the direct portion of the muscle from the medial side to enter its substance at about 12 mm. from the origin while the blood supply is derived from the superior muscular branch of the ophthalmic artery.

The trochlea or pulley of the superior oblique consists of a finely grooved and curved plate of hyaline cartilage which is attached to the periosteum of the frontal bone by fine strands of fibrous tissue, thus forming a tube through which the tendon slides. The tendon, as it passes through the trochlea, is invested by very lax areolar tissue with a poorly formed endothelial lining but according to Macalister[14] there is hardly a true synovial membrane lining the trochlea. The elongation of Tenon's capsule which envelops the tendon up to the pulley is fixed to and terminates at the latter. Embryologically the pulley was a specialized part of the sheath of the muscle at its origin, which was situated near the orbital margin, but the need for a longer muscle belly in mammals has led to the development of the pulley and the retrogression of the origin backward toward the apex of the orbit.[10]

Maddox[15] has suggested that the reason why the superior oblique has a pulley is that since the speed with which a muscle's point of insertion moves is proportional to its length, it is necessary for the superior oblique, the virtual origin of which as regards its action is from the pulley, to have a long, fleshy, reflected portion extending to the back of the orbit if it is to keep pace with the movements of the recti.

Whitnall[10] suggests that as regards this advantage over the inferior oblique, the reason may be that prolonged looking downward is more important for daily work than looking upward and, therefore, the excursions of the eye due to the superior oblique are more amply provided for than those of the inferior oblique.

Physiology

The principal action of the superior oblique is to turn the eyeball down and

inward. There are two subsidiary actions of the muscle, the first being abduction of the eyeball and the second intorsion of the upper part of the vertical meridian. The main action of the muscle increases when the eye is turned inward and becomes practically nil when the eye is abducted. Thus, it is seen that when the globe is turned medially by the internal rectus and then depression is desired, the superior oblique of that eye exerts the strongest force upon the eye that is possible. When the eyeball is turned outward, the tendon of the superior oblique is situated so that it is almost at right angles to the anterior posterior axis of the globe and consequently its main action, that of depression of the bulb, is reduced to zero. At the same time, however, the secondary actions of the muscle increase when the globe is turned outward, because the tendon of the muscle lies in such a position that its effect on intorsion and abduction is greatest. Conversely, when the globe is adducted, the effect of the superior oblique on abduction and intorsion is markedly decreased.

Another function of the superior oblique, combined with the inferior oblique, has been advanced by various authors among whom are Theobald,[16] Fuchs,[17] Duane,[18] Jackson,[19] and Bielschowsky.[20] This is that the two obliques act in opposition to the four recti when they tend to pull the globe back into the orbit. Samuel Theobald[16] advanced the theory that the principal function of the obliques, assuming that they did resist the action of the four recti in pulling the globe back into the orbit, was to cause the eye to rotate, "with precision, about a fixed center, a provision so essential to accurate vision, and, especially, to perfect binocular vision."

That the physiologic function of the superior oblique has been interfered with is shown in two reports, one by Peter,[21] in 1934, and the other by Sanford Gifford,[22] in 1942, in which transplantation of the tendon of the muscle to the tendon of the internal rectus was performed in cases of paralysis of the third nerve. In each case the eye, in the primary position, was rotated outward, and in each case the external rectus was recessed prior to the transplantation of the superior oblique. Both authors reported that abduction was limited by the total procedure, but failed to mention that the eye could be adducted to any degree beyond the midline as a result of the operative interference. This leads one to the speculation that the cosmetic improvement in these cases was due to the recession of the external rectus and not to the transplantation of the superior oblique.

In support of the theory of the transference of function in the transplantation of the extraocular muscles is the work of Olmstead, Margutti, and Yanagisawa,[23] in 1936, who conducted experiments on the extraocular muscles of dogs, cats, and monkeys in which various muscles were transposed with a view to finding out whether coördinated movements after operation might not be the result of the interaction of the undisturbed muscles, and, if real transference of function does occur, whether there is possible a brief period of readjustment, or learning, which would indicate that the original conducting pathways are predetermined, and new ones must be laid down to meet the changed conditions.

After the series of experiments in which muscles were tenotomized and other operations in which muscles were transplanted, these authors came to the conclusion that the first movements of eyes of animals coming out of anesthesia after operation were in the direction that one would expect if impulses to muscles were coming out over the usual pathways, but gradual adjustment to the new situation took place with the lapse of time.

Leinfelder and Black,[24] in 1942, studied the effect of the superior oblique, along with the other extraocular muscles, in re-

covery of muscular function following tenotomy of the recti muscles. These authors outlined a series of experiments in which the physiologic effects of the superior oblique could be controlled and interpreted while effectual transposition of the muscles was being accomplished in successive operations.

These operations consisted in tenotomizing and resecting the superior oblique in monkeys, either before or after other transposition operations were done. These experiments showed that interference with coördinated rotations did not occur as long as two muscles retained their normal anatomic and physiologic relationships. This is illustrated by the recovery of coördination when only the four recti were transposed; whereas, failure of recovery occurred when the superior oblique was also tenotomized.

The authors conclude that the two intact oblique muscles might be considered capable of giving the proprioceptive impulses necessary for recovery of associated movement; whereas, only one muscle is inadequate. In other words, the superior oblique has no special function in giving the necessary proprioceptive impulses when it is acting alone.

It would seem then that the basic physiology of the superior oblique reverts to the action of depression of the globe as its main function with intorsion and abduction as the secondary functions. It is true that there may be other functions of the muscle, but these are at present purely within the realm of speculation, and it is with the obvious functions of the muscle and the alterations thereof that this paper is concerned. There is here no thought of altering these functions, but merely of the most logical manner of increasing them in cases of paresis of the muscle.

Pathologic physiology

Bielschowsky[25] has stated that, if, in a case of orthophoria, a single muscle becomes paretic, deviation in the primary position is always present, being latent or manifest according to the intensity of the paresis and the function of the paretic muscle. In a case of heterophoria the paretic deviation is modified by the anomalous position of rest. In any case of paresis the position of rest must be altered by the loss of tonus of the paretic muscle and the intact tonus of the other muscles. If this is the only reason for deviation, orthophoria will be restored as soon as the paresis is cured. This cannot happen if the deviation is caused, in addition, by the development of a secondary contracture of the antagonist of the paretic muscle, due to a change in its structure. In any case of typical paresis of a single muscle the angle of deviation increases or decreases according to whether the movement of the eye is in the direction of action of the paretic muscle or of its antagonist.

Diagnosis of muscular palsy can be made if movement of the paretic eye in a certain direction is limited, but it must be remembered that even a paretic muscle can bring the eye to the normal limit by means of an excessive innervation. In many cases of palsy an anomalous position of the head is a characteristic sign, which is often explained as an endeavor to make up for the function of the paralyzed or weakened muscle by turning the head in the direction in which the eye muscle had been acting before it was paralyzed.

Bielschowsky has modified this rule to the effect that the patient chooses the least inconvenient position of the head by which the paretic muscle is sufficiently disburdened so that binocular single vision can be obtained. In cases of trochlear nerve palsy the head is tilted toward the shoulder of the sound side and at the same time rotated on the vertical axis so that the paretic eye is rotated outward.

Trochlear nerve paralysis is the most frequent type of paralysis of a single vertically acting muscle and the most striking

sign of this is habitual torticollis. The ocular origin of this kind of torticollis was first recognized by Cuignet.[26] He, however, could not explain the connection any more than could Landolt[27] in his paper on the subject.

Prior to Landolt, A. Nagel,[28] in 1871, had supposed that in cases of slight paresis of an elevator or depressor muscle, a vertical and rotary deviation would be caused by tilting the patient's head toward one side, a supposition based on the discovery that a parallel rotation of the eyes around the visual axis is produced by tilting the head toward the opposite side.

In a case of right trochlear nerve palsy if the head is tilted toward the right shoulder, there will arise a vestibular excitation of the vertical motor muscles which are able to produce a parallel rotary movement of the eyes to the left, the movement being produced in the left eye by the two inferior muscles and in the right eye by the two superior muscles. The paralyzed right superior oblique cannot compensate the elevating and adducting component of the superior rectus, from which a vertical and lateral deviation of the right visual line must result; whereas, in the normal person both the visual axes would be stationary.

If the head of the patient with the paretic right superior-oblique muscle is tilted toward the left side, both inferior muscles of the right eye and the superior muscles of the left receive the vestibular innervation to rotate the eyes around to the right. This movement can be performed without the coöperation of the paretic muscle. Consequently, no deviation of the visual axis will result. The more the sound muscles are burdened, the more favored will be the paretic muscle. The habitual tilting of the head in trochlear nerve palsy is thus understandable. If the head is tilted toward the shoulder of the sound side, the paretic superior oblique is favored and binocular single vision is obtained.

Bielschowsky[29] believes that in cases of "incurable" paralysis of the superior oblique a contraction of the inferior oblique muscle of the same eye prevents the decrease of the vertical deviation in looking upward as seen in typical cases, and finally the deviation becomes entirely independent of vertical movements.

Etiology

Many cases of superior-oblique paralysis have been reported in opthalmic literature, most of them having been one or two isolated cases. It is well recognized that next to paresis of the external rectus, paresis of the superior oblique is the most frequently occurring weakness of an individual muscle.

Snell,[30] in reporting some cases of traumatic paralysis of the superior oblique, in 1919, stated that approximately 60 percent of the cases of traumatic disturbances of the superior oblique make a satisfactory recovery wthin eight months. He held that the disturbances of this muscle due to indirect injury were most likely to recover, and even those due to direct injury where the muscle or its tendon has not been completely severed, have ceased to cause diplopia or annoying symptoms after a few months.

Sorsby,[31] in 1932, reported a case of paralysis of the superior oblique due to a knife wound, which penetrated the upper inner angle of the orbit. Savin,[32] in 1934, reported the case in which a boxer was struck in the face and immediately had a diplopia which proved to be consistent with paresis of the superior oblique. This persisted for months and was finally relieved to some extent by a recession of the homolateral superior rectus.

Probably the most comprehensive single report on the etiology of paresis of the superior oblique is that of Bielschowsky,[29] in 1939, who holds that there has been an undeniable increase in the percentage of cases of paralysis of the trochlear nerve. He does not feel that this in-

crease can be attributed to an improvement in methods of investigation, since all the cases included in the statistics he reports had been examined solely by him. Up to 1908 all cases of trochlear nerve paralysis amounted to 10 percent of all cases of paralysis of the extraocular muscles, or not quite half as many as the the cases of paralysis of the abducens nerve. From 1908 to 1932, the percentage of cases of superior-oblique paralysis increased to 20 percent and that of abducens-nerve paralysis remained the same as before or about 25 percent. This author believes that the striking increase is due to the introduction of Killian's operation and similar radical operations on the frontal sinus. In support of this belief, the author reports 15 out of 80 cases seen by him between 1923 and 1932 which had definitely been caused by operations on the frontal sinus.

All cases of paralysis of the extraocular muscles will show approximately the same relative etiology. In other words, there is no specific cause which singles out one individual muscle. It is the general consensus that trauma is the most frequent cause of these disturbances in ocular motility. Syphilis is thought to play a prominent part and next in frequency are cases of congenital origin and those due to encephalitis. Two rare cases are mentioned by Bielschowsky of paralysis of the abducens nerve due to severe loss of blood. These recovered spontaneously within a year's time. Pareses of various extraocular muscles have been reported as a complication of diabetes.

In support of the theory of Bielschowsky[29] mentioned above that the striking increase in pareses of the superior oblique is due to the great increase in radical frontal sinus operations, one has but to consider the approach to the frontal sinus in a radical operation, as seen in various illustrations in texts and monographs on exposure of this air space, to wonder why there are not 100-percent pareses of the superior oblique in this operation.[33, 34] It can be granted that the operation is necessary to relieve a condition that is amenable to nothing else but radical surgery, and that the resultant paresis of the superior oblique generally clears up spontaneously, but at that point we arrive at an impasse. We must agree that the radical operation for frontal sinusitis is necessary in some cases and that the best approach so far devised is that most commonly in use by the majority of otolaryngologists. The pulley of the superior oblique can easily be damaged by this approach either by a slip of the chisel, an overbite of the rongeur or simply damaged by the retractor. The ophthalmologist should regard this operation as a necessary evil, and, in those cases in which spontaneous recovery does not occur, he should be prepared to correct as far as possible the distressing diplopia that results from such surgery.

Paresis of the superior oblique

Signs and symptoms

As has been mentioned previously, the most striking sign of paresis of the superior oblique is habitual torticollis with the head most frequently tilted toward the opposite side from that of the paretic muscle. There is, of course, a hypertropia which increases when the eye is carried into the field of action of the superior oblique. Subjectively, there is the vertical diplopia increasing when the paretic eye is carried down and in, and, in some cases, a tilting of the images due to a disturbance in the torsion effect of the superior oblique. In addition to these symptoms many patients will have nausea, and even occasionally vomiting, particularly when an attempt is made to carry the head straight after an habitual torticollis has been established.

Surgical correction

The direct attack upon the superior-oblique muscle, either in paresis or over-

action, has been, for the great majority of ophthalmologists, something to be avoided at all costs. The principal objection seems to have been that the tendon of the muscle is too difficult of access.

Jackson[19] stated that because of its deep insertion, operative interference upon the tendon of the superior oblique near its insertion is not practicable. He advocated transplantation of the superior rectus for paresis of the superior oblique and, by his procedure, the tendon of the superior rectus was recessed and also placed slightly more temporally in order to exert more influence in causing intorsion of the globe. Landolt[35] recommended advancement combined with resection of the inferior rectus in cases of underaction of the superior oblique of the same eye.

Snell[30] held that when operation had been decided upon in paresis of the superior oblique the choice was between a tenotomy of the superior rectus of the same side and a tenotomy of the inferior oblique of the same side.

Banister[36] advocated advancing or tucking the inferior rectus of the affected eye sufficiently to bring the eye on a level with the other eye in the primary position. Savin[32] reported a case of diplopia due to paresis of the superior oblique relieved by recession of the superior rectus of the same eye.

Jaensch,[37] in reporting on a case of binocular trochlear paralysis, advocated recession of the inferior recti as the first step and this was to be followed by myectomy of the inferior oblique, if necessary.

White,[38] in discussing paralysis of the superior oblique, gives the following criteria for operative correction: if the hyperphoria is moderate, a recession or tenotomy of the inferior rectus of the opposite eye gives good results. If there is a secondary contracture of the inferior oblique of the same eye, causing a marked hyperphoria or hypertropia in the upper field, a tenotomy of the homolateral inferior oblique is indicated. If the vertical deviation is marked, White thinks it may be safer to tuck the superior oblique first, this to be followed by a tenotomy of the inferior oblique of the same eye, a recession of the inferior rectus of the opposite eye or both, depending on the subsequent measurements.

Spaeth[42] recommends recession of the contralateral inferior rectus in paresis of the superior oblique, while Dunnington,[43] in 1931, in quoting Duane's table of choice, advocated tenotomy of the inferior oblique of the same eye or recession of the inferior rectus of the opposite eye.

Jackson,[39] Peter,[21] Wiener,[40] Sanford Gifford,[22] and Wegner[41] have all reported cases of transplantation of the tendon of the superior oblique to the insertion of the internal rectus in cases of oculomotor palsy, holding that the tendon of the oblique when transplanted in this condition tends to act as an internal rotator.

As far as can be determined, surgery on the muscle itself in cases of disturbances of motility due to the superior oblique has been described by four authors. Hughes and Bogart,[44] in 1942, described their method for recession of the trochlea in cases of overaction of the superior oblique. Axenfeld[45] reported myotomy of the inferior oblique followed by "extirpation" of the trochlea for cosmetic purposes by exclusion of both obliques. Van der Hoeve[46] stated that tenotomy of the superior oblique was seldom performed, but that according to Czermak and Elschnig one method is to progress from the conjunctiva after detachment of the superior rectus. Wheeler[1] reported his method for advancement of the underacting superior oblique, in 1934.

My interest in the surgical correction of paresis of the superior oblique was stimulated by the report of Wheeler[1] on his advancement procedure for underaction of the muscle. The method which I now use is essentially a modification of Wheeler's procedure and was devised simply because it seemed to offer a little surer

method of achieving the desired result. In the six cases of paresis of the superior oblique which are reported in this paper, seven operations were performed. Wheeler's method was followed in the first three operations. After failure with this procedure, the writer's modification was introduced in the second operation on the third case and followed in the last three cases.

Resection of the tendon

Because of the posterior location of the insertion of the tendon of the superior oblique, general anesthesia is almost indispensable and, in the six cases reported, intravenous sodium pentothal was found to be an ideal anesthetic.

A traction suture is placed through the sclera just above the upper limbus and the eye turned well down by this means. The conjunctiva is incised over the insertion of the superior-rectus tendon. Tenon's capsule is opened and the rectus delivered on a muscle hook (fig. 1).

This muscle is freed of its subconjunctival attachments by means of sharp dissection with scissors and a double-armed 4-0 plain-catgut suture is passed through the tendon close to the insertion. The tendon is then cut between the suture and the globe and the superior rectus is retracted and freed by blunt dissection from the underlying tendon of the superior oblique. An additional traction suture may be placed through the stump of the rectus (fig. 2).

A muscle hook is passed backward over the globe and under the tendon of the superior oblique which it engages. Another double-armed 4-0 plain-catgut suture is passed through the tendon at a variable distance from its insertion, depending upon the amount of correction that is necessary (fig. 3).

The tendon is cut just distal to the suture and the free portion of the tendon then cut free from the globe at its insertion (fig. 4). The two ends of the suture are passed through the stump of the tendon and tied (figs. 5 and 6). The superior rectus is sutured back into position and the conjunctiva closed with plain catgut or fine silk.

The advantages of this modification of Wheeler's operation are two. In the first place, in the original procedure described by Wheeler, the tendon of the superior oblique is tucked without providing for the apposition of raw surfaces and, after one failure with this method, in which the adhesions failed to form at all, the writer came to the conclusion that if two raw surfaces were brought in apposition the chances of a firm union would be much better. Subsequent operations have proved this to be true. In the second place, the work of Fortin[13, 47] and Genet[48] and others has shown that the two oblique muscles of the eye have their insertions in the sclera close to, or in, the macular region. In view of this, it would seem that the insertion of sutures through the sclera in this region would definitely tend to produce more trauma to the macular region than the introduction of sutures merely through the stump of the original insertion into the sclera.

A word should be interjected at this point as to the ease or difficulty in operating upon the tendon of the superior oblique. The principal objection to surgery upon the tendon itself has been voiced by von Graefe[49] and Jackson,[19] both of whom stated, in effect, that the tendon was too difficult of access to permit surgery upon it. Wheeler,[1] himself, in describing his operation states, "It cannot be said that the operation is convenient or easy, but technically it is entirely possible and reasonable."

With the above premises the writer must disagree. The approach to the tendon of the superior oblique is certainly not too difficult for any competent ophthalmic surgeon and once the tendon is exposed, the remainder of the procedure is not complicated nor technically difficult.

Fig. 6 (McGuire). Shortened tendon of superior oblique in position.

No definite rules can be given as to the amount of tendon to be resected, but an immediate overcorrection is to be desired. An estimate of the amount of tendon to be resected can be obtained by having the globe turned strongly down and in by means of the traction suture and, with the eye in this position, grasping the tendon with a muscle forceps at various distances from the insertion and then doubling the tendon over upon itself by carrying the forceps toward the insertion. If the forceps are placed upon the tendon in such a position that when they are moved over to the insertion the tendon is fairly tight, the ideal amount of tendon to be resected will have been determined. The suture should then be placed in the tendon at this point and the tendon between the suture and the insertion resected.

Postoperatively there is generally more reaction following this procedure than is usual with operation upon the recti muscles and this is no doubt due, in large measure, to the fact that the insertion of the tendon is so far posterior on the globe. The reaction will subside markedly within a week or 10 days and it has not been found necessary to do more than firmly bandage the operated eye at any time.

Case reports

Case 1. M. J. G., aged 34 years, a Lieutenant in the USNR, was admitted to the hospital under the general diagnosis of strabismus. His chief complaint was diplopia when the head was held straight. Aside from the usual childhood diseases with uneventful recoveries, the past history was entirely irrelevant. There was no history of head injury or other trauma. This officer stated that he had really never noticed diplopia until he had entered the service, but that he had always tilted his head toward his left shoulder. On entry upon active duty, he felt that he was conspicuous because he was in uniform and had a head tilt. He then determined to straighten his head in order to appear more natural. However, he found on attempting this that a marked diplopia was produced and he became so nauseated that at times vomiting occurred. He was consequently admitted to the hospital for treatment and disposition.

Physical examination on admission was entirely negative with the exception of the eyes. Laboratory studies revealed nothing of significance. Vision in each eye was 20/20. The media were clear and the fundi and intraocular pressure were normal. Muscle-balance tests by the screen and parallax method of Duane produced the following findings: Right hypertropia of 50 prism diopters and esotropia of 10 p.d. for both distance and near in the primary position. In the cardinal directions of gaze for near the findings in prism diopters were: eyes up and right RHT 20, ST 10; eyes right RHT 30, ST 10; eyes down and right RHT 30, ST 10; eyes up and left RHT 40, ST 5; eyes left RHT 50, ST 10; eyes down and left RHT 54, ST 10. There was a corresponding vertical diplopia, which increased when the eyes were carried into the field of action of the right superior oblique, and it was noted that this officer carried his head habitually tilted toward the left shoulder. On the basis of these findings, a diagnosis was made of paresis of the right superior oblique of congenital origin. It was felt that the hypertropia was the primary difficulty and that the esotropia would not bother him if the vertical deviation was corrected.

Under intravenous sodium pentothal anesthesia an advancement of the tendon of the right superior oblique was performed according to the technique described by Wheeler. Postoperatively there was moderate reaction, but this subsided markedly within 10 days. Three weeks after operation muscle balance was right hypertropia 14 and esotropia 10 prism diopters for both distance and near in the primary position. Additional measurements were: U&R RHT 0, EST 10; R RHT 10, EST 10; D&R RHT 10, EST 10; U&L RHT 10 EST 10; L RHT 15, EST 10; D&L RHT 22, EST 10. There was no further subjective diplopia although a vertical diplopia could still be elicited by the usual methods. The head tilt was markedly improved, but there was still some present to take care of the relatively slight imbalance which remained. Six months after operation the results were essentially the same as noted three weeks postoperatively. It is of some interest to note that this officer, following his operation, went to sea on an aircraft carrier and that as late as Christmas, 1945, stated in a letter to me that he had had no further symptoms and that he was very grateful for the operative result.

Case 2. H. M. W., aged 19 years, was admitted to the hospital with chief complaint of diplopia —duration lifetime. The patient stated that there had been a vertical diplopia present as long as he could remember, but that he could overcome this by tilting his head. He did not remember when he first discovered this. The past history was irrelevant and the physical examination and laboratory routine were negative with the exception of the eyes. Vision was 20/20 in each eye. The only significant finding in the examination of the eyes was in the muscle balance. There was a

right hypertropia for both distance and near of 14 prism diopters. Other measurements were: U&R orthophoria; R RHT 4; D&R RHT 8; U&L RHT 16; L RHT 20; D&L RHT 25. There was a corresponding vertical diplopia increasing in eyes down and left and a head tilt of moderate degree toward the left shoulder. A diagnosis of paresis of the right superior oblique was made and an advancement of the tendon by the Wheeler method was performed under intravenous anesthesia. Seven weeks postoperatively there was a residual right hypertropia of 4 prism diopters for both distance and near in the primary position, RHT 4 in eyes left and RHT 7 in eyes down and left. In the remainder of the cardinal positions orthophoria prevailed. The remaining vertical imbalance was compensated for by a slight head tilt, but this was not nearly so marked as the tilt prior to operation. Subjectively the patient felt much improved.

Case 3. J. R. F., aged 26 years, was admitted to the hospital with a diagnosis of "paralysis of ocular muscle." This young man stated that he was well until about a year before admission when he began to notice some blurring of vision. His general health had been excellent prior to the onset of this symptom and had remained so ever since. There was no complaint of diplopia. The past history and the laboratory studies were irrelevant. Neurologic and general physical examinations were negative with the exception of the eyes. Vision in each eye was 20/20; media were clear; fundi and intraocular pressure were normal. Muscle-balance tests gave the following results: right hypertropia of 7 prism diopters for both distance and near. Other measurements were: U&R orthophoria; R orthophoria; D&R RHT 5; U&L RHT 8; L RHT 14; D&L RHT 26. Although the patient had never complained of diplopia, there was a head tilt to the left and when the head was straightened there was a definite diplopia which corresponded to the muscle balance and increased in eyes down and left. A diagnosis of paresis of the right superior oblique was made.

Under sodium-pentothal anesthesia, a Wheeler advancement was carried out on the tendon of the right superior oblique. The postoperative course was uneventful, but upon examination two weeks after the operation, the muscle balance remained essentially unchanged, and it was apparent that nothing had been accomplished by the operation. It was believed that probably the suture between the tucked superior oblique and the sclera had pulled out before adhesion had taken place.

Five weeks after the first operation the original operative field was explored and the tendon of the superior oblique was found in its original position without any shortening effect whatever from the Wheeler procedure. At this time a resection of the tendon, as previously described, was carried out. The postoperative course was uneventful and the patient was shortly discharged to duty. Five months after operation this man was seen as an out patient for a final check at which time he stated that since his discharge from the hospital he had been doing office work without difficulty and that his symptoms had been relieved. There was an orthophoria in all cardinal directions of gaze except in eyes down and left where there remained a residual right hypertropia of 6 prism diopters.

Case 4. A. J. B., aged 26 years, was admitted with diagnosis of "insufficiency of ocular muscle." The main complaint was of diplopia when the head was held in the upright position. This condition had been present since childhood when the patient had fallen from a tree and struck his head on the roots, becoming unconscious for a short period. The general physical, neurologic and laboratory examinations were entirely negative as were X-ray studies of the skull. Ocular examination revealed vision to be 20/30 in the right eye corrected to 20/25 by a +0.5D. cyl. ax. 45°; and in the left eye to be 20/20. The media were clear, the fundi and tension normal. Muscle balance showed a right hypertropia of 10 prism diopters for distance and 12 for near in the primary position. Other measurements were U&R EX 5; R orthophoria; D&R RHT 8; U&L RHT 4, EX 5; L RHT 18; D&L RHT 32. There was a corresponding vertical diplopia increasing in the field of action of the right superior oblique, and a head tilt to the left. On the basis of the history and the muscle findings a diagnosis was made of paresis of the right superior oblique of traumatic origin. A resection of the tendon of the right superior oblique was then performed under sodium-pentothal anesthesia. Following his discharge from the hospital, the patient was followed in the outpatient department and three months after operation stated that he felt much relieved by the surgical procedure. At this time there was orthophoria for both distance and near in the primary position with a residual right hypertropia of 3 prism diopters in eyes left and of 9 p.d. in eyes down and left.

Case 5. J. W. F., aged 23 years, was admitted to the hospital with the diagnosis of "insufficiency of ocular muscle." He gave a history of having had double vision for as long as he could remember when the head was held straight, but this diplopia was eliminated by tilting the head to the right. General physical, X-ray and laboratory examinations were negative. Vision in each eye was 20/20 and the eyes were normal throughout with the exception of the extraocular muscles. In the primary position there was a left hypertropia of 14 prism diopters for both distance and near. Other measurements were: U&R LHT 5; R LHT 18; D&R LHT 27; U&L orthophoria; L LHT 8; D&L LHT 12. There was a corresponding vertical diplopia.

A diagnosis of paresis of the left superior oblique was made and under sodium-pentothal anesthesia a resection of the tendon of this muscle performed. The postoperative course was not unusual and one month after operation there was orthophoria for both distance and near in the primary position, and there was no vertical imbalance except in eyes down and right where there was a left hypertropia of 6 prism diopters.

Case 6. W. H. B., a man, aged 49 years, was admitted to the hospital with a diagnosis of frontal sinusitis. There was a history of intermittent bilateral frontal headaches of one month's duration. Clinical and X-ray examinations of the sinuses failed to reveal any pathologic changes. Laboratory studies were negative in all respects. The headaches increased rapidly in severity and on neurologic consultation it was felt that he probably had a subdural hematoma although there was no history of injury. A trephination was done on the skull and a fairly large subdural hematoma was found on the right side and evacuated. Following the operation, the patient began to complain of diplopia and then stated that this had been present for about the same length of time as his headaches but that he had neglected to mention the symptom. Approximately three weeks following the cranial operation the patient was seen in consultation by the eye service. The ocular examination was entirely negative with the exception of the muscle balance. There was a left hypertropia of 6 prism diopters for both distance and near in the primary position. Other measurements were: U&R LHT 8; R LHT 16; D&R LHT 23; U&L orthophoria; L orthophoria; D&L LHT 4. A diagnosis of paresis of the left superior oblique secondary to intracranial damage was made. Six weeks later the muscle findings were the same as measured above and it was believed that he was not going to regain the use of the superior oblique by spontaneous recovery. Consequently, a resection of the tendon of the left superior oblique was performed under sodium-pentothal anesthesia. The postoperative course was uneventful and two months later the diplopia had cleared up and there was orthophoria in all directions of gaze except in eyes down and right where there was a residual left hypertropia of 4 prism diopters.

COMMENT

Prior to 1934, when Wheeler[1] described his operation for advancement of the tendon of the superior oblique, paresis of this muscle had been treated surgically by one of three methods or a combination of these, that is, tenotomy of the inferior oblique of the same eye, recession of the inferior rectus of the opposite eye, and recession of the superior rectus of the same eye, with the first two methods being preferred by most operators. In rare instances the homolateral inferior rectus has been advanced. It would seem that none of these methods directly attacks the main problem. Complete paralysis of the superior oblique is rare and what the ophthalmologist is confronted with in the vast majority of cases of disturbance of motility of this muscle is an underaction, or a paresis, of the muscle. Granted that such is the case, the most logical primary surgical procedure in relieving the distressing symptoms of this condition is upon the paretic muscle itself. If such a procedure does not result in relief of the condition, the other methods may then be put into use. However, it is believed that with resection of the tendon of the superior oblique in paresis of this muscle as the primary step, secondary procedures will seldom be necessary and the patient will be saved the inconvenience, not to mention the expense, of several operations, the results of which cannot even be estimated in advance.

In regard to the oft propounded theory that the tendon of the superior oblique is too difficult of access to permit easy operation the writer firmly believes that the sooner this is forgotten, the better. With adequate exposure, by means of a traction suture pulling the eye down and in, the difficulties of access to the tendon are theoretical rather than real.

SUMMARY

A brief historical review of the earliest surgery upon the extraocular muscles is presented.

The anatomy, physiology, pathologic physiology, and the etiology of paresis of the superior oblique is discussed.

The surgical correction of underaction of this muscle is reviewed and a modification of Wheeler's advancement operation is presented.

NOTES, CASES, INSTRUMENTS

A NEW DRAINAGE OPERATION FOR THE RELIEF OF GLAUCOMA*

OSCAR LAVINE, M.D.,
AND KARL H. LANGENSTRASS, M.D.
Washington, D.C.

Drainage operations in the field of glaucoma therapy meet only with incomplete and uncertain success. As an example one may consider the iridencleisis operation and its postoperative events. The scleral incision tends to close immediately and tightly, due to the inherent elasticity of the scleral tissue. The incision heals quickly and firmly because large areas of the mesodermal surfaces are in intimate contact. The included iris tends to undergo pressure atrophy as the result of sharp compression by the scleral lips. This event renders the operation practically valueless. A similar unfavorable outcome may be observed fairly frequently in all drainage operations now in vogue for the relief of ocular hypertension.

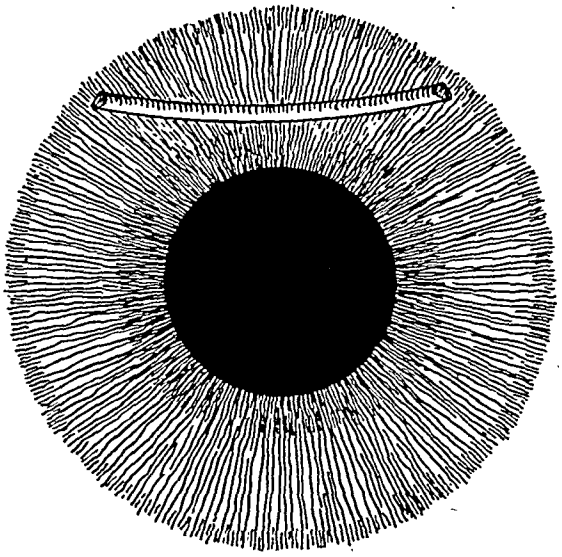

Fig. 1 (Lavine and Langenstrass). The corneal groove.

In reviewing the reasons for such failure, the following possibility was considered. All drainage operations form, or try to form, a passageway through connective tissues. As soon as the draining instrument (knife, keratome, spatula) is withdrawn, however, the draining canal collapses. The raw connective-tissue surfaces come in close contact. Fibroblasts proliferate. The channel starts to be closed almost immediately by scar formation. The glaucoma syndrome returns, because fluid production again exceeds fluid absorption.

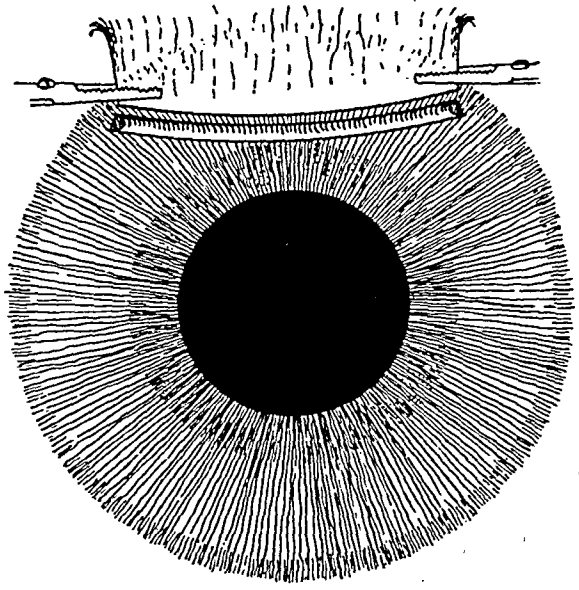

Fig. 2 (Lavine and Langenstrass). First conjunctival flap.

It would seem that a satisfactory drainage opening should ultimately be so constructed that its opposing walls receive a lining which has little or no tendency to fuse. To line the channel with epithelium in order to create a real physiologic duct

* From the Ophthalmologic Service of St. Elizabeth's Hospital.

would hold out hope for more favorable and lasting results.

Since it is well known that corneal fistulas heal very poorly, if at all, it seems desirable to take advantage of this fact and to make the drainage opening in the peripheral zone of the cornea. However, the fluid from the anterior chamber should not flow directly into the conjunctival sac. It should first find its way into a thin-walled, epithelium-lined channel or duct. This duct should then open into the conjunctival sac at some distance. A sort of safety valve would thus be created, and aqueous fluid would force its way out into and through the drainage channel only during periods of increased intraocular pressure. At times of normal, or subnormal, intraocular pressure, the epithelium-lined channel would collapse and thus constitute an effective barrier

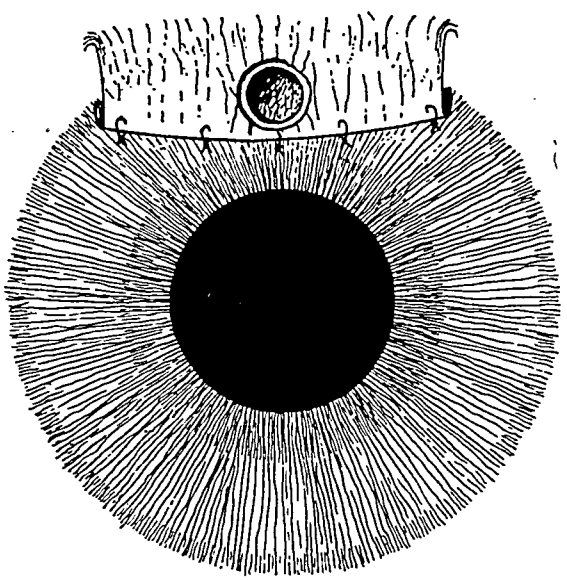

Fig. 3 (Lavine and Langenstrass). Sutures completed. Corneal trephine opening visible through second conjunctival flap.

against possible infection of the anterior chamber and also against the development of prolonged hypotonia.

The following procedure is therefore recommended. A very narrow strip of cornea is deprived of both epithelial and subepithelial tissue. The resulting corneal groove is arranged along a horizontal line under the upper lid. Five millimeters above the superior limbus, a conjunctival incision is made parallel to the corneal

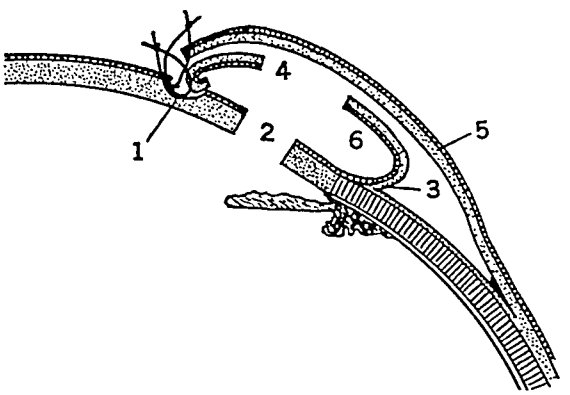

Fig. 4 (Lavine and Langenstrass). Diagram of result. (1) Corneal groove. (2) Corneal trephine opening. (3) First conjunctival flap, inverted. (4) Circular conjunctival excision. (5) Second conjunctival flap, not inverted. (6) Epithelium-lined epicorneal duct.

groove. A conjunctival flap is dissected free and reflected downward over the upper cornea. Its free conjunctival edge is sutured to the roughened area in such a way as to have its mesodermal surface rest against the raw tissue in the corneal groove. To cover the mesodermal surface of this conjunctival flap, a second conjunctival flap is brought down from the region of the upper fornix. Conjunctivocorneal sutures are drawn through its free edge and left untied. The next stage of the operation constitutes the creation of a corneal fistula. A small circular excision is made in the first, or central, conjunctival flap about 1 mm. inward from the limbus. A corneal trephine opening is now made through the center of that small conjunctival window. An Elliot trephine, 1.5 mm. in diameter, is used. A small piece of iris is excised beneath the region of the corneal fistula. The sutures of the second or outer conjunctival flap are now tied.

This operation creates a permanent

corneal fistula. That fistula is covered by an epithelium-lined conjunctival flap. This flap acts as a safety valve. The fistula is protected from infection by a fairly long epicorneal duct. That duct is entirely lined with epithelium. Corneal epithelium forms the floor. The conjunctival epithelium of the first, or central, conjunctival flap lines its roof. These two surfaces are smooth and have little or no tendency to fuse. This epithelium-lined epicorneal duct collapses (and thus guards the corneal fistula) at times of relatively normal intraocular pressure. The duct opens and functions as a capillary drain whenever the intraocular pressure exceeds a certain critical level.

Technical details of this procedure have been worked out in a series of operations on human cadavers and in animal experiments. We have recently had an opportunity to perform the operation on several patients with chronic glaucoma. We are not reporting clinical data in this preliminary communication, except to say that we were favorably impressed with the ease of execution of the method and with the smooth postoperative course. Whether the pressure reduction will continue to maintain itself indefinitely at a desirable level remains to be seen.

SUMMARY

A theory is offered to account for the transient effect of many drainage operations in glaucomatous eyes. A new operation for lasting pressure reduction is proposed. A corneal fistula is connected with an artificially created epithelium-lined duct. The duct remains permanently open. It acts in the manner of a safety valve, closing the fistula at periods of normal or near normal pressure. The relatively long collapsible duct tends to reduce the opportunity for contamination of the anterior chamber to a minimum.

1801 Eye Strect, N.W. (6).

A CASE OF FIXED STRABISMUS*

LUIS MARTÍNEZ, JR.,† M.D.
Guadalajara, Jal., Mexico

The case which I am about to record is rare, and I have encountered no similar one in our national records and hardly any in the foreign literature. The patient is Mr. J. R. F., aged 60 years, residing at Mexicali, Lower California (Baja California). He came to see me on April 3, 1944. He was accompanied by a member of the family, because he could not obtain sufficiently useful vision even with the compensatory inclination of the head which is habitual in some cases of strabismus.

Inspection showed bilateral convergent strabismus, the most pronounced that I had ever seen in my professional practice. The cornea of the right eye was almost completely concealed at the internal canthus, and that of the left eye was exposed only as regards its outer half (fig. 1). The onset of the trouble had occurred 30 years previously, and there had been slow and progressive increase of the deformity to the point of complete incapacity for work. The patient's occupation had been that of a farmer.

No ocular movement could be demonstrated. There was a chemotic spot in the outer part of the left bulbar conjunctiva. There was apparently no action of the superior or inferior rectus of either eye, or of the obliques. It was impossible to investigate White's sign as to differentiation between involvement of the rectus and oblique muscles. After the usual laboratory examination, I proceeded to operation, in the performance of which I had the advantage of the assistance of Dr. Enrique Avalos González. The operation

* Read before the Asociación para Evitar la Ceguera en México, August 11 to 16, 1947.
† Translated by Dr. William H. Crisp, Denver, Colorado.

was performed on April 5th, beginning with the left eye. The plan was to execute retro-implantation of the internal rectus and the Blascowicz operation on the external rectus.

The conjunctival incision had to be made more or less blindly, because it was impossible to move the eye with the fixation forceps. I succeeded in taking hold of the internal rectus, and cautiously introduced the strabismus hook, using cautiously sustained but energetic traction.

I sectioned the insertion of the muscle. This behaved like a fibrous, inextensible, extremely short and tense band which fixed the eyeball in the nasal portion. Immediately upon division of this band, it was possible to move the eyeball in all directions. We proceeded to suture the internal rectus in front of the equator, in view of the possibility of subsequent overaction of the external rectus. We then did the Blascowicz operation on the external rectus, resecting this muscle to the extent of leaving the position of the eye somewhat overcorrected. The external rectus gave the impression of being narrowed and slender, and extremely flaccid.

At the moment of freeing the eye, and in the presence of decided limitation of the operative field, we failed to become conscious of adhesion of the inner and upper part of the cornea to the inner end of the lower eyelid in the region of the lacrimal punctum. There was thus exposed an adherent leukoma, and the manipulation resulted in perforation of Descemet's membrane, emptying of the anterior chamber, and an iris hernia. The last was excised.

Operation on the second eye was attended by the same difficulties as in the left eye. In performing the Blascowicz operation on the external rectus we were surprised to find a torn condition of a good many of the fibers of the muscle. This condition was explained when some

Figs. 1 and 2 (Martínez). Showing the condition of the patient before and after operation.

days later an excellent colleague told me that he had attempted and achieved mobilization of this eye by means of fixation forceps!

The recto-implantation of the right external rectus was supplemented by two long fixation sutures which were tied firmly about 1.5 cm. beyond the external canthus, over a cushion of gauze, in order to insure overcorrection.

The postoperative course was extremely satisfactory, as may be noticed from Figure 2. The patient was dismissed on May 2, 1944, with perception of shadows for the right eye and vision of 5/10 in the left eye, without correction.

Discussion

There can be no doubt that the retraction syndrome resulted from fibrous degeneration of the internus muscles. In such a case it is sometimes impossible to establish the diagnosis completely before operation. After such an operation, normal movements are not to be expected, but from the esthetic and utilitarian point of view, as in the present case, the result is encouraging. Microscopic examination of the contracted muscle clearly shows fibrosis to be responsible for the strabismic fixation, although the essential cause for such a condition is not known. Fixation may be either unilateral or bilateral.

SUBRETINAL HEMORRHAGE SIMULATING SARCOMA OF THE CHOROID*

A CLINICAL PATHOLOGIC REPORT

JOSEPH LAVAL, M.D.

New York

HISTORY

Mrs. G. M., aged 48 years, was seen by Dr. Benjamin Esterman on April 13, 1945, with a history of blurring and tearing of the left eye of three days' duration. The eyes had been entirely normal in the past and aside from having required reading glasses, they needed no attention.

Examination disclosed the right eye to be normal, with 20/30 vision corrected to 20/20, clear media, normal fundus and tension. The left eye had vision of 20/200 due to a large central scotoma extending downward and nasally. Inspection through a dilated pupil disclosed a pigmented mass at the macula, about 6 disc diameters in size and about 5 diopters elevated. It was quite round and extended to the upper temporal portion of the left disc. A retinal artery and vein coursed over its surface but none of the vessels in the fundus were engorged. There were no exudates, hemorrhages, or other pathologic conditions in any portion of the fundus. Ocular tension of the left eye was 16 mm. Hg (Schiøtz). There was no pulsation, exophthalmos, or limitation of motion of either globe.

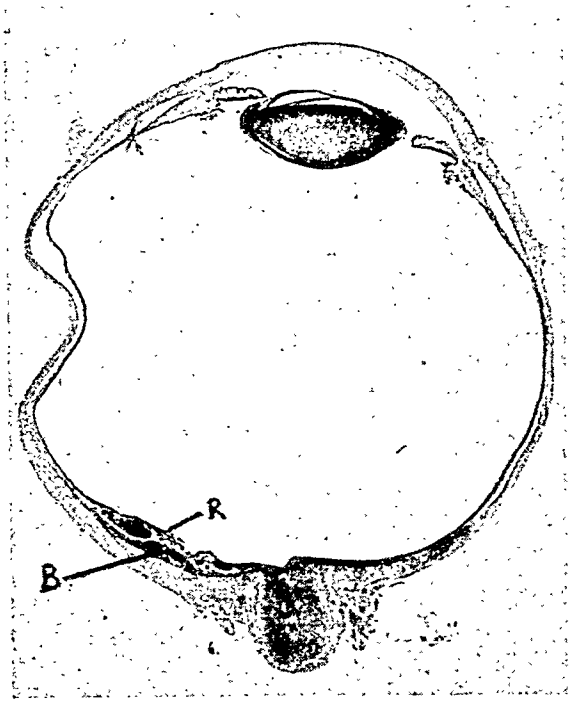

Fig. 1 (Laval). There is blood (B) lying between choroid and retina (R). The latter is detached as far as the disc in the region of the hemorrhage.

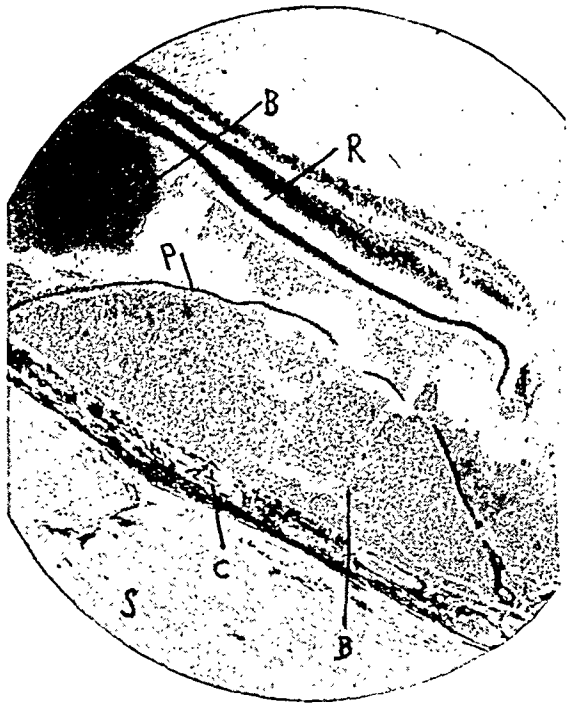

Fig. 2 (Laval). The pigment epithelium (P) is broken in three places allowing the blood (B) from the choroid (C) to break through and detach the retina (R). (S) is the sclera.

A diagnosis of melanosarcoma of the left choroid was made and confirmed by Dr. R. T. Paton. A general physical examination disclosed no evidence of metastasis. The blood pressure was 120 mm. Hg (systolic) and 80 mm. Hg (diastolic). An enucleation was performed April 18, 1945.

* From the laboratory of the Manhattan Eye, Ear and Throat Hospital.

PATHOLOGIC REPORT

The globe was normal in size and shape. There were no extraocular masses. On section, a dark solid mass was noted in the macular area extending to the disc (fig. 1).

Microscopic studies showed no abnormalities in the globe except for the region of the macula and the adjacent area (fig. 2). Here a large hemorrhagic mass was present, lying between the choroid and the detached retina. The pigment epithelium had been separated from the choroid by the mass of blood which had broken through the pigment epithelium in three distinct places. The blood which seeped through these three areas caused the detachment of the retina to follow. There was no blood in the vitreous. The choroidal vessels were quite full, but there was no evidence of sclerosis in the retinal or choroidal vessels. There was some perivascular infiltration with round cells at some of the larger choroidal vessels but no involvement of the vessel walls. Serial sections of the globe showed no evidence of tumor.

COMMENT

It occasionally happens that an eye is enucleated for a possible malignant melanoma only to find a subretinal hemorrhage on sectioning the eye. In the past 15 years this is the third time I have seen it at the laboratory of the Manhattan Eye, Ear, and Throat Hospital. This particular case is quite interesting because of the possibility of a disciform macular degeneration developing if the eye had not been enucleated. However, it is now two years since the original macular hemorrhage in the left eye and nothing has developed in the right eye. The retinal vessels in the right eye, according to Dr. Esterman who sees the patient a few times a year, are normal. The patient still has a normal blood pressure, her blood sugar is normal, and the urinalysis has never shown any abnormal findings. The perivascular infiltration of round cells about some of the larger choroidal vessels is the only indication of vascular disease and its significance is hard to evaluate.

136 East 64th Street (21).

BOECK'S SARCOID

REPORT OF CASE WITH AN UNUSUAL PRECIPITATING FACTOR

MORRIS KAPLAN, M.D.
Denver, Colorado

Boeck's sarcoid is generally considered to be a rather rare disease, and yet a perusal of recent literature proves it to be surprisingly common. The disease has been well described, especially by Levitt in the *Archives of Ophthalmology*, in 1941.

The eye is one of the favorite sites for this general disease and many cases are first seen by the oculist. In reports totaling 100 cases, 43 presented ocular involvement. Of these 43 cases, 28 were of uveitis, 7 involved the lids, 9 the lacrimal glands, and 6 the conjunctiva. Ten cases ended in phthisis bulbi and 7 of these 10 cases were bilateral. Thus seven percent of the cases ended in complete blindness. As is well known, the disease is almost identical with tuberculosis, differing from it only in absence of caseation in its tubercules and in absence of acid-fast organisms. The diagnosis is usually missed at first and is later established by tissue studies of biopsy specimens or by X-ray studies of the chest or of the phalanges.

CASE REPORT

The case herein described presents several unusual features. A 52-year-old woman, touring in South America, reached down to pet a dog in a private home. With great force, the dog bit her over the right eye. The upper jaw struck

the upper lid just below the brow and the lower jaw struck the lower lid at the orbital margin. The two resultant skin lacerations were treated almost immediately by a physician, who gave a prophylactic injection, the nature of which the patient did not ascertain. The eye itself seemed entirely uninjured. Three days later she noticed a painless swelling in the middle of the upper lid. This continued to enlarge for several days, causing a very noticeable bulging of the upper lid. It remained painless. About five weeks later, she presented herself at this office for treatment.

Just before she left for South America, she had had a routine refraction and examination at which time no appreciable irregularities were noted. She now presented this painless mass within or behind the right upper lid. It was freely moveable and measured 2 by 2 by 3 cm. The lid was quite protuberant and in mild mechanical ptosis. No other deviation from the normal was seen and the eye itself remained quite normal.

The mass felt exactly like an organized hematoma, which was considered as the most likely diagnosis. Local treatment consisted mostly of hot applications. Under this regimen, the mass became somewhat larger and moved from the midline of the lid to the outer third. The new ptosis was unsightly and, since the diagnosis now seemed obscure, surgical removal was decided upon.

Under local anesthesia the mass was easily isolated. It was found to extend back into the retrobulbar space into the orbital fat. It was easily removed. It was indurated, felt like cartilage, and had a yellowish hue. It obviously was not a hematoma. The wound healed uneventfully in a few days and the area resumed its normal appearance.

Laboratory report

Gross. The specimen consists of an elongated, gray-white to gray-yellow fragment of tissue removed from the right orbit. The sectioned surface is grayish white streaked with yellow.

Microscopic. Microscopic examination of the nodule removed from the region of the right eye shows it to be composed of fibrous tissue in which are well-circumscribed nodules consisting of epithelioid cells. In these collections are multinucleated giant cells of the Langhans' type. Cuffing the collections of nodules in some areas are small accumulations of lymphocytes. Caseation necrosis is not demonstrable. Special stains fail to reveal the presence of acid-fast bacilli.

Diagnosis. Boeck's sarcoid of the right orbit.

Internist's report

The patient was referred to her internist, who also had examined her thoroughly before she left for South America and had found no irregularities. She again underwent exhaustive study, and no appreciable abnormalities were found. X-ray reports were as follows.

Chest, both feet, and hands. Examination of this individual's chest reveals minimal spondylitis in the dorsal spine. There is no other evident abnormality. The dome of the left diaphragm is rather hazy and indistinct. The pleura is otherwise negative. The cardiac and aortic shadows are of normal size, shape, and position. The left hilar shadow is rather prominent, with a rounded configuration suggesting mediastinal adenopathy. The superior portion of the right hilar shadow assumes a rounded, smooth-bordered appearance which would be consistent with a small node on the right. The markings radiating from the left hilum into the left base are definitely intensified and more soft and granular than usually seen. The lung fields are otherwise essentially clear.

Summary. The findings in the chest are

not conclusive but may be considered supporting evidence of the pathologic report of biopsy.

Comment

Because of the biopsy report, anteroposterior views of the small bones of the hands and feet were obtained. There are small rounded, sharp, sharply demarcated excavations on the outer aspect of the articular surface of the terminal phalanx of the middle finger bilaterally and on the outer aspect of the right index finger. There are small osteophytes lying intimate with the joint spacing of the distal interphalangeal articulation of the middle fingers bilaterally. The excavations described could be on the basis of sarcoid depositions. The vertical trabecular pattern in the phalanges of the hands may be slightly exaggerated. This has been described as an early change in the presence of sarcoid. There is no other X-ray evidence of bone or joint change.

The internist recommended that no treatment be instituted and that the patient be observed at regular intervals.

It seems reasonable enough to agree with the pathologist that this is a case of sarcoidosis. It does not seem reasonable to assume that this sarcoid was caused by the dog bite, or could have been caused by any trauma, or could have grown so quickly if it had. It is not impossible that the tumor could have existed in the retrobulbar tissues above the eyeball and that the violent trauma could have caused its rupture forward behind the lid.

If a tumor of such size had existed two weeks before the accident when a routine examination was made, some interference with ocular movement should have been evident. This was not the case. There was no diplopia and no exophthalmos.

THE PROBLEM OF STRABISMUS IN CHILDHOOD*

With especial reference to convergent strabismus in infancy and early childhood

James W. Smith, M.D.
New York

Superstition and fear on the part of misinformed parents, and the lack of a standardized diagnostic and therapeutic approach by ophthalmologists, are responsible in part for the unsolved problem of strabismus. Parents regard the eye as the most delicate organ in the body and view with horror the prospect of surgery on a child 2 or 3 years of age. They seek refuge in the story of the neighbor's boy who outgrew his esotropia —unaware that he only achieved this result after total and irreparable amblyopia. Usually a grandmother can augment the parents' fear with several examples of convergent strabismus followed postoperatively by divergent strabismus.

Blame for the latter result must be charged to ophthalmic confusion created by conflicting and often prejudiced schools of thought.[1] A convergent case can only be converted into divergence by excessive tenotomy of the internal recti muscles or failure to diagnose preoperatively the presence of a complicating vertical strabismus.

Causes of squint

Originally, I followed the teachings of Worth and Duane, but the neuro-anatomists and physiologists have challenged their views. Bielschowsky and Chavasse disagree in part with Worth and ignore

* From the Departments of Ophthalmology, New York Post Graduate Medical School and Hospital, Columbia University, and the Hospital for Joint Diseases. Read before the New York Society for Clinical Ophthalmology, January 6, 1947.

Duane's views on congenital superior rectus weakness. Chavasse[2] has originated a new entity—inhibitional palsy of the contralateral antagonist. Adler[3] upholds Bielschowsky's views that an isolated primary vertical motor paralysis is most commonly due to paralysis of the superior oblique muscle, but is willing to concede that the vast majority of cases of secondary vertical motor paralyses (that is, convergent squint associated with a noncomitant vertical deviation) more nearly fit into the picture of paralysis of a superior rectus.

I cannot understand the recent references in the literature regarding the frequency of superior oblique paralysis. Bielschowsky, in his large clinic at the University of Breslau, observed only 80 cases during the years 1923 to 1932. At a previous meeting in this Academy, I[4] reported only 50 cases from private practice over a 25-year period. When authorities disagree, the student, without facilities for guided clinical observation, must grope in the dark field of trial and error.

Conditions favoring development of squint

Conditions which favor the development of squint are anisometropia, opacities of the media, fundus disease, disorders acquired in infancy, and congenital anomalies that make the vision in one eye much worse than in the other. Other factors are heredity, hypermetropia, and the presence of a congenital vertical deviation. Chavasse considers "congenital defect of the fusion faculty" to be akin to a miracle and cites many traumatic and inflammatory lesions (prenatal and in infancy) that can produce muscle imbalance and acquired fusional impairment.

We operate too late to regain fusion and vision. Our so-called good results refer in the main to eyes that are cosmetically acceptable to parents. The child's disappointment is not evident until adult life when he is handicapped by the lack of binocular single vision and stereopsis.

Convergent strabismus

At what age does unilateral convergent strabismus manifest itself? In Worth's[5] series 13 percent of the cases appeared before the first year; 18 percent between 1 and 2 years; 25 percent between 2 and 3 years; 19 percent between 3 and 4 years; 11 percent between 4 and 5 years; 7 per cent between 5 and 6 years; and 7 percent after 6 years of age. In 75 percent of the cases, deviations were apparent before the end of the fourth year. Essentially, alternating strabismus appears even earlier in infancy. In 34 percent of the alternating cases, diagnosis was made before the first year, and in 19 percent, between the 1st and 2nd year of life. (13 percent were seen between the 2nd and 3rd year, and 16 percent between the 3rd and 4th year.) In 53 percent of the cases, the alternating strabismus was present before the end of the second year, and a total of 84 percent was apparent before the end of the fourth year. (About 2.3 percent of school children, aged 5 to 14 years, were found to have convergent strabismus, and about 0.2 of 1 percent had divergent strabismus.)

Constructive restoration

At what age does the infant manifest fusion? By the end of the first year the child evidences a definite desire for binocular single vision. We all know that the fusion faculty normally reaches its full development before the end of the sixth year. This fact, coupled with the high incidence of convergent strabismus before the end of the fourth year, indicates that our best opportunity for constructive restoration is between the ages of 2 to 6 years.

The exact measurement of the strabismus in degree of arc or prism diopters is

only of academic interest. Hirschberg's corneal light-reflex test, in which each millimeter of deviation represents about 15 prism diopters, is the best method that can be used with infants. After the second year more accurate determinations can be made with prisms and the cover test.

Estimation of the error of refraction is of vital importance. Under complete cycloplegia, retinoscopy reveals many cases with 2 to 8 diopters of hypermetropia and astigmatism. If the convergence excess is not complicated by vertical muscle imbalance, wearing glasses with full correction constantly will decrease the deviation or relieve the strabismus completely. In this age group, ointments induce more reliable cycloplegia than drops.

Visual tests for infants

A crude record of visual ability is desirable. By the time the average parent can be induced to bring an infant with fixed unilateral strabismus for examination, vision in the deviating eye is subnormal. My purpose in utilizing visual tests is to impress upon the mother how much damage has been done and to enlist her coöperation against further deterioration. The present-day tendency of waiting until the child can read the illiterate E or Snellen test types often reveals advanced amblyopia at the age of 3 or 4 years.

Evans[6] recently demonstrated his visual tests for infants, utilizing the movement of iron filings of various sizes on a white plastic tray. An infant interested in the filings being moved by a magnet on the underside of the tray will resent having its fixing eye covered thereby affording an excellent clue to amblyopia. At the ninth month the visual acuity is at least 6/72; at two years, 6/12; at three years, 6/9; and later, when the Snellen charts can be discerned, 6/6.[2] White marbles varying in size from ½ to 1½ inches in diameter can also be used to test vision in young children. This procedure can be performed in a few minutes and succeeds with most children old enough to walk. At a distance of 18 to 20 feet, the 1½-inch sphere corresponds roughly to 6/60 or 20/200 and the ¾-inch sphere, to 6/24 or 20/80. Improvement in vision after wearing glasses or following occlusion can be demonstrated to the parent as the patient proceeds to see smaller sized marbles.

Know child psychology

I have seen competent physicians who were long on knowledge but short on child psychology. Nervous mothers may cause children to cry in the waiting room, but the same children rarely display their temper in the presence of a sympathetic and kind doctor. The young child comes only for amusement. Its confidence, and your time, can be saved best by making a game out of the consultation.

Any device, musical or electrical, that engages the tot's attention should be utilized to gain your diagnostic goal. Come down to the child's level—even if you have to get down on the floor to observe muscle actions or for ophthalmoscopy or retinoscopy. Occasionally your best efforts will be thwarted by a spoiled brat. Be ready to admit failure cheerfully and send the bounder home with a lollipop or a penny. You will probably have better luck next time.

Muscle measurements in children are reliable only if the patients are completely relaxed. Unlike consultations on adults, time is unimportant. The child can return again and again until the necessary information has been obtained.

We see too many children with total amblyopia because some ophthalmologist found it inconvenient and time consuming to perform an accurate refraction upon or to treat an unruly child of 2 or 3 years.

The patients in the younger age range

afford us the best opportunity for correction of strabismus with less surgery, or in favorable cases without surgery. Even more gratifying is the preservation of binocular single vision by persistent treatment if started early.

Prescribing glasses

If the vision with glasses is subnormal in one eye, the ophthalmologist is duty bound to restore vision to normal, if possible, by atropinization or occlusion of the fixing eye. Early diagnosis and the early institution of treatment before amblyopia becomes marked will effect gratifying return of function in favorable cases within two months.

I have prescribed nonshatterable glasses in cases of accommodative convergent strabismus for patients 18 months of age. To the mother's amazement, the decrease in deviation and/or the visual improvement was so marked that the tiny tots insisted upon wearing the glasses constantly. These children will also permit the introduction of ½-percent atropine ointment in the fixing eye.

Occlusion to be effective must be total and continuous for days or weeks at a time. While this treatment is heroic and resented by the patient, it permits a rapid evaluation of the possibilities for visual restoration and decrease in the angle of squint.

Orthoptic training

Selected children between the ages of 3 and 6 years will coöperate with the orthoptic technician in an attempt to regain binocular single vision with the aid of one of the major amblyoscopes. Although the ideal time for fusion training is supposed to be prior to the sixth year, I have seen adults regain vision in an amblyopic eye following injury or disease in the normal eye.

When the strabismus is unilateral and these medical techniques are ineffective, early operation is indicated. Even the ardent advocates of orthoptic training deplore delay in these cases. I operate on high degrees of convergent strabismus with low insignificant hypermetropia between the age of 2 to 4 years. Only in these patients have I been successful in restoring binocular single vision.

Comment

Before concluding this topic, I want to stress the importance of diagnosing and treating convergent strabismus at the earliest age possible, if we wish to achieve normal vision in both eyes, binocular single vision, and normal fusion power. The therapeutic measures that may be employed to achieve an ideal result are: (1) Correction of errors of refraction. (2) Occlusion of the fixing eye. (3) Atropinization of the fixing eye. (4) Orthoptic training. (5) Surgery.

"Both as regards incidence of *onset*, and hope of cure, the age of innocence is the critical age."[2]

Divergent strabismus

Accommodative convergence insufficiency and nonaccommodative convergence insufficiency resulting from psychic disorders and debilitating systemic conditions are the chief causes of divergent strabismus in childhood. The early clinical signs are marked exophoria for near with normal near point of convergence. Later, in the stage of transient exotropia, the convergence near point recedes, exophoria is present for distance, and the prism divergence increases. If untreated, the transient exotropia is converted into a continuous strabismus. In the last phase, contracture of the external rectus and stretching and weakening of the internal rectus produces absolute impairment of inward and excess of outward rotation.

Examine for myopia

The arrest of these changes in the accommodative cases can be effected by a more vigorous approach to the problem of myopia. Children should be examined in the preschool period for stigmata of myopia. An exophoria for near or mild precrescent changes temporal to the optic nerve are premonitory signs of myopia, even in the presence of 20/20 and emmetropia. Too many children are permitted to indulge in all forms of convergence abuse, such as reading on their backs or even worse, sprawled on the floor with their eyes about four inches from their stacks of poorly-printed comics. When they are eventually referred by their school teachers, 3 to 5 diopters of myopia and varying degrees of transient exotropia are present. Early and full correction has forestalled the development of accommodative convergence insufficiency in about 10 percent of my cases with progressive myopia. Ocular hygiene should be explained to the parent and patient. Glasses must be worn constantly. The time interval between examinations must be set by the refractionist and not by the parent to avoid the necessity of marked increases in the lens prescription.

Fortunately, the fusion apparatus is fully developed in these patients and, after glasses have been prescribed, convergence exercises will do much to offset the advance of the divergence tendency.

Early management essential

Although we advocate early operations in convergent strabismus with low hypermetropia, in divergent strabismus, surgery is reserved for the advanced cases of long duration with extreme deformity. In fact, many cases operated upon prior to the age of 10 years will have a recurrence of almost the same degree of divergence requiring secondary surgery. A final word regarding congenital weakness of the elevator and depressor muscles. Many cases of divergent strabismus in which surgery not only failed but actually resulted in convergent strabismus are due to a complicating vertical muscle imbalance. In a previous paper,[7] I stressed the diagnostic importance of head tilt and associated skeletal deformities as positive evidence of vertical muscle imbalance in every case of convergent and divergent strabismus.

Once again, I would like to appeal for the early management of convergent strabismus. More patience with these little patients means perfect binocular single vision. Some of the divergence cases can be prevented or arrested by better ophthalmic supervision in the treatment of myopia.

SECTION ON OPHTHALMOLOGY

March 20, 1947

DR. BURTON CHANCE, M.D., *chairman*

ABSORPTION FROM THE VITREOUS

DR. LUDWIG VON SALLMANN (by invitation) presented a paper on "Some Factors Operative in Absorption from the Vitreous," an abstract of which follows.

In view of the difficulties in examining the fluid exchange in the posterior segment of the eye by the orthodox method, a new approach was selected with the practical aspect of the problem in mind. The experiments were grouped: (1) According to phenomena of diffusion in the vitreous and of its liquefaction. (2) In relation to the activity of the ciliary epithelium. (3) According to the influence of the basal metabolism. (4) On the basis of clinical methods used to speed up absorption from the vitreous.

The dependence of the diffusion of hemoglobin on the structural integrity and the viscosity of the vitreous was studied by injecting pigs' hemoglobin into fresh intact pigs' vitreous. In exposing the latter to a temperature of 37.5°C., the hemoglobin diffused throughout the vitreous within 18 hours; whereas, the spreading was very slow at refrigerator temperature. When hemoglobin was injected after autolysis of the vitreous had taken place upon storage of the preparations for 24 hours at room temperature, no difference in the diffusion of the hemoglobin was noticed at various temperatures. It was concluded that autolytic liquefaction, or lowering of the viscosity of the vitreous, had resulted in the speedy diffusion in eyes which had been exposed to 37.5°C. in the first series of experiments.

The effect of liquefaction on diffusion or spreading and absorption of foreign matter was investigated in an extensive series of *in vivo* experiments on 24 rabbits. Partial liquefaction was induced by injecting various amounts of a purified and concentrated hyaluronidase prepared by Dr. Karl Meyer from bull testes; this mucolytic enzyme acts on the substrate of the vitreous. The enzyme dilutions were introduced together with suspensions of the animals' own red cells, which served as the test substance. Early spreading of the red cells and moderately accelerated absorption were observed clinically and histologically in the eyes which had received more than 10 gammas of the enzyme. When the dose exceeded 50 gammas, the treatment elicited a conspicuous inflammatory response from the inner membranes of the eye. Even 2 of 5 eyes of the 50-gamma series reacted with marked signs of inflammation. The rest of that group and the eyes injected with 10 or 25 gammas exhibited early loosening of the clot of red cells and somewhat earlier absorption without apparent toxic side action. It seemed that the partial liquefaction induced by the mucolytic enzyme caused the early spreading of the red cells in the vitreous, and this in turn may have facilitated the speedier breakdown of the erythrocytes and their absorption. It is evident that at the present time the toxic action of a medium dose of the enzyme obviates its practical use.

The problem of active absorption possibly exercised by the ciliary epithelium was studied on the basis of R. Hoeber's

work on the active transfer of a group of sulfonic dyestuffs through the wall of the proximal tubules of frogs' kidneys. Hoeber found that this transfer depended on the polar-nonpolar configuration of the dyestuffs, since the dyes, with the sulfonic groups attached to one of the benzene or naphthalene rings, were transferred through the wall in contrast to the dyes in which each of the benzene or naphthalene rings carried a sulfonic radical. The present experiment on albino rabbits, albino rats, and frogs, with the use of various techniques, did not give evidence that the dye in the vitreous had penetrated the ciliary cells or had accumulated in intracellular vacuoles except in one instance among 60 eyes. Despite the negative results, further studies are warranted.

The influence of the basal metabolism on resorption was again studied on suspensions of the animals' own red cells injected intravitreally. Five litters of albino rats (34 animals) were divided into three groups so that litter mates were distributed among the three series. The first group of 12 rats were thyroidectomized by Dr. G. K. Smelser when the rats were two weeks old. The second group of 12 animals received daily subcutaneous injections of thyroxin (1 mg. per 100 gm. body weight). After the injection of a small amount of the animal's own red cells, the density and extent of the cell deposits in the vitreous were estimated by ophthalmoscopy and graded. The 68 eyes were examined three times a week, and the graded findings were tabulated so that the resorption could be expressed in curves when plotted against time. Thyroxin had no clear effect on the growth of the animals or on resorption of red cells from the vitreous when compared with a control series of 10 untreated normal animals. The thyroidectomized rats showed greatly retarded growth and, in general, flat resorption curves; that is, the red cells disappeared more slowly from the vitreous than in the 20 control eyes.

The last group of experiments was designed along the lines of clinical methods used in the therapy of hemorrhages and other opacities of the vitreous. The effects of subcutaneous and subconjunctival injections of hypertonic salt solutions, of iontophoresis, and of artificial fever were examined. The animals' own red cells or a concentrated solution of inulin introduced into the vitreous was the test substance. Only the short bouts of fever repeated daily for two weeks had, in rats, an indisputably beneficial effect on the rate of disappearance of the red cells from the vitreous (40 animals).

Discussion. Dr. Irving H. Leopold. The vitreous humor has been the subject of investigation by numerous men for many years and has involved a knowledge of special techniques, of physical chemistry, and of ophthalmology. Duke-Elder, Robertson, Hodgeson, Goedbled, Baurmann, and others have worked on this problem for years. None have contributed more to our present knowledge of the vitreous than has Dr. von Sallmann. It was a pleasure to hear him speak on aspects of the vitreous humor, because on this subject he is certainly an authority.

The vitreous humor is a colloidal structure, and as a colloidal structure may exist as a sol or a gel. Sols are colloidal states in which the solid particles are dispersed in a fluid medium, and gels are colloidal states in which the solid particles, so to speak, join hands, and form a framework in which the liquid medium is dispersed.

Most of the evidence, and much of the more recent evidence has been contributed by Dr. von Sallmann, is in favor of the vitreous humor being a gel. It is not a very stable gel. The liquid and the solid phase are in an unstable equilibrium, and

this can be upset easily. When the vitreous gel is disturbed, the transparency of the vitreous is altered.

There are two ways, roughly, in which the vitreous transparency can be changed with the production of vitreous opacities. First, by disturbing the gel of the vitreous and secondly, by the influx of new materials such as red cells, exudates, and foreign bodies. Examples of the first mechanism are senile vitreous opacities. These are thought to be due to the aging of the gel, changing it into the sol state. All gels tend to break down to the sol state as they age. Myopic vitreous opacities are thought to result from movement of the vitreous gel in an enlarged globe. Liquefaction of the vitreous gel by proteolytic enzymes may result in opacities.

The other group of opacities are due to the influx of new material, such as red cells, which Dr. von Sallmann discussed tonight. We all recognize the problem of intraocular hemorrhage as a serious one. Anterior-chamber hemorrhage is still an unanswered therapeutic problem, but vitreous hemorrhage offers an even greater therapeutic problem. In vitreous hemorrhage we are not only concerned with the resorption of blood, but we have to maintain the status quo of the vitreous gel; or reconstruct it, if it is disturbed. Dr. von Sallmann has given us some ideas on the method of reabsorption of the cells, but at the same time has suggested methods which disturb the structure of the vitreous body.

It is interesting to observe workers in other fields of medical science turning to the eye as an aid in solving their own problems. This has happened in the case of the spreading factor. Dr. von Sallmann has reviewed their observations and added more of his own in order to solve some ophthalmologic problems. Duran Reynals found that if vaccinia virus were injected into the testes of rabbits, one could be more certain of takes than if the injections were made in other areas of the body. He could get much more severe infection by such injections. He then found that if an extract of the testes were injected into the skin prior to vaccinia injections, he could also facilitate systemic spread of the virus and increase the number of takes. He thought that the testes extract facilitated the spread of the vaccinia by hydrolyzing the viscous mucoproteins in the connective tissues.

These spreading factors were then found to hydrolyze hyaluronic acid. As you know, Karl Meyer and his coworkers isolated this mucopolysaccharide from the vitreous humor. Other investigators then turned to the vitreous humor, an excellent substrate of hyaluronic acid, as a place in which to compare and study the activity of various spreading factors. They measured the ability of the various spreading factors to reduce the viscosity of the vitreous humor. Most spreading factors are thought to act through hydrolysis of hyaluronic acid. However, ascorbic acid is also known to reduce the viscosity of the vitreous. It does not work theoretically, as the other spreading factors, and for that reason, many people do not consider it a spreading factor. Nevertheless, it can, when properly employed, reduce the viscosity of the vitreous humor, and it is quite possible that it may help in this manner in the resorption of vitreous hemorrhage. Vitamin C has been used in the past as a therapeutic agent in intraocular hemorrhage. It was thought that it built up intercellular cement substance and reduced the capillary permeability, thus preventing further bleeding. It was not generally realized that it might reduce the viscosity of the vitreous, and facilitate greater distribution of red cells and earlier resorption. It may not be as toxic as hyaluronidase and, perhaps, can be injected directly into the vitreous without

producing the untoward effects of hyaluronidase.

The observations of the influence of thyroidectomy on reabsorption of blood are worthy of note. In 1936, Jeandelize and Drouet reported on cases of recurring vitreous hemorrhage. They reported that all of their patients with this disorder had some degree of hyperthyroidism, and felt that they could prevent recurrences by irradiating the pituitary body thus producing lowered thyroid activity. It is interesting that the lower thyroid activity may work toward the prevention of hemorrhagic recurrences, and at the same time retard the resorption of existing hemorrhages.

For years fever therapy or shock therapy have been recommended for resorption of vitreous hemorrhage, usually without any well-founded, controlled experiments to back up the recommendations. Dr. von Sallmann has given us controlled data to show the value of artificial fever.

There is some question about the circulation of fluid in the vitreous humor. As you know, the vitreous body is not thought to have any metabolism. It is supposed to be a product of the surrounding cells. It probably does not utilize oxygen or produce carbon dioxide. Regardless of this lack of necessity for metabolic interchange, there is some evidence of a flow of fluid through the vitreous. This has been demonstrated in rabbits, but not satisfactorily in man. This flow is thought to be from the ciliary body toward the optic nerve. Certainly the diffusion of the red cells would not tend to substantiate the idea of such a direction of flow in the vitreous. The diffusion was in all directions from the site of injection into the vitreous.

Dr. Francis Heed Adler. I had not intended to discuss this paper largely because of a feeling of inadequacy. I rise, as they say in parliamentary language, to a point of order; that is, to object to the statement in Dr. von Sallmann's speech in which he mentioned my name as contributing to our knowledge of the vitreous. Although I have been interested in some of the physiologic problems of the vitreous, the work to which he referred is chiefly work in my laboratory done by Dr. Irving Leopold, and the full credit should be given to him.

It seems to me from what has been said about hyaluronidase that that is practically a closed door. The danger threshold between the effect that is experimentally demonstrable lies too close to production of retinal damage, which is also demonstrable. This is comparable to some anesthetics, which perhaps are good anesthetics, but the threshold of anesthesia is very close to that of death.

I would be interested in having Dr. von Sallmann comment further on the question of thyroxin, particularly in relation to the water-binding properties of thyroxin, and on the anterior pituitary hormone and the part it plays, in producing exophthalmos. I wonder if he has taken into consideration the relation between thyroxin and the anterior pituitary hormone in this particular condition, and whether he has anything further to say on this particular subject, because I think that it is a lead which offers us something.

Finally, I can confirm from the clinical point of view the effects of fever therapy on the absorption of vitreous hemorrhage. It is certainly one of the chief therapeutic measures that we have to draw on at the present time.

Dr. Ludwig von Sallmann. I want to thank Dr. Leopold and Dr. Adler for their interesting discussion. I am sorry that I cannot offer anything on the relationship of the thyroxin experiments to the pituitary function. I did not go into detail on the thyroxin injections, because the results were rather erratic. Sometimes

a fairly significant increase in absorption of the red cells was obtained, but in other instances there were flat absorption curves.

Dr. Francis Heed Adler. Why did you use thyroxin? What theoretical consideration led you to suspect that you might get some effect from thyroxin on the absorption of the vitreous hemorrhages?

Dr. Ludwig von Sallmann (closing). Hans Eppinger studied the effect of thyroid preparations on the water threshold, in 1914, and he described the speedy absorption of tissue fluid in certain types of edema. These observations on the water threshold and the stimulation of the basal metabolism by thyroxin were the theoretical bases of my experiments.

George F. J. Kelly,
Clerk.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

January 6, 1947

DR. BENJAMIN FRIEDMAN, *president*

The program was devoted to a discussion of ophthalmic problems in children.

VISUAL FUNCTIONS IN INFANTS

DR. ALFRED KESTENBAUM said that the time of development of the various forms of eye movements were shown in tests performed on about 70 infants. Optically elicited movement (O.E.M.) means movement toward a peripherally appearing object and hence is a function of a peripheral retinal point. The O.E.M. is a gliding movement which tries to keep the image of a moving object on the macula and hence is a function of the macula. Up to the age of 4 to 6 months there is no gliding follow movement; it is substituted by a cogwheel movement. Optokinetic nystagmus appeared at the age of 3 to 6 months. Acoustically elicited eye movement appears very late, usually not before six months of age. Vestibular reaction of the eye on head rotation, present immediately after birth, was found to be at first in the form of a simple deviation.

Dr. Kestenbaum stated that visual acuity can be estimated by the following procedures: (1) Examination of the direct and of the indirect pupillary reaction: at birth; (2) Marcus Gunn's pupillary test (for optic-nerve lesions): at birth; (3) pseudo-anisocoria test (for optic-nerve lesions): at birth; (4) follows movement test (for disturbance of macular vision): 4 to 6 months; (5) optokinetic nystagmus test (for disturbance of macular vision): 3 to 6 months.

The field of vision can be examined by the O.E.M. test in the form of the fact-test at from 2 to 4 weeks. Eye motility can be studied by: (1) O.E.M. test (possible only if the visual field is preserved): 2 to 4 weeks; (2) vestibular compensation test: at birth. Phoria and tropia can be studied by screening tests.

Marcus Gunn's test consists of alternation between illumination of the right eye with occlusion of the left eye and illumination of the left eye with occlusion of the right eye. If in the first case a pupillary contraction occurs, but in the second a pupillary dilatation occurs, the presence of a lesion of the nerve fibers of the left eye may be assumed. This test is modified in the pseudo-anisocoria test in which the finally resulting pupillary sizes, after occlusion of the right eye, are observed and not the movements of the pupil. After occlusion of the left eye, the size of the pupils are exactly measured and compared with each other. The latter two signs are especially valuable in the diagnosis of retrobulbar lesions. Inability to follow a moving object and absence of optokinetic nystagmus indicate disturbance of macular vision. In the O.E.M. test, an object is brought into the field from without. When the eye turns toward the ob-

ject, it proves that the object has been seen. Systematic application of this O.E.M. test in eight directions gives a fairly good visual field. Dr. Kestenbaum concluded that the strongest attraction on the infant's eye is exercised by a human face entering the visual field.

Management of infantile glaucoma

Dr. David H. Webster reported the operative results in six cases of infantile or congenital glaucoma. All the cases were operated during the first week of life. Three cases in which the tension remained normal following iridencleisis did not develop buphthalmos. One case in which aniridia was an associated anomaly did not do very well following an attempted iridencleisis. In spite of repeated trephinations development of buphthalmos occurred in two cases.

In the course of 35 years, Dr. Webster said that he had seen eight cases. The condition is recognized by the steamy white cornea, 14 to 16 mm. in diameter. The creation of a new filtration channel to compensate for the structural defects in the angle of the anterior chamber is accomplished by iridencleisis.

Retrolental fibroplasia

Dr. Algernon B. Reese stated that for over a hundred years basically related lesions have been reported under various synonyms including tunica vasculosa lentis, congenital fibrous tissue back of the lens, congenital connective tissue in the vitreous with and without detachment of the retina, remains of the hyaloid system, and so forth. Formerly such lesions were rare, and occurred in full-term infants, and were usually unilateral. During the last 10 years there has been an increased incidence of these lesions which have been reported in premature infants and bilaterally.

Dr. Terry has called these more recent cases retrolental fibroplasia. He believes that the condition appeared after birth (not before the fourth month). He considered it a newly acquired disease.

Dr. Reese said that Dr. Payne and he believe that both lesions mentioned are one and the same, basically. He felt that the lesion is congenital, although at times the matrix may be inconspicuous at birth and becomes more pronounced after birth by hyperplasia. He explained the greater incidence on the basis of the fact that more premature children now survive. He called attention to the fact that this eye lesion is frequently associated with hemangiomatous manifestations elsewhere.

Dr. Reese cited the opinion of Dr. Krause that this lesion is characteristically associated with mental retardation, and that these two manifestations are due to a faulty development of the neuroectoderm over that portion where it forms the retina as well as the brain. Dr. Krause called the condition congenital encephalo-ophthalmic dsyplasia. Dr. Reese said that he did not agree with Dr. Krause's concept because:

1. The eye lesion is not characterized by a dysplasia of the retina but by the presence of fibrous tissue in the vitreous. This fibrous tissue may contain any of the derivatives of the mesoderm such as cartilage, smooth muscle, fat, connective tissue, and blood vessels.

2. Remains of the hyaloid artery, or some of this system, is a common finding and would not be expected in retinal dysplasia.

3. Mental retardation due to a brain dysplasia or agenesis does not seem to be an integral part of the lesion. Excluding the cases of hydrocephalus, only 30 percent of these cases show mental retardation. It seems more likely that the mental retardation present in these cases is due to prematurity (82 percent of Dr. Krause's cases were premature), to cerebral anoxia, and to hydrocephalus. Furthermore, autopsy findings presented by Dr. Krause did not seem convincing re-

garding the pathologic evidence of a cerebral agenesis.

Dr. Reese stated that the etiology of this eye lesion is not clear. It seems likely that the same factor producing the prematurity also produces the eye lesion. The mothers of these children give a high incidence of bleeding during pregnancy, and a history of respiratory infection is common. The affected eyes sometimes show evidence of inflammation. This is manifested by residua of iritis or choroiditis, and microscopically by the presence of round cells in some of the cases. There are instances of subclinical maternal infections producing congenital anomalies in the eyes of the offspring. Dr. Reese cited the case of a bilateral retrolental fibroplasia occurring in the offspring of a mother who had rubella in the fourth month of pregnancy.

Discussion. Dr. Kornzweig questioned the possible time of occurrence of the toxic influence. It must occur after full development of the hyaloid system. The hyaloid system reaches the height of its development during the second to third month, then it atrophies. The ciliary processes are formed after the third month and touch the lens after the fourth month. The toxic influence must, therefore occur between the third and fourth month concluded Dr. Kornzweig.

Dr. Sitcheska agreed that these patients have well-developed mentality.

Dr. Mandelbaum asked if it is always possible to see the vascular structure of the tissues or whether the lens is too dense.

Dr. Friedman asked whether X-ray studies show areas of calcification, as in glioma. He remarked that in these cases the pupil does not dilate well and if atropine is used glaucoma may result.

Dr. Reese (in closing) replied: (1) That of 18 patients, 16 were normal mentally. (2) In answer to Dr. Mandelbaum's question, that cataractous changes can occur and prevent the view of the tissues and also a cloudy cornea may prevent it. (3) In answer to Dr. Friedman, that X-ray studies do not show any calcification.

Congenital cataract after maternal rubella

Dr. Charles Perera stated that the occurence of congenital malformations (cataract, cardiac abnormalities, mental retardation, deaf-mutism, and other defects) following maternal rubella was reported from Australia in 1942 by Gregg, and confirmed the following year by Swan and his colleagues. Reese brought this to the attention of American ophthalmologists in 1944. Since then a number of reports have appeared on this subject.

The ocular pathologic changes reported by Swan in three infants dying from congenital defects, by Terry, and by Cordes and Barber in an 8-week-old embryo showed retardation in the development of the involved eyes, necrosis of the nuclear portion of the lens, and degenerative changes in the equatorial lens fibers. These findings are consistent with the clinical observations of microphthalmos, nuclear cataract, and diffuse lens opacification in these children. Microscope preparations of the eyes of a 10-week-old fetus, obtained from a woman who had rubella during the seventh week of pregnancy, show degenerative changes in the fetal lenses in the central and posterior portions.

A patient seen in November, 1946, was the 3-year-old daughter of a woman who had rubella late in the second month of pregnancy. The girl was unable to walk or talk, and had diffusely hazy lenses and a variable esotropia.

Dr. Perera discussed the treatment of congenital cataract with special reference to extraction of the lens, needling, and through-and-through discission of the lens.

This type of cataract may result from the passage of the virus or toxic substances through the placenta into the fetal circulation or through the amniotic fluid. He stressed the need for further investigation of this subject by studies in the field of pathology and by more surveys such as those reported from the Vanderbilt University Hospital, in 1945, by Conte, McCammon, and Christie.

Discussion. Dr. Smith asked whether discission should be performed during the first or second month of life, or be postponed to the 11th to 12th month. Dr. Smith also agreed on the use of a through-and-through discission because of the danger of glaucoma.

Dr. Perera (in closing) replied that in his opinion early operation is advisable before the sixth month, preferably during the second or third month.

Strabismus in childhood

Dr. James W. Smith presented this subject. His paper is published in full on page 85 of this issue of the Journal.

February 21, 1947

Profuse hemorrhage in pterygium

Dr. Marin Amat and Dr. Marin Enciso presented the case of a woman, aged 57 years, who was admitted to their service in the ophthamologic clinic of the Provincial Hospital in Madrid. The patient presented a chronic suppurating dacryocystitis and an internal membranous pterygium in both eyes. She was operated on and both lacrimal sacs were removed in one session without anything abnormal occurring either during the operation or after the operation.

A few days afterwards, on December 3, 1946, they removed in one session both pterygia similarly without the least complications. The postoperative course was perfectly normal and on the seventh day the bandage was removed. But during that night the right eye began to bleed and it was necessary to bandage the eye again in order to check the bleeding. The next morning the bandage was removed. On the night of the same day, another hemorrhage occurred in the small operative wound of the pterygium of the right eye, but this hemorrhage was very profuse. It was not possible to check the bleeding with a compression bandage because the latter became immediately saturated with blood. The doctor on duty had to renew the bandage several times and give many coagulating injections of cebion E (vitamine K), coaguleno, and zimema, without being able to stop the bleeding effectively.

The following morning the patient was in shock (cold, with a barely perceptible pulse, with vomiting), necessitating the giving of a subcutaneous injection of 500 cc. of physiologic saline and also a transfusion of 300 cc. of whole blood. By these means the hemorrhage was stopped and did not recur. Thereafter the patient slowly improved and was discharged as cured on December 23rd.

In view of such an important complication we undertook to investigate the etiology, but nothing in the family history or the biologic analysis gave any clear insight into the cause. The only outstanding factor was that the woman was in very poor circumstances and had subsisted for a long time on practically a hunger diet, which indicated that she was in a state of avitaminosis with a consequent lack of vitamin K and a reduction in the production of thrombokinase.

Pseudoglioma of metastatic origin

This was a case of a little girl, aged 26 months, who showed a morbillous exanthem with temperature and sudden appearance. All of the symptoms disappeared the following day. The next day

she awoke with her whole body swollen. There was intense oliguria and an analysis of the urine showed albuminuria, hematuria, and cylindruria. Two days passed without any change in the picture. On the fourth day of the sickness there appeared a whitish spot, ring shaped, which covered a large part of the pupil of the right eye. A similar spot appeared on the left eye the following day. The eyes presented a picture of a bilateral uveitis with an intense ciliary reaction and with hypopyon. On the same day penicillin was administered (27,000 units every three hours) until a total of 1,700,000 units had been given. The general condition became improved. The spot in the left eye disappeared in the first 24 hours and that on the right eye after about 10 days.

When the child was examined on January 17th, there was a slight circumcorneal congestion and dilated pupils without reaction to light but without any inflammatory manifestations at the anterior pole. With the ophthalmoscope could be seen a yellowish white mass in the vitreous body in both eyes which prevented a view of the fundi of the eyes and verified the absence of vision. There was hypotension in the right eye.

Three phases in this clinical history stand out: (1) general symptoms; (2) the false picture of nephritis, which showed the time that intervened between the general infection and the ocular metastasis; (3) the presence of ocular symptoms.

The diagnosis is a pseudoglioma of both eyes of metastatic origin subsequent to a septic process from which the patient had suffered. Prognosis as to vision is unfavorable because one could not hope for any recovery of vision. The chief point to emphasize is the success of penicillin in the treatment of ocular metastasis without which, in this case, probably both eyes, certainly one of them, would have terminated with a panophthalmitis.

FOREIGN BODY IN SCLERA

DR. MARIN AMAT presented a case of a foreign body embedded in the external sheath of the sclera alongside the optic nerve after having crossed the eyeball. It was a case of an accident of occupational origin, relating to a railroad worker who, while working on the track on January 21, 1947, was struck in the right eye by a foreign body. Radiographs of the orbit were immediately taken, one frontal, one lateral, the latter in two exposures (while looking up and while looking down) which were positive and showed the presence of an intraocular foreign body.

Consequently, a search was made by the scleral or posterior route and the proper point of the giant electromagnet was introduced into the operative wound. Notwithstanding repeated trials, removal failed and enucleation of the eye became necessary. A couple of days afterwards the eye was removed. On dissecting it the following details were noted: (1) Total detachment of the retina with abundant yellowish subretinal liquid. (2) Absence of any intraocular foreign body. (3) The presence of a circumscribed hemorrhagic focus in the ciliary region and an extensive zone of whitish infiltration in the process of organization. (4) What had seemed to be foreign bodies in the lens and in the retina were nothing more than a true tattooing by the iron salts. (5) The hard nodule alongside the optic nerve showed on dissection to be a small piece of iron, triangular in shape with a pointed vertex, which was imbedded in the external sheaths of the sclera, in Tenon's space, and encased by reparative tissue arising from the external sheath of the optic nerve and from Tenon's capsule. These explained the various findings which resulted from the path of the foreign body, and also explained the false radiographic localization.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

OPHTHALMIC PUBLICITY

At the recent meeting of the American Academy of Ophthalmology and Otolaryngology, there were two important contributions, the public and press reactions to which merit some comment. These two contributions both dealt with procedures which had been highly and luridly publicized in the lay press. Both contributions were largely negative in their conclusions. Through the public relations officer of the Academy, the representatives of the press were authoritatively informed of the negative results. These negative conclusions, the results of long and patient investigation, received, with one or two notable exceptions, little or no comment in any of the newspapers, whereas the gaudy claims of the proponents of these forms of therapy, claims based on personal enthusiasm and unsupported by scientific investigation, had previously been heralded far and wide across the country by the various news agencies.

The first of these contributions related to

the corneal-transplant operation. The careful studies of the five speakers in the symposium showed the operation to be one of limited applicability, of uncertain results, with many contraindications, and was especially contraindicated in patients with vision of 20/100 or better, where there was a greater chance of permanent blindness than of improvement of vision. At best, in the over-all statistics, only approximately one third of the patients undergoing this operation had material improvement of vision. It was quite true, however, that in specially selected cases, notably in keratoconus and slight central corneal scarring without undue vascularization, spectacular visual improvement, not possible by any other means, might be expected in a materially higher percentage of cases.

The second contribution dealt with the results of tissue therapy and the administration of cod-liver oil in patients with pigmentary degeneration of the retina, the so-called Filatov treatment. Here a careful investigation of the results of this treatment in a large number of patients failed to reveal any evidence supporting the wide claims made by the proponents of this form of therapy. A limited number of the patients showed some slight subjective improvement in the usual level, but in no greater number and of no higher degree than had been reported with the other widely different forms of treatment formerly proposed—vitamin therapy, sympathectomy, estrogenin and androgenin treatment, vasodilators, and reduction of the intraocular pressure. Objective examination of these patients, before and after treatment, showed little or no change in the visual fields or light adaptation. The conclusion appeared inescapable that, so far as this careful investigation was concerned, there was no evidence at hand to support the extravagant claims which had been so widely made.

At first glance it appears surprising that the various news agencies, whose function it is to disseminate "news," and the lay press of the country, which should strive to lay pertinent information before the public in readable form, exhibit little or no interest in negative results. On thought, however, the answer appears easy. Negative results are not "news," and the publication of results invalidating already published claims is, at best, only a wet blanket and, at the worst, may precipitate on the heads of the publishers recriminations and even damage suits.

A case in point which well illustrates this is the attitude recently taken by the Curtis Publishing Company. The question of various eye exercises for myopics had been widely publicized, and indeed apparently endorsed by a number of prominent periodicals. The Curtis Publishing Company had taken no part in this publicity, but nevertheless was deeply interested in its possible humanitarian application and its publicity value. Through the agency of the editor-in-chief of one of their major publications, they undertook to finance a thorough investigation of the possible beneficial results of such treatment. As a result of their offer, a joint investigation of this treatment was undertaken by a group of psychologists and optometrists on the one hand, and the team from the Wilmer Institute staff on the other. The Wilmer Institute team acted only as judges of any results observed. The results of this study, published in full in the medical press, were largely negative. These negative results were duly transmitted to the Curtis Publishing Company who, since they had financed the psychology-optometry phase of the investigation, had just right for first publication after the reports had appeared in the medical journals. However, in as much as the results were negative, the Curtis Publishing Company had no interest in publishing them or commenting upon them. They simply charged off their investment. The publication of the results, from their standpoint, might only have touched off a controversy, uninteresting to the great body of their readers, and in which they had no inclination to participate.

Such a specialty as ophthalmology is par-

ticularly susceptible to the ill results of misleading publicity. The blind have an emotional appeal to the seeing world. Any form of treatment which promises to alleviate or cure blindness is immediately of interest to the general public, any claims supporting such treatment find sympathetic ears, and any agency endorsing the proposed form of therapy finds ready supporters. In short such forms of treatment are interesting and appealing "news," which the public is anxious to read and the press, therefore, correspondingly anxious to publish. While, undoubtedly, in many instances the publicizing of these unproven forms of therapy is animated by the most altruistic motives, nevertheless in other instances this does not appear to be true. It must regretfully be admitted that there are a few ophthalmologists who avail themselves of this sentimental appeal for the purpose of self-advertising. Were the news agencies as industrious in circulating the results of investigations which disprove these spectacular forms of treatment, and the lay press as eager to print them as they are to publicize the original claims, it might well have a deterrent effect on the self-advertisers.

Although the reaction of the press to negative results is understandable, the question may well be asked—does it reflect a healthy interest in the public welfare and is it in line with the humanitarian motives which one would assume underlay the dissemination of information relating to these apparent cures? There the answer should be an unequivocal "No."

As was pointed out in the discussion of the paper on pigmentary degeneration of the retina, mankind is afflicted with a host of maladies, often congenital or degenerative, about which the conscientious physician can do little or nothing. These unfortunates are constantly seeking for some relief or cure of these conditions for which they can obtain little alleviation from legitimate doctors. They are ripe fruit, ready for the plucking. As the late Sir William Osler once remarked, "People love to be fooled, and the sons and daughters of Circe are still in our midst." When there is a demand, there is usually a supply. The publicization of unproven and often utterly fallacious remedies is followed by a deluge of inquiries on the doctors and medical centers for information as to their value. There must then ensue a long period of patient investigation to validate or invalidate these claims. If the claims are validated, as is rarely the case, the fundamental investigator receives but scant public recognition—the bulk of the glory goes to the proposer or instigator of the treatment, to the man who thought up the dream. If the claims are invalidated, the investigator gets no thanks for his labors, and may often be the subject of attack in one form or another. At the best the whole incident is quickly forgotten.

The lay press cannot escape its responsibility. If the press is willing to publish the unfounded and unproven claims of enthusiasts and self-advertisers, to give them wide publicity, and often to make them the subject of special articles and Sunday features, it should be equally willing, even anxious, to follow up the subject and give equal publicity to legitimate releases of investigators which disprove the former extravagant claims. If false hopes are aroused in the minds of sufferers from untractable ailments by injudicious publicity, the same agents responsible for the publicity should do what they can to rectify their error. Only thus can their public duty be discharged. The present policy of exploiting sensational claims and soft-pedaling the results of investigations which disprove these claims, is playing into the hands of self-advertisers and, in some cases, of charlatans.

Alan C. Woods.

ECLIPSE RETINITIS

On November 12th there occurred a partial eclipse throughout the greater part of the United States. Along the Eastern Sea-

board the time of its visibility varied between 16 and 34 minutes. In the San Francisco Bay area the duration was two hours and 31 minutes.

During the two weeks following the eclipse the staff of the Division of Ophthalmology of the University of California saw 23 cases of eclipse retinitis. There must have been many more cases observed by other ophthalmologists and many more persons must have had light attacks that cleared quickly and therefore were not seen.

Most of the cases occurred in children between the ages of 11 and 15 years, although there were also some adults. All gave the history of loss of vision following the observance of the eclipse without protective glasses or film. Vision at the time of examination ranged from 15/200 to 20/30. Examination of these patients revealed that many of them had a central scotoma, while in some instances a relative scotoma was present.

On fundus examination the macular area showed an edema which in two of the cases corresponded in shape to the actual eclipse. In one patient the retina had the appearance of a central angiospastic retinopathy. At the end of two weeks, vision had returned to normal in most instances with no appreciable fundus changes. In one boy, aged 13 years, vision has remained at 20/40 and the appearance of the macula in each eye suggests an early hole in the macula. In another patient, a Negress, vision has remained at 20/70 in each eye and the macula has the appearance of an early hole in the macula.

Most of the patients were unaware of the possibility of damage to the eyes from looking at the eclipse without the proper protection. In one instance, a boy, aged 11 years, looked at the eclipse while at school under the direction of the teacher. He was given some sort of dark glasses but apparently did not use them all of the time. Some of the patients had the belief that an ordinary pair of so-called dark glasses was sufficient protection. In any event, it was apparent that the laity has not been sufficiently warned of the dangers of eclipse retinitis.

"Eclipse burns" are not new and have been observed many times. During the last war they were seen a number of times among Navy personnel. It was usually observed following the use of the long glass, a monocular telescope of 20 times magnification. The burns usually resulted from "following an enemy plane into the sun." There was pain at the time of the exposure followed by loss of central vision and subsequent formation of a typical hole in the macula.

The process results from the passage of infrared rays through the layers of the retina to be absorbed by the pigment layer, where they are degraded into heat and may produce a thermal lesion. This is accompanied by swelling and edema of the retina, together with congestion of the underlying choroid, and frequently leaves a permanently pigmented scar. Probably the most extensive work on this subject is that of Verhoeff and Bell* who showed that the effects known as eclipse blindness are wholly thermic and are due to the intense concentration of the solar energy upon the retina by the refractive system of the eye itself.

Clinically the immediate effect in the milder cases is a marked scotoma which does not pass away promptly but leaves more or less "serous cloudiness" of vision that may last a few weeks. In the severer cases the scotoma is commonly central and generally of small extent, in a large percentage of cases corresponding fairly well to the dimensions of the sun's image. Wide variations from this may result due to repeated fixations overlapping. Metamorphopsia sometimes appears. In the milder cases, the scotoma tends to contract with the lapse of time, and normal vision is regained within some weeks; whereas, in the more severe cases the scotoma and loss of vision are per-

---

* Verhoeff, F. H. and Bell, Louis. Proc. Amer. Arts and Sci. 51:630-811 (July) 1916.

manent. Experimentally Verhoeff and Bell were able to show that the size of the lesion is 3 mm., corresponding in size to the size of the sun's image on the retina. They also give the critical time for the development of eclipse blindness as one minute or less. Based on the cases seen among Navy personnel, it would seem that the use of the "long glass" apparently very materially shortens the time of exposure necessary to produce eclipse blindness.

Eclipse blindness is discussed in most of the textbooks but in almost none of them is there any description of the proper precautions to be taken to avoid damage to the eyes. Duane in Fuchs's textbook states that eclipse blindness occurs in patients "who watched an eclipse with glasses which were not sufficiently smoked." No mention is made of what constitutes a "sufficiently smoked" glass.

An eclipse of the sun is usually described in the press a number of days in advance so that the appearance of the phenomenon is well known. In view of the experience in San Francisco and other localities it would seem the duty of the ophthalmologists of a community to issue a warning through coöperation of the local county medical society and the press. These warnings could also describe the necessary precautions. It has also been suggested by a member of the staff that the National Society for the Prevention of Blindness or some similar organization might make it its duty to keep posted on the appearance and location of eclipses of the sun. The society could send press releases to the communities involved, describing the dangers and giving the proper precautions to be employed.

Above all it would seem that teachers should be warned of the dangers so that their pupils would not be exposed to the possibility of permanent loss of vision.

It is hoped that this editorial may stimulate some organization to give this problem its attention.

Frederick C. Cordes.

OBITUARY

SELIG HECHT
(1892-1947)

On September 18, 1947, the scientific world sustained an irretrievable loss in the untimely and sudden death of Selig Hecht, a distinguished investigator and teacher, and professor of biophysics in Columbia University. Dr. Hecht's achievements in the

Courtesy of *Newsweek*

Selig Hecht

field of general physiology and, in particular, visual physiology, rightfully gave him the distinction as a world authority on visual function.

Dr. Hecht was born in Glogow, Austria, on February 8, 1892, and was brought to this country by his parents when he was six years of age. He attended public school in New York City and later the Townsend Harris Preparatory School before entering the College of the City of New York where, as a student, he early displayed that rare intellectual curiosity and scientific ability which so characterized his entire career. Before the completion of his college course, he served as research assistant for

the United States Bureau of Fisheries. After receiving his B.S. degree he was appointed for a year as assistant pharmacologist in the Bureau of Chemistry of the United States Department of Agriculture. He then undertook graduate work at the Harvard Zoological Laboratory, receiving his Ph.D. degree in 1917. During his graduate years, he was an Austin teaching fellow at Harvard University. The summer following the receipt of his doctorate he conducted scientific research at the Scripps Oceanographic Institute at La Jolla, California. In the fall of 1917 he went to Omaha, Nebraska, where he served for four years as assistant professor of physiology in the Creighton Medical College. During the summers of these years, he carried on intensive investigations at the Marine Biological Laboratory at Woods Hole, Massachusetts. His researches there were concerned largely with the photosensitivity of the mollusca. These studies laid the basic foundations for his later investigations which dealt primarily with the photochemistry of human vision.

In 1921-22, Dr. Hecht went to England on a National Research fellowship and became an investigator in E. C. C. Baly's Spectroscopy Laboratory at the University of Liverpool. Upon return to this country, he was associated for two years with the late Prof. Lawrence J. Henderson in the laboratory of biochemistry at Harvard University. With the aid of a Rockefeller Foundation fellowship, he again went abroad, spending the year, 1924-25, at the zoological station in Naples, Italy, and the following year in Barcroft's Laboratory in Cambridge, England. In 1926, he was appointed associate professor of biophysics in Columbia University and, in 1928, was promoted to full professorship of biophysics, which position he held until his death.

The broad training in physics, chemistry, and biology that he received in this country and abroad equipped him most admirably for his scientific career. Physics and chemistry were precision tools which he used most effectively in his investigations on the kinetics of retinal photosensory processes. His bibliography, consisting of 116 publications, is concerned largely with the problems of vision in man and in animals. He wrote extensively upon many fundamental aspects of the subject, such as retinal adaptation to changing illumination, visual acuity, color vision, and the like. In recent years he became intensely interested in Planck's quantum theory of light as applied to human vision. In this connection he measured the number of light quanta necessary to produce a minimum stimulation of the human retina. As national Sigma Xi lecturer in 1944, he lectured on this subject in many American universities under the title "Energy and Vision."

During World War II, he was active in many projects concerned with vision as related to the armed forces. He was responsible investigator for various contracts for the armed forces and the O.S.R.D. He was a member of the Army-Navy O.S.R.D. Vision Committee which, after the war, became the Army-Navy National Research Council Vision Committee. Recently he lectured before the National War College in Washington on the subject "Scientific Discoveries and Social and Military Needs."

Dr. Hecht was also made a member of the Emergency Committee of Atomic Scientists, a group of nine scientists headed by Dr. Albert Einstein and formed for the purpose of acquainting the public with the problems of atomic energy. In this connection his recent and timely book *Explaining the Atom* has received high praise as a popular exposition of nuclear energy. In an editorial tribute to Professor Hecht for this book, the *New York Times* said, "We need more research scientists and teachers like him—men who are as brilliant in the laboratory as they are in the classroom or on the printed page, and, above all, men who have so little academic snobbery in them that they consider it a duty, as Clark Maxwell did in his time, to talk of science to the

common people in simple homely figures of speech that they can understand."

Dr. Hecht did possess that rare ability to discuss highly technical data in such fashion as to make the subject intelligible and stimulating to practically any audience. If he was forced to employ equations, he made sure the audience understood what the equations meant. As a lecturer he was dramatic. His subject matter was always presented with excellent logic or, may I say, with logical excellence. To listen to him develop a subject for an hour was indeed an aesthetic pleasure.

Despite Dr. Hecht's devotion to his laboratory and the many problems that constantly bothered his searching mind, he graciously shared his time for the benefit of others. He was a member of the editorial board of the *Columbia Biological Series,* the *Biological Bulletin,* the *Monographs on Experimental Biology,* and the *Journal of the Optical Society of America.* He gave freely of his time to lecture on various biologic subjects at the New School for Social Research in New York City. Recognition of his scientific achievements came to him in many forms. In 1941, he received the Frederick Ives Medal from the Optical Society of America, and, in 1942, the Townsend Harris Medal from the alumni of the College of the City of New York. He was a fellow of the American Association for the Advancement of Science, a member of the National Academy of Sciences, American Society of Zoologists, American Society of Naturalists, American Physiological Society, Optical Society of America, Harvey Society, Phi Beta Kappa, and Sigma Xi.

Although Dr. Hecht possessed a high degree of individualism, he was never a lone worker. He gave a great deal of time and energy to his graduate students, who received excellent training under his scientific leadership. A number of his students have taken prominent academic positions in the field of general physiology. Not only is his passing a tragic loss to the scientific world, but as acting President Fackenthal of Columbia University so aptly expressed it, "He will be missed by many people, in many ways."

Samuel R. Detwiler,
Professor of Anatomy,
Columbia University.

CORRESPONDENCE

The search for aqueous veins

Editor,
American Journal of Ophthalmology:

The following may answer questions raised by some visitors to my aqueous-veins exhibit at the October meeting of the Academy of Ophthalmology, concerning the difficulties connected with the search for aqueous veins.

In 1941, I found them in more than 26 percent of the patients examined with the Bausch and Lomb corneal microscope (American Journal of Ophthalmology, 25:32, 1942). But even with a simple 10-

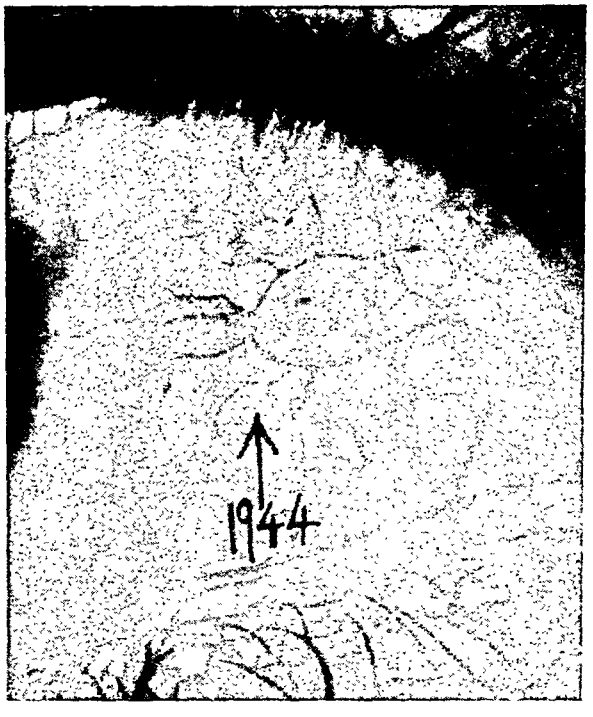

Fig. 1 (Ascher). An aqueous vein and its emptying into a stratified vessel. (5×)

times magnifying loupe, under good flash-light illumination, 14 percent of all normal eyes will show at least one aqueous vein (American Journal of Ophthalmology, 29:1384, 1946).

With 20- to 40-times magnification, and good illumination with not too narrow a

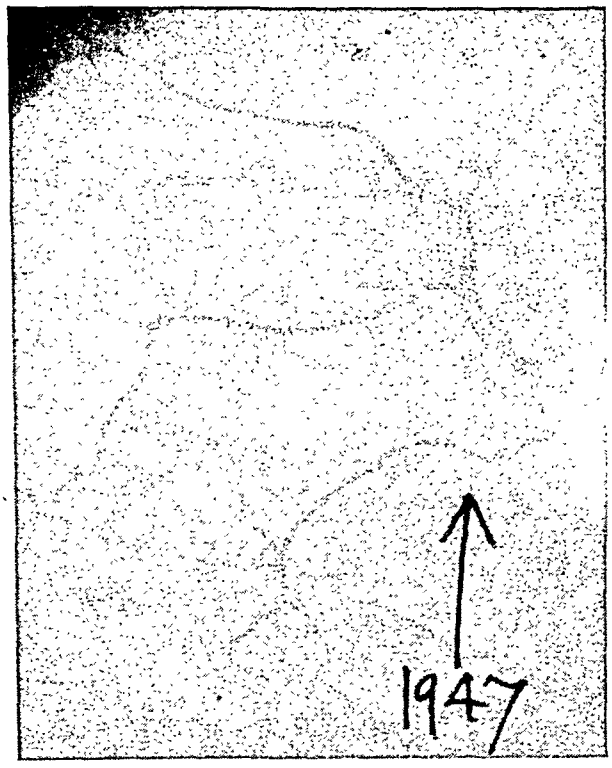

Fig. 2 (Ascher). A picture of the same vein taken 35 months later. (20×)

beam, aqueous veins are found more often. Goldmann (Ophthalmologica, 111:147 1946) saw them in 75 percent of all normal eyes; De Vries (De zichtbare afvoer van het kamerwater, Drukkerij Kinsbergen, Amsterdam, 1947) examined 113 patients and found in all of them at least one aqueous vein; he, however, devoted to the study of one patient—including photography—as much as two hours and confessed that in some cases the search for an aqueous vein was comparable to the search for a needle in a haystack.

While I thought that the majority of aqueous veins were located near the nasal and temporal horizontal meridian, Goldmann found most of them in the temporal lower and nasal lower quadrants and De Vries counted, among 409 aqueous veins, 168 in the nasal lower quadrants.

Here, I should repeat some of the diagnostic characteristics described five years ago (American Journal of Ophthalmology, 25:1183, 1942): The origin is in or near the limbus, often with a U-like or figure-6-like arch, or from the limbal capillaries, or—these are the largest and deepest aqueous veins—from a scleral emissary. The color of the aqueous veins is paler than that of regular veins—sometimes it is as clear as water—and often strata of different shades are seen running parallel to each other along the vessel wall. The width of aqueous veins is approximately between 0.01 and 0.1 mm. and their length varies between fractions of millimeters and one centimeter or slightly more.

Having published numerous drawings of aqueous veins, I think I should add here two photographs showing one aqueous vein and its emptying into a stratified recipient vessel, taken from the same eye of the same patient at an interval of 35 months; both pictures are unretouched and prove the constancy of aqueous veins as anatomic structures.

Cincinnati, Ohio.

Inverse cyclodialysis

Editor,
American Journal of Ophthalmology:

In the July, 1947, issue of the Journal is an article by Dr. Robert N. Shaffer about inverse cyclodialysis. In the same issue Dr. H. Saul Sugar recommends the inverse method as preferable because it tends to reduce trauma.

Blaskovics gives a complete description of the inverse cyclodialysis in his book "Eingriffe am Auge" published in 1938. A horizontal incision, 10-mm. long, is made above the insertion of the superior rectus, 10 mm. from the limbus. For fixation, Blaskovics recommends a suture through the superior rectus or a strabismus hook. The capsule is

opened directly below the insertion of the muscle and the sclera is exposed.

A strictly radial scleral incision is made at the 12-o'clock position, starting below the insertion of the superior rectus extending 4 mm. toward the limbus. The dialysis is performed exactly as described by Shaffer. If one wishes another dialysis, it is performed in the opposite direction, but Blaskovics found keratic precipitates if the dialysis was too extensive. He does not mention any difficulties in reintroducing the spatula. Maybe he was such an excellent surgeon that there was no bevel with his incision.

Since reading Dr. Shaffer's paper, I have used the inverse cyclodialysis in several cases with equally good results. The main improvements in this operation since it was originated by Blaskovics seem to me to be the following:

1. Gonioscopy for the selection of the best operative site.
2. Fixation of the eyeball with a scleral suture if the incision is not done below the superior rectus muscle.
3. Air injection into the anterior chamber to prevent or stop bleeding.
4. Postoperative position of the patient's head.

Dr. Shaffer and Dr. Sugar deserve great credit for their papers which reintroduce and modify the inverse cyclodialysis for American ophthalmologists.

Oakland, California.

BOOK REVIEWS

GIFFORD'S TEXTBOOK OF OPHTHALMOLOGY. By Francis H. Adler, M.D., professor of ophthalmology, Universty of Pennsylvania Medical School. 4th edition. Philadelphia and London, W. B. Saunders Company, 1947. 512 pages. Price, $5.50.

This book, termed by the publisher the fourth edition of "Gifford's Textbook of Ophthalmology," has undergone such radical changes in appearance, arrangement, illustrations, and text that it might well have been offered as a completely new volume. The reputation of Dr. Adler is such that one would not have thought it necessary for the publisher to capitalize on the Gifford name while at the same time eliminating most of the personality of the original author. Carful comparison of the present edition with the third edition reveals occasional sentences and paragraphs retained in unchanged form but for the most part the text has been completely rewritten with some material omitted and a considerable amount added. Numerous new illustrations, many of them excellent, have been included.

Dr. Adler's interest in physiology has led to the inclusion of much subject matter not ordinarily found in a textbook of this scope. Considerable detail is presented on the visual pathways and 50 pages are devoted to disturbances in ocular motility. That these are accurate and well presented will be anticipated by any reader familiar with the author's (revisor's) teachings and writings but it may be wondered whether much of this material is not at the level of postgraduate teaching. On the other hand, methods of refraction and surgical procedures have been greatly minimized, as is proper in a textbook prepared ostensibly for undergraduate medical students and general practitioners. The chapters on "Ocular Manifestations of General Disease" and on "Ocular Disorders Due to Diseases of the Central Nervous System" are particularly valuable and appropriate.

Another innovation is the addition of bibliographic references at the end of each chapter. These have been somewhat arbitrarily selected and are far from complete but may suggest additional reading for the more advanced student.

Many of Dr. Gifford's special procedures in therapy, such as delimiting keratotomy and the use of trichloracetic acid in corneal ulcers, are briefly mentioned but not always as originally advocated. For example, in the use of trichloracetic acid the essential thing

is to have no excess of acid on the very fine-tipped applicator (Gifford always removed the excess by wiping on his thumb nail) and not the subsequent irrigation with normal saline as advocated in the present text. The metric system for recording visual acuity has been substituted for the "foot" system, although the latter continues to be the most widely used in this country in spite of all theoretical objections.

There is naturally a legitimate difference of opinion as to what a textbook on ophthalmology intended for use by medical students should contain. The author of any such text is obliged to reach a compromise between completeness and the brevity and concise presentation essential to his purpose. Unfortunately, the medical curriculum is so crowded that in most schools ophthalmology, the "queen of the specialties," is often relegated to an undeservedly inferior position on the part of the administrative authorities and students. The number of hours assigned for didactic and clinical work in this field are wholly inadequate for a highly comprehensive study. Students have neither the time nor the inclination, unless they possess a very unusual interest, to read voluminous treatises on the eye. The particular task of the teacher, then, is to emphasize the recognition of the more important eye diseases and particularly the relation of the eye to general disease. In correlation with this, reference books aimed at this particular educational level are essential.

As a *reference book* for undergraduate medical students and general practitioners this new edition of Gifford's well-known textbook, rewritten by Adler, is excellent and deserves wide use. The format and typography are pleasing and the material is well prepared and authentic. Its greatest value, however, lies for students at the postgraduate level who, beginning a real study of ophthalmology, seek a simplified dissertation on the eye before delving into the more complicated and extensive discussions found in the standard reference books and in the current literature. It would also not be surprising if practicing ophthalmologists found it extremely convenient and useful.

William A. Mann.

A HANDBOOK OF OCULAR THERAPEUTICS. By the late Sanford R. Gifford, M.D. Revised by Derrick Vail, M.D., D.O. (Oxon.). 4th edition. Philadelphia, Lea & Febiger, 1947. 336 pages. 66 illustrations. Price, $5.00.

In the revision of Gifford's masterpiece, Vail has blended with admirable skill the personal approach of the original author with the later advances in ocular therapeutics. Gifford's teaching has been most influential in determining modern therapeutic practice, especially among the younger ophthalmologists, and his handbook has become a recognized classic in its field. As administrator of this heritage, Vail was a natural choice both because of his long intimacy with Gifford and their common background of professional ideals and ophthalmic tradition.

Future editions, while preserving the best of Gifford's contribution, will undoubtedly reveal more of Vail's own personality. Revision involves the triple responsibility of creation, preservation, and destruction. In the present volume, Vail has been probably unduly conservative in adding new material or deleting old. Among the additions are recent studies in chemical burns of the cornea, the newer therapy of seborrheic blepharitis, a discussion of D.F.P. (diisopropyl fluorophosphate), typhoid vaccine for vasodilatation, and the differential treatment of thyrotoxic and thyrotropic exophthamos. Agents whose place in ocular therapeutics is not yet established, such as rutin, the antihistamin drugs, and the newer mydriatics have been judiciously omitted.

Some new ideas that might have been included are glycerine for clearing the cornea in acute glaucoma to permit ophthalmoscopy, the diagnostic patch test for tuberculosis,

BAL (2,3- dimercaptopropanol) for the elimination of arsenic in tryparsamide and other reactions, gelfoam and thrombin for hemostasis, and merthiolate and zephiran as alternative preservatives for ophthalmic solutions. In the discussion of sulfonamides, their mechanism of action is insufficiently detailed, sulfapyridine might well be omitted, and sulfadiazine given much more emphasis. Sulfacetimide is no more than listed. The text reflects the previous need for economy in the use of penicillin, but the present tendency is toward massive concentration in subconjunctival injections and in ophthalmic ointments. The deteriorating action of adrenalin on penicillin is more than counterbalanced by the prolonged localization that its proper use insures.

The book deals brilliantly with office surgery, but neglects attention to some aged but excellent procedures, such as cautery puncture for ectropion, entropion, and lymphangiectases, Agnew's incision for acute dacryocystitis through the cul-de-sac, and Crigler's compression maneuver for congenital impatency of the nasolacrimal duct.

Each edition of Gifford's *Therapeutics* has been a significant improvement over its predecessor, and the present edition meets the challenge worthily. This slim volume, though crammed with information, is written with an effortless style that makes cover to cover reading as enjoyable as the contents are profitable.

James E. Lebensohn.

FUNDAMENTALS OF CLINICAL NEUROLOGY. By H. Houston Merritt, Fred A. Mettler, and Tracy Jackson Putnam. Philadelphia, The Blakiston Company, 1947. 289 pages, 96 figures, index. Price, $6.00.

Ophthalmologists, as a general rule, confess to some weakness in neurology. Most of us are aware of the neurologic conditions that lie within our field, but not many are truly expert in this branch of medicine that is so important to ophthalmology. The authors have given us a much needed tool with which to work. The volume is beautifully illustrated and executed. It covers the entire field of clinical neurology in a most economical yet lucid fashion, and the reputations of the authors vouch for its accuracy. Ophthalmologists will find it most useful in refreshing their recollections of neurologic disorders, and valuable in the interpretation of problems met with in their daily practice.

Derrick Vail.

DISEASES OF CHILDREN'S EYES. By James Hamilton Doggart, M.D., St. Louis, C. V. Mosby Co., 1947. Clothbound, 288 pages, 210 illustrations, including 32 colored plates. Price, $10.00.

In his preface, the author disclaims any special knowledge about this particular phase of ophthalmic practice. He also states that he did not have a large clinic on which to draw for material, but because of his wartime assignment he had become interested in the subject and had thought that collecting in one book the material from previous publications that might be considered particularly applicable might serve a useful purpose. The reviewer thinks that he has done this satisfactorily but that all of the material is available in the best textbooks. It is hard to understand the need for a book devoted exclusively to the eyes of children. However, if one desires a book confined to the problems of this subject, he might add this volume to his library. It is well prepared, of an acceptable size, in good print with good illustrations and a substantial binding, characteristic of the products of this publisher.

Lawrence T. Post.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Haden, Henry C. **The development of the ectodermal framework of the optic nerve, with especial reference to the glial lamina cribrosa.** Am. J. Ophth. 30:1205-1214, Oct., 1947. (15 figures.)

Wilczek, Marian. **The lamina cribrosa and its nature.** Brit. J. Ophth. 30:551-565, Sept., 1947.

Since the work of Fuchs in 1916 there has been little research on the nature of the lamina cribrosa. Fuchs stated that some of the internal fibers of the sclera extend through the nerve fibers across the foramen sclerae and form the sieve that gives this membrane its name. Wilczek made detailed studies by means of serial sections and wax plate reconstructions of the area of the membrane in fetal, post-natal, and adult life. He found that the lamina is composed of neuroglia fibers from the dural and pial coverings of the optic nerve as well as from scleral fibers. It is not an independent structure but is simply the strongest part of the septal system of the nerve. The function of the lamina is essentially the fixation of the nerve in the scleral canal where it is subject to danger of traction. The serial sections proved, in addition, that at the level of the lamina the nerve bundles are subject to the most constriction and hence are most easily damaged by inflammatory processes, edema and intraocular pressure. (14 figures.) Morris Kaplan.

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Braley, A. E., and Alexander, R. C. **Virus studies in lymphomatoid diseases of the ocular adnexa.** Am. J. Ophth. 30: 1369-1380, Nov., 1947. (4 figures.)

Brown, A. L., and Nantz, F. A. **Corneal wound healing II: variations in adhesive power of fibrin. In vitro studies** Tr. Am. Ophth. Soc. 44:85-92, 1946.

The authors present experimental evidence of the adhesive power of fibrin in the cycle of corneal healing in the rabbit and dog. By an ingenious method employing standardized corneal strips and various concentrations of fibrin the ten-

sion of the adhesive power of fibrin in experimental wound healing was accurately measured under varying conditions. C. D. F. Jensen.

Carsten, M. E. **A rapid procedure for the embedding of eyes.** Arch. Path. 44: 96-100, July, 1947.

Preparing eyes for microscopic study is a very slow process. Rapid methods of dehydration and embedding cause shrinkage and consequent distortion. Where rapid diagnosis is called for and experimental work is being done a water soluble embedding medium which would not shrink or dehydrate tissues was being sought.

The author describes a method of embedding eyes by means of water-soluble "carbowax" (polyethylene glycol) and "carbowax" ester used in succession. There is no shrinkage, dehydration, or fungus growth associated with the technique. The tissue is well preserved.

By this method sections can be cut as thin as 7 microns, but for easy mounting 10 to 15 microns is preferable.

Francis M. Crage.

3

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Aldrige, W. H., Davson, H., Dunphy, E. B., and Uhde, G. I. **The effects of di-isopropyl fluorophosphate vapor on the eye.** Am. J. Ophth. 30:1405-1412, Nov., 1947. (1 figure.)

Ferraro, A., Roizin, L., and Givner, I. **Ocular changes in rats on diets deficient in amino acids. II. Corneal dystrophy due to valine deficiency.** Arch. Ophth. 38: 342-352, Sept., 1947.

In this preliminary communication, the authors report observations on rats reared on a valine-deficient diet. Changes develop in the cornea, in addition to general changes and structural alterations in other organs, that seem to be the result of edema and progressive degeneration, and gradually lead to keratinization and disorganization of the epithelium of the cornea. These changes in the eye appear to be reversible if treated in time. (6 figures, 11 references.)

R. W. Danielson.

Ferraro, A., and Roizin, L. **Ocular involvement in rats on diets deficient in amino acids. I. Tryptophan.** Arch. Ophth. 38:331-341, Sept., 1947.

During the past four years, the authors have been studying the effects of various diets deficient in amino acid on the growth, development and morphology of various tissues and organs, endocrine glands and nervous system in rats. Ocular involvement occurred with diets deficient in tryptophan and valine. Tryptophan is able to prevent, improve and cure the general clinical, as well as some of the ocular symptoms produced experimentally by tryptophan-deficient diets. These changes are of two types. The earlier changes characterized chiefly by water splitting of the lens fibers and vacuolation were found to be reversible under tryptophan treatment. The more advanced changes which lead to disorganization of the structure of the lens seem to be irreversible. (4 figures, 7 references.)

R. W. Danielson.

Gillette, D. F. **Visual disturbances due to digitalis.** Tr. Am. Ophth. Soc. 44: 156-165, 1946.

The author reviews the literature concerning the types of visual disturbance that can result from mild and more severe forms of digitalis intoxication. He presents three interesting cases of digitalis poisoning, two of which were characterized by central scotomata and diminished visual acuity. Withdrawal of the drug

permitted the relatively prompt return of normal vision. In each case several types and degrees of chromatopsia are described. C. D. F. Jensen.

Matteucci, P. **Sympathetic innervation and neuro-vegetative regulation of the uvea.** Rassegna ital. d'ottal. 16:283-292, July-Aug., 1947.

Animal experimentation leads the author to several conclusions regarding the nerve control of the uvea. Rapid degeneration of the vegetative fibers of the iris after resection of the ciliary nerves indicates that the iris contains no nerve ganglia. The caroted sinus, with its sympathetic, vagal and sensory innervation is an important regulatory center of uveal circulation. Uveal vasomotor fibers do not all stop in the superior cervical ganglion; some follow the pericaroted sympathetic. The influence of the cervical sympathetic upon ocular tension may be a result of its control of capillary tone.
Eugene M. Blake.

Robbie, W. A., Leinfelder, P. J., and Duane, T. D. **Cyanide inhibition of corneal respiration.** Am. J. Ophth. 30:1381-1386, Nov., 1947. (4 figures.)

von Sallmann, L., and Dillon, B. **The effect of di-isopropyl fluorophosphate on the capillaries of the anterior segment of the eye in rabbits.** Am. J. Ophth. 30: 1244-1262, Oct., 1947. (8 figures, 43 references.)

Scuderi, R., and Morone, G. **Action of vestibular stimulation on the pressure in the central retinal artery.** Riv. di oftal. 2:22-36, Jan.-Feb., 1947.

In 25 persons between 14 and 30 years of age, the retinal arterial diastolic pressure was measured before and 15, 30, 45, 50, 90 seconds, 2, 3, 4, 5, and 10 minutes after the caloric and rotary stimulation of the labyrinth. Both the caloric test of Veits and the rotatory test of Barany regularly produced a decrease of the intraärterial pressure, amounting to five grams (Baillart) after the rotatory tests and seven grams after the caloric test, and lasting for two to three minutes. The drop in arterial pressure always occurred in both eyes and was of the same duration as the nystagmus which accompanied the tests. The decrease in arterial pressure in the retinal arteries is not due to a drop in general blood pressure.
K. W. Ascher.

Sloan, L. L., and Gilger, A. P. **Visual effects of tridone.** Am. J. Ophth. 30:1387-1405, Nov., 1947. (25 figures.)

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Borsello, G., and Gomirato, G. The adaptation curve and the visual field behavior to normal and attenuated light in neurasthenic constitutional syndrome. Riv. Oto-neuro-oftal. 21:278-311, Sept.-Dec., 1946.

In 14 neurasthenic patients between 25 and 35 years of age dark adaptation was retarded and reached terminal values inferior to normal. The visual fields in normal light showed a slight concentric contraction for green. In dim light the chromatic field was very much more contracted than in normal subjects. The authors discuss the probable pathogenesis of these changes concluding that they are in part a local result of the general neuro-vegetative-endocrine changes and in part an expression of a miopragic constitution of the retina. (15 figures, bibliography.) Melchiore Lombardo.

Boström, C. G., and Kugelberg, I. **Official color sense control in Sweden.** Arch. Ophth. 38:378-380, Sept., 1947.

This paper describes the development and use of the authors' color sense tests in Sweden. R. W. Danielson.

Clark, W. E. Le Gros. **A possible central mechanism for color vision.** Nature 160:123-124, July 26, 1947.

The author suggests that the correlations in this article (together with those reported in a previous paper) offer further presumptive evidence that the six-layered pattern of the geniculate nucleus (that is, two sets of three layers for the two eyes) may be related to color vision. However, further and more detailed correlations need to be established, and much more experimental evidence is required in order to put this thesis to a crucial test.

Theodore M. Shapira.

Dubois-Poulsen, A., and Rozan, A. **Graphic study of accommodative fatigue.** Ann. D'Ocul. 180:206-237, April, 1947.

Made partly from a toy railroad and track, the apparatus used is a modification of that used by Howe and Berens-Stark. It consists essentially of a continuous cord tracking on several pulleys which is attached to a square vertical frame. To the cord a target and a recording stylus are attached. The examinee by pulling the posterior vertical part of the cord down simultaneously moves the target nearer his eye and the stylus proportionately up.

For 195 office patients records were made for three minute periods with oscillation periods of approximately 45 to 60 seconds, in an illumination of 8 to 14 lux. In 30 percent accommodative fatigue was observed during the test. In 40 to 50 percent the accommodation remained constant, and in 28 percent the accommodation increased during the test. In monocular fixation fairly marked variations were observed between the static and the dynamic near points. This difference was increased by fatigue and was roughly proportionate to the rapidity of contraction of the ciliary muscle. Relatively little variation occurred in the same subject on repeated tests. With binocular vision the curves were essentially similar except that the decrease of the dynamic near point was less accelerated. Accommodative fatigability changed little with age or sex or with quantitative and qualitative variations of illumination within reasonable limits. In hypermetropic and astigmatic subjects accommodative fatigue was greater than in the mypopic. General bodily exhaustion was observed to be a more important factor than muscular fatigue. The results obtained following the instillation of parasympatheticomimetic and sympatheticomimetic drugs, and in hyperemia and increased ocular tension were not conclusive although it is probable that increased accommodative fatigability is frequently an early sign of ocular hypertension. (13 figures, 13 references.)

Chas. A. Bahn.

Gernandt, B., and Granit, R. **Single fiber analysis of inhibition and the polarity of the retinal elements.** J. Neurophysiol. 10:295-302, July, 1947.

This article is not readily abstracted to a form shorter than its summary which appears below. A condensation of this article may be found in Nature 159:806, 1947.

"Single fiber responses have been isolated from the nasal region of the cat's retina with the micro-electrode technique and tested by illumination and polarisation of the retina between fixed electrodes.

The pure on-elements respond to threshold cathodal polarisation with an on-effect. An increase of current strength by some 30 percent elicits a threshold anodal off-effect.

The pure off-elements (inhibited by

light) have opposite polarity. They respond to cathodal polarisation at the threshold with an off-effect, to anodal stimulation of the same strength with an on-effect (not elicitable by light).

The on-off-elements are either "cathodal" or "anodal", depending upon their off/on-ratio determined by illumination at threshold strength. They are held to be combinations of on-paths and off-paths.

The results form the basis of a simple explanation of the nature of inhibition in the retina in terms of the horizontal and amacrine cells." Elek Ludvigh.

Gernandt, B. **Colour sensitivity, contrast and polarity of the retinal elements.** J. Neurophysiol. 10:303-308, July, 1947.

This article is not readily abstracted to a form shorter than its summary which appears below. A condensation of this article may be found in Nature 159:806, 1947.

"The micro-electrode technique and the cat's retina have been used for a first analysis of the spectral sensitivity of well-isolated retinal elements during anodal and cathodal polarisation. It was found that, depending upon the polarity, different spectral regions were enhanced or depressed so that polarisation proved a convenient and very direct method of color analysis.

The on-elements were sensitive to short wave-lengths only, the off-elements to both long and short wave-lengths; the on-off-elements had humps or depressions in various regions. The regions in which enhancements or depressions chiefly occurred were (in the order enumerated) 0.520, 0.600, 0.470, and 0.570μ, the humps in 0.600μ being particularly large.

The on- and off-components of the isolated spike of an on-off-element were often differentially sensitive to "contrasting" regions of the spectrum, suggesting that the two components are running in different but adjacent and well-synchronized fibers."

Elek Ludvigh.

Hartridge, H. **Recent advances in the physiology of vision.** Brit. M. J. pp. 913-916, June 28, 1947.

The author uses retinal micro-stimulation to form geometric images of a diameter equal to one-fifth of a cone unit. A green ray (5,200 A.U.) moved less than one-fourth of a cone unit on repeated tests. Different fixation points were found for the following colors: red, orange, yellow, green, blue green, greenish blue and blue. A white beam remained white wherever it was situated on the retina unless conditioning colored lights were present in the visual field. The white then took on all seven previously mentioned colors. Color mixture experiments showed that the seven colors could be produced when various proportions of the others were mixed. Young's theory of color vision is discussed in the light of the seven color receptors.

From the response curves and tests for hue discrimination, the author concludes there are at least five types of receptors for color in the retina. There is a loss of color vision normally when reducing the visual angle or the illumination is reduced in peripheral vision. Colored objects which subtend small angles often become altered and appear to be of another color. The author concludes that there are at least seven receptors for color in the human retina. (11 figures.)

Kinsey, V. E. **Transfer of ascorbic acid and related compounds across the blood-aqueous barrier.** Am. J. Ophth. 30:1262-1266, Oct., 1947. (5 figures, 4 references.)

Mann, Ida. **Contact lenses.** Brit. J. Ophth. 31:565-568, Sept., 1947.

To the newly formed Contact Lens Society, Mann delivered this presidential address as a plea for the accumulation of more data and the planning of further experiments. The problem of contact lenses is unusual in that animal experimentation is almost impossible because visual acuity and subjective tolerance are not measurable. The problems of prisms, of cylinders and of bifocals still demand much work.

The most pressing problem is that of tolerance. Mann sent a questionnaire to 100 patients for whom she had fitted lenses without subsequent control of data. Of 61 who had myopia 11 had an error of 5.00 diopters or less, and the others up to 22 diopters. Ten patients who were given one lens only for monocular aphakia did not wear it. Of 11 who had conical cornea 9 wore the lens all day, and none was a complete failure. The patients were all asked if, knowing what they know now, they would go in for contact lenses again. Sixty-four replied unhesitatingly yes and 19 gave an equally emphatic no. Seventeen said if they could be made more comfortable they would say yes. Must the lenses be worn every day for good tolerance? Fifty-five wore their lenses every day, 47 had enough tolerance for a full day's work and 31 wore them more than 12 hours every day. On the other hand 9 wore them only occasionally with excellent tolerance so that daily wear was not considered necessary. Tolerance could not be associated with any special condition of the eyes, except that in conical cornea contact glasses were almost always successful and in monocular aphakia always useless.

To the questions concerning solutions, 49 answered that they insert their lenses dry, 22 patients used normal saline and 9 used tap water. Obviously much has to be learned about solutions and much has to be done for the whole problem of contact lenses. Morris Kaplan.

Mann, I., and Sharpley, F. **The normal visual (rod) field of the dark-adapted eye.** J. Physiol. 106:301-304, July, 1947.

The rod visual field of the completely dark-adapted eye was mapped out within 90° limits from the fixation point for 33 normal individuals. The mean angular radius of the plotted fields for 80 subjects (including 47 previously tested) is given by age groups, and a tendency for the field to contract with advancing age is observed. The possible reasons for this contraction with age are discussed.

Theodore M. Shapira.

Matteucci, P., and Carucci, E. **Mydriasis and acute intraocular hypertension.** Ann. d'ocul. 180:360-365, June, 1947.

In rabbits, mydriasis is not primarily produced by acute ocular tension. Pupillary dilatation is basically caused by a reflex parasympathetic photomotor paresis or by hyperfunction of the sympathetic control. In a first group of rabbits, ligature of vorticose veins was performed at once; in a second group retrobulbar injection of nicotine preceded the ligation of the vorticose veins. In a third group the ciliary nerves were resected, then the vorticose veins were ligated. After the vorticose vein ligation the tension rose from 20 to 50 mm. Hg during the first day and by the fifth day decreased to approximately 15. The pupil size remained at 4 mm. practically constantly. There was also no parallelism between the ocular tension and the pupillary size in the other two groups. (4 figures, 15 references.) Chas. A. Bahn.

Pascal, J. I. **A radical innovation in contact lenses.** Arch. Ophth. 38:381-382, Sept., 1947.

After discussing the history of attempts to make contact lenses comfortable, Pascal says that an experimental study as to what kind of curve would best fit the great majority of eyes brought to light the almost unexpected emergence of the cone. It was found that if the scleral section was made conical, and the angle of the cone was so chosen that it rested tangentially against the eyeball a minimum of pressure was exerted. Instead of a large bearing surface between lens and sclera, it was found that sometimes a narrow tangential band one to three mm. wide set inside the edge of the lens gave more comfort than any other surface.

R. W. Danielson.

Pascal, J. I. **The power or powers of a lens.** Brit. J. Ophth. 31:570-572, Sept., 1947.

The method of calculating reduced surface power of the crystalline lens is simplified by what is called the "dam" formula: $D = aM$. In this formula a is the difference between the two indices and M is the curvature in metrecs which is obtained by dividing the radius in mm. into 1000. Morris Kaplan.

Rezende, Cyro de. **Mirror writing.** Arq. brasil. de oftal. 10:20-31, 1947.

The author quotes a number of previous writers on the subject, and then records and illustrates a personal case, in a boy of eight years. Other conditions were normal. The vision of the right eye was 0.2 that of the left eye 1.0, and the refraction was apparently normal. The mirror writing involved words and drawings, but not numbers. (References; an excellent full-page illustration of the peculiarity discussed.) W. H. Crisp.

Rose, H. W., and Schmidt, I. **Factors affecting dark adaptation.** J. Aviation Med. 18:218-230, June, 1947.

A survey of the literature on factors affecting dark adaptation is reported. Experimental data are presented that show that caffeine-metrazol (caffeine .05 gm., metrazol .1 gm.), mild muscular exercise, strychnine nitrate .005 gm., ultrasonic vibrations of 24,000 c.p.s., .003 gm. fervitin, .05 gm. ephedrine hydrochloride, .05 gm. octin D, stimulation of taste with saccharin, or the administration of 266,000 I. U. of vitamin A in emulsion or oil daily for sixteen days, do not significantly affect the dark adaptation of normal subjects. Elek Ludvigh.

Sebas, S. R. **Optical correction of astigmatism.** Rev. brasil de oftal. 6:17-24, Sept., 1947.

The author's routine method includes the clock dial, the ophthalmometer, skiascopy, and the use of test lenses as described by Donders ninety years ago. Cases of "spasm of accommodation," he would refer to the neurologist before undertaking the measurement of refraction. He has apparently little respect for the use of cyclopegics in the measurement of astigmatism. W. H. Crisp.

Temple Smith, E. **Thoughts on refraction.** M. J. Australia 2:69-71, July 19, 1947.

Cycloplegics should never be used as a routine measure, but only when indicated. In children atropine is indicated because of the amazing faculty the child has for suppressing hypermetropia and in young adults cycloplegics should be used when ciliary spasm is suspected. A subjective examination is necessary in presbyopic adults to check the retinoscopy. An examination in cycloplegia necessitates two or three visits with loss of time, and causes annoyance to the business man. Mydriasis is obtained by using a mixture of cocaine, adrenalin, and neo-synephrine.

Complete dilatation of the pupil, in the presence of small errors, causes confusion by giving conflicting retinoscopic reflexes, but should be used to examine the extreme periphery of the retina.

DIAGNOSIS AND THERAPY

Adrogué, E., and Wolf, J. A. **Gonioscopic examination; its technique with Goldman's contact glass.** Arch. chilenos de oftal. 3:305-312, Nov.-Dec., 1946.

The authors remark that so recent a work as that of Berens and Zuckermann on diagnostic examination of the eye does not mention Goldman's procedure. The various details of the technique for examination according to Goldman are carefully explained, under the headings of previous adjustment of the lamp, placing of the contact glass, and the actual examination, as well as interpretation of the image in optical sections. In conclusion the authors discuss the principal difficulties which may occur during the gonioscopic examination; including irritability of the eye calling for repeated anesthetization, occasional inversion of the eyelids causing appearance of the lashes in the gonioscopic image, absence of the necessary layer of liquid between cornea and the gonioscopic lens, excessive obliquity of the source of illumination, and the development of corneal edema. (2 figures, references.) W. H. Crisp.

Bellows, J. G., and Farmer, C. J. **Streptomycin in ophthalmology.** Am. J. Ophth. 30:1215-1220, Oct., 1947. (3 figures, 9 references.)

Calogero, V. N. **Rubrophen treatment of ocular tuberculosis.** Riv. di oftal. 2:58-69, Jan.-Feb., 1947.

Rubrophen, a triphenylmethane derivative, was introduced into therapy by Sailer, in 1937. For extrapulmonary tuberculosis, it is used either in comprettes containing 0.15 gram, or intravenously in doses of 0.30 gram with the addition of 0.08 gram of sodium bisulfite. Five percent ointment can be administered in a lanolin base. The therapetutic dose of 0.30 is 1/150 of the fatal dose of 50 grams for a patient who weighs 70 kilograms. In five patients suffering from anterior segment tuberculosis and observed for many years the application of the rubrophen, oral and parenteral, proved beneficial. (Bibliography.) K. W. Ascher.

ten Doesschate, J. **Perimetric charts in equivalent projection allowing a planimetric determination of the extension of the visual field.** Ophthalmologica 113:257-270, May, 1947.

As stated in the title, the purpose of this study was to design perimetric charts that would lend themselves to planimetric measurement. To meet this requirement the perimetric findings which are spatial values obtained on the inside of a sphere have to be transferred to or projected onto a plane surface in such a way that all areas enclosed by a closed line on the sphere are directly proportional to the corresponding areas on the surface of projection (the principle of equivalent projection). Since none of the existing perimetric charts meets this requirement, the author by applying spherical trigonometry, devised one in which the relationship between perimetric angle (or

angle of eccentricity) and radial distance on the chart is as follows:

perimetric angle in degrees	linear (radial) distance in units of lengths
10	4.9
20	9.8
30	14.6
40	19.4
50	23.9
60	28.3
70	32.4
80	36.4
90	40.0
100	43.3
110	46.3

Such a chart is suitable for planimetry but not free of distortion. The result of the planimetric measurement, that is a figure expressing area, is useful for statistical purposes, but does not express the practical usefulness of the visual field. A round concentric field of a certain area is doubtlessly more useful than a hemianopic field of the same area.

The author has also designed a chart in which the area of the field is a measure of the number of functioning receptor units. Such a chart, however, is clinically impractical. Peter C. Kronfeld.

Guy, L. **Dangerous explosion of transilluminator.** Arch. Ophth. 38:382-383, Sept., 1947.

The author reports that his Lancaster transilluminator exploded when turned on. The tip hit the wall with sufficient force to break the plaster. Fortunately, the instrument had not yet been inserted behind the eyeball. R. W. Danielson.

Halbron, P., and Aitoff, H. **Local use of penicillin in external gonococcic affections of the eye.** Rev. brasil de oftal. 6:25-29, Sept., 1947.

The authors describe seven cases in which penicillin was used locally, either in collyrium or in ointment. The collyrium contains a concentration of 5,000 Oxford units per cubic centimeter. The ointment contains 1,000 Oxford units per gram. Both preparations, kept in the refrigerator, remained effective for a week. Local treatment with penicillin of gonococcic ophthalmia represents a real advance over previous forms of therapy.
W. H. Crisp.

Ingalls, R. G. **Current status of penicillin in ocular infections.** Am. Practitioner 1:680-683, Aug., 1947.

Only those diseases caused by bacteria sensitive to penicillin are cured by the drug. As larger doses are being used, more bacteria that are sensitive are being found. Failure with bacteria usually sensitive may be due to resistance built up from inadequate doses, or to the need for high initial dosage. In the treatment of intraocular infections one should not await the laboratory findings, but should begin immediately with penicillin and sulfonamide therapy. Infected traumatic wounds of the anterior segment may be treated with penicillin solution. In vitreous infection, intravitreal injections of purified penicillin should be used. (References.) Bennett W. Muir.

Johnson, M. H. **Method for restoration of human orbits following necroscopy enucleation.** Am. J. Ophth. 30:1298, Oct., 1947.

Magitot, A. **Tissue therapy.** Ann. d'ocul. 180:376-378, June, 1947.

Is tissue therapy worthwhile? Based upon a résumé of the literature, the pros and cons are summarized as described by Filatov and Verbitska. The treatment consists essentially of intramuscular in-

jections of cod liver oil prepared in a specific manner and of subconjunctival and subcutaneous tissue implantations. For the subconjunctival implantations placenta is used but the subcutaneous injections consist of a varied assortment of biologic entities ranging from aloes to ovaries. In the treatment of pigmentary retinal degeneration and many other ocular affections ranging from trachmatous pannus to sclero-choroidal myopia, its usefulness is somewhat problematic. The essential factor in the treatment is apparently a new type of "Biologic Activator" which seems to be a sonorous but somewhat meaningless term. Improvements are recorded in such small units that only God and the authors can measure the progress. Chas. A. Bahn.

Sorsby, Arnold. **Penicillin in ophthalmia neonatorum.** Brit. M. J. pp. 913-916, June 28, 1947.

Penicillin was used in the treatment of ophthalmia neonatorum by a variety of methods. In thirty cases local instillation of drops containing 2500 units per ml. at five-minute intervals gave good results. In fifty-two cases these drops were given at one-minute intervals and the eyes became clear within an average time of 33 hours. Twenty-seven patients recovered within 48 hours when drops containing 10,000 units per ml. were used. In fifty-one cases the use of penicillin in an oily or solid vehicle at less frequent intervals was unsatisfactory.

Four systemic injections of 200,000 units at intervals of three hours combined with local medication was followed by recovery within 46 hours in 84 percent of patients. In infection with diphtheroid organisms or inclusion bodies treatment was not limited to penicillin. In no case has penicillin treatment failed to remove all anxiety within a few hours. (11 tables.)

H. C. Weinberg.

Sorsby, A., and Ungar, J. **Distribution of penicillin in the eye after subconjunctival injection.** Brit. J. Ophth. 31:517-528, Sept., 1947.

Comparisons of intraocular concentrations of penicillin after various routes of application were made. Subconjunctival injections with and without adrenalin were compared with instillations of highly concentrated ointment and with intravenous injections. By far the most satisfactory therapeutic concentration was obtained by the injection of the drug in 50,000 unit doses dissolved in 0.5 cc. of 1 to 1,000 adrenalin solution beneath the conjunctiva in cocaine anesthesia every six hours. The concentration reached in all the eye tissues was several times greater in the 50,000-unit dose than with a 20,000-unit dose and was maintained considerably longer. When injections are made with adrenalin fairly substantial levels of penicillin are still present in the fellow eye at the end of 4 to 6 hours. The ointment used contained 50,000 units per gram and the intravenous injections were of 25,000 units. In both these routes, the concentrations were considerably less in all tissues than with the subconjunctival injection with adrenalin. (14 tables.)

6

OCULAR MOTILITY

Adler, F. H., and Jackson, F. E. **Correlations between sensory and motor disturbances in convergent squint.** Arch. Ophth. 38:289-300, Sept., 1947.

The important factor in the production of convergent comitant squint is the primary force which turns the eyes in, i.e. the excessive convergence innervation. In only one group is one thoroughly cognizant of the manner in which an abnormal convergence stimulus is produced and how it causes squint. This is the group in

which the convergence is due to excessive hypermetropia. It is the purpose of this paper to consider the senory relationships found in all types of convergent squint and to determine the correlations between the sensory abnormalities and the motor disabilities in the hope that some light may be thrown on the source of this excessive convergence. One hundred and seventy-five private patients form the basis of this study. In this statistical analysis, the most striking feature is the relationship between the type of correspondence and the angle of squint. Persons with squints of low angle have predominantly normal correspondence, whereas persons with squints of 15 to 20 degrees and over usually have anomalous correspondence. The squints of low angle fall largely into the accommodative group; the squints of large angle belong predominantly in the class for which no causal factor is known. Age of incidence, duration of squint and presence or absence of amblyopia have little to do with determining the type of correspondence. It is possible that the cause of the squint of undetermined origin is anomalous correspondence itself. (4 references.)

Azzolini, U. **Two cases of Tuerk-Stillings' syndrome, one of them of the inverted type with preserved abduction and missing adduction.** Riv. di oftal. 2:12-21, Jan.-Feb., 1947.

The syndrome of Tuerk, called syndrome of Stilling by French authors, consists of unilateral absence of abduction, while adduction of the same eye is restricted and accompanied by enophthalmos and narrowing of the lid fissure. Discussing the numerous explanations proposed in the literature, Azzolini prefers the assumption of multiple anomalous muscle insertions for his cases. (12 photographs, bibliography.) K. W. Ascher.

Burian, H. M. **Sensorial retinal relationship in concomitant strabismus.** Arch. Ophth. 37:504-533, April, 1947.

This is a continuation of a paper on the same subject. The clinical picture of anomalous retinal correspondence and its interpretation is discussed with the presentation of illustrative case reports. Not all patients with concomitant strabismus develop anomalous correspondence. The first prerequisite is a certain amount of binocular cooperation.

The principles of treatment of anomalous correspondence are outlined. Under this heading are discussed occlusion, surgery to restore normal position, prisms, and orthoptics. In discussing surgery, the author states that every child with strabismus should have his eyes straightened before entering school or shortly thereafter. (To be concluded.)

John C. Long.

Coachman, E. H. **A new syndrome, the association of latent vertical phoria with endocrine dysfunction.** South. M. J. 40: 656-665, Aug., 1947.

A series of cases is presented in which the patients were made more comfortable after refraction when special stress was put upon vertical imbalances. These defects are brought out or made more evident by total occlusion of one or the other eye for 48 hours and measured with the usual Maddox rod.

The author has noted an association of symptoms, namely scanty eyebrows in the outer third, subnormal temperature, low blood pressure and slow pulse, such as are commonly found in decreased activity of the thyroid. There is a generalized edema especially of the lids and face, and along the medial aspect of the lower part of the tibia.

The patients commonly complain of periodic headaches which are usually unilateral and occur around or between the

eyes and radiate to the occiput, down the neck and into the scapular areas. The headaches are apt to follow movies, sewing, reading, card playing or driving, and may even be present upon awakening. Sensitivity to changes in position or motion is prominent. Children are poor readers, or skip lines entirely. Wearers of dark glasses are apt to have vertical imbalances, and when corrected by proper prisms are made comfortable with clear glasses. A. G. Wilde.

Neely, J. C. **The Treatment of traumatic diplopia.** Brit. J. Ophth. 31:581-642, Oct., 1947.

This dissertation is in its essentials an apologia for active and more radical treatment of the diplopia which has been shown to be a not infrequent result of an injury to the head or face. The author discusses diagnosis and treatment and documents his opinion by liberal quotations from the records of 55 patients, members of the Royal Air Force personnel. The illustrations include reproductions of photographs, X-ray films and Hess charts. Diplopia is usually caused by a paresis and not a paralysis of an extraocular muscle and the vertically acting muscles are most often involved. In the majority of cases the "closed" head injury and not the penetrating wound is the cause of diplopia. Injuries to the orbit tend to be overlooked owing to the severity of other injuries, yet the restoration of the normal anatomy of the parts is of immediate importance. Well planned eye muscle surgery aided by orthoptic exercises is the best means of restoring binocular single vision. Once the vertical deviation has been reduced by operation to manageable proportions, the binocular reflexes strengthened by orthoptic training will enable the patient to maintain fusion within the range of normal ocular movement. If the deviation is considerable it is best to carry out the correction in stages rather than risk overcorrection and another relative paresis which may prove more troublesome to patient and surgeon than the first. O. H. Ellis.

CONJUNCTIVA, CORNEA, SCLERA

Attanasio, V. **Epidemic keratoconjunctivitis.** Boll. d'ocul. 25:481-500, Oct.-Dec., 1946.

Five cases of keratoconjunctivitis that occurred in patients whose ages ranged between 16 and 34 years are reported in detail. The disease was monocular and characterized by initial swelling and redness of the caruncle and the plica which was followed by the appearance of follicles on the fornix and palpebral conjunctiva. The pre-auricular glands were swollen. Photophobia and profuse tearing were among the common symptoms. Corneal lesions lasted a few months and left more or less defective vision. The usual course of the disease ranged from two to four weeks. The etiology and the treatment are discussed. The instillation of lemon juice combined with sulfamide therapy shortened the course. (4 figures, bibliography.) Melchiore Lombardo.

Bartolozzi, R., and Leoz de la Fuente, G. **Fatty degeneration of the cornea.** Arch. Soc. oft. hisp.-amer. 7:558-564, June, 1947.

The authors describe three cases of this rare affection, of which only 15 cases have been reported. A woman 40 years old, had a primary corneal peripheral lipodystrophy. A man, 24 years of age, sustained a burn of the right cornea in infancy, and

this eye was much more extensively involved than the left. The third patient had congenital aniridia, coronary cataracts and a peripheral bilateral lipodystrophy. Visual acuity was severely impaired in all three patients. None of them had a demonstrable disturbance of the cholesterol metabolism. Their ingestion of fat was limited by economic conditions. The lipodystrophy was therefore attributed to a disturbance in the local oxidation which transformed invisible cholesterol into a visible form. The literature is reviewed, and it is noted that therapy is ineffective. (7 illustrations.) Ray K. Daily.

Castelli, A. **Keratoplastic surgery.** Rassegna ital. d'ottal. 16:253-269, July-Aug., 1947.

The author performed 12 transplantations of corneal grafts, of which 11 healed with clear transplant Six of the patients had keratoconus, 2 congenital familial degeneration of the cornea, and 4 had corneal complications of trachoma.

The technic was essentially that used in the United States. The author uses a 5-mm. trephine and advises the operation particularly for keratoconus and for corneal scars that are not total or vascularized. Eugene M. Blake.

Chace, R. R., and Locatacher-Kohorazo, D. **Keratoconjunctivitis due to a diphtheria-like organism.** Arch. Ophth. 37: 497-503, April, 1947.

A woman, 26 years of age, had a bilateral keratoconjunctivitis for approximately seven years. The tissue of the mucocutaneous juncture of the lids was replaced by a scar and trichiasis was severe. There was roughening and redness of the conjunctiva of the fornices with papillary hypertrophy. The corneas showed a thin vascularized membrane with some staining with fluorescein. The patient was somewhat undernourished. Very detailed studies by culture and animal inoculation identified the causative organism as one of the Corynebacterium xerose group. Treatment has consisted in the removal of the cilia, sulfathiazole ointment and penicillin ointment. In spite of clinical improvement, the organism still appears in heavy growths in culture.

John C. Long.

Chavarria Iriarte, F. A. **Progressive, circular, bilateral fibro-vascular degeneration of the cornea.** Arch. Soc. oft. hisp.-amer. 7:565-571, June, 1947.

The patient, a woman 61 years old, suffered from recurrent corneal marginal ulcers for a number of years. During this period of observation she developed a progressive bilateral circular pannus, which in some areas assumed the aspect of degenerative keratitis, with a slight corneal depression. A small zone of deep grayish infiltration in the cornea, without blood vessels, which extended beyond the vascularized area was biomicroscopically demonstrable. The differential diagnosis of corneal pannus is discussed. The etiology of the degenerative lesion in this case remains unknown. (3 illustrations.)

Ray K. Daily.

Chuliá, Vicente. **Five cases of Groenouw's corneal dystrophy in one family.** Arch. Soc. oft. hisp.-amer. 7:572-577, June, 1947.

Groenouw's nodular corneal dystrophy occurred in the eyes of a man, 60 years old, and in the eyes of his mother, of her brother and of this brother's two sons. A slight increase in the blood calcium was found. No new data are presented. (3 illustrations.) Ray K. Daily.

Colombo, Giuseppe. **Four cases of keratitis superficialis vesiculosa disseminata, three of them associated with formation of corneal filaments.** Riv. di oftal. 2:1-11, Jan.-Feb., 1947.

Keratitis filamentosa is not a disease entity; filaments may appear on the corneal surface whenever vesicles of the epithelium are formed as a result of trauma, inflammation or, degeneration. Vesicles of the corneal epithelium are broken and rolled by the lid movements to form the characteristic threads. Neurotrophic factors may be involved. (1 drawing.) K. W. Ascher.

Franklin, H. C. **Prophylaxis against ophthalmia neonatorum.** J.A.M.A. 134: 1230-1235, Aug. 9, 1947.

Since Credé of Leipzig instituted the 2-percent silver nitrate prophylaxis of ophthalmia of the new born, that method has become mandatory in most countries although the concentration was reduced to one half because the original is uniformly irritating. Even this can cause a chemical conjunctivitis when undissolved crystals get into the eyes, or when the solution has become concentrated by evaporation.

Solutions of silver nitrate decompose slowly and the liberation of a small amount of nitric acid augments the irritating effect.

Ophthalmia neonatorum was once regarded as uniformly gonorrheal in origin but the term is now applied to any inflammatory process that appears within two weeks after birth. The staphylococcus, a diphtheroid bacillus, and pneumococcus may be the etiologic agent and the latter can be as destructive of the cornea as the gonococcus.

Believing that penicillin possesses the virtues but not the vices of the older agent, the author used it for a four month period. The crystalline sodium salt was employed in a concentration of 2,500 units per cc. in isotonic sodium chloride. The solution was not kept longer than one week, and when not in use was refrigerated below 59°F. Within one hour after delivery, secretions were removed from the lids, the conjunctival sac was washed with 2 to 3 cc. of isotonic sodium chloride, and one drop of the penicillin solution was instilled. This procedure was carried out in the nursery for three days.

It was found that the irritation of the eyes was much less after penicillin than after silver, and the prophylactic action of the former is just as effective.

A. G. Wilde.

Gallego Asorey. **Keratomalacia.** Arch. Soc. oft. hisp.-amer. 7:469-476, May, 1947.

A typical case of keratomalacia is reported in a child two years old in whom nutritional deficiencies were found to be the cause. Twenty days after he was first seen the child died of a pulmonary disease. J. Wesley McKinney.

Gonçalves, Danilo. **Corneal ulcer in chickenpox.** Rev. brasil. de oftal. 6:31-36, Sept., 1947.

The condition was seen 21 times in ten months. Such ulcers may have serious consequences as to vision. Prophylaxis by disinfection of the eyes and the nasopharynx is recommended. No case of associated depigmentation of the iris (false vitiligo) was seen. W. H. Crisp.

Kilgore, G. L. **The value of corneal peeling or corneal resection in ophthalmology.** Tr. Am. Ophth. Soc. 44:100-112, 1946.

The author presents his method of corneal peeling or corneal resection. He first injects physiological solution along the line of initial incision to avoid danger of damage to the posterior corneal lamellae. Resection is of particular value where the scar is limited to the anterior half of the cornea. Visual results then compare favorably with those of keratoplasty. Aphakia is not a contraindication. Indica-

tions and contraindications are systematically listed. Keratoplasty can be performed if corneal resection fails. Several cases of successful corneal resection are described in detail. C. D. F. Jensen.

Laval, J., and Schneider, J. **Modified Snellen suture for prolapsed chemosed conjunctiva.** Arch. Ophth. 38: 375-377, Sept., 1947.

The authors describe a case in which a new operative procedure, a modification of the Snellen suture for ectropion was used successfully in the treatmentof prolapsed chemosed conjunctiva of the lower eyelids. This procedure has the twofold purpose of restoring the prolapsed conjunctiva and of reforming the inferior fornix. (2 references.)

R. W. Danielson.

Leoz de la Fuente, G. **Superficial filamentous keratitis and lattice-shaped keratitis profunda.** Arch. Soc. oft. hisp-amer. 7:553-557, June, 1947.

Leoz de la Fuente reports an unusual combination of an acute filamentous keratitis with a keratitis profunda in interlacing straiae as described by Haab and Dimmer, in an obese woman, 59 years old, with hypertension. That the cause was an infection is concluded from the prompt recovery in eleven days when 20-percent sulfathiazole solution was instilled after failure to improve with heat, dionin, and yellow oxide of mercury. The literature is reviewed. No new viewpoints are presented. (2 illustrations.)

McKinney, J. W. **Indication for corneal transplantation.** South. Surg. 13:622-625, Sept., 1947.

Corneal transplantation is indicated where the superficial ulcers or burns have not affected the deep corneal stroma, deep ulcers or opacities involving the central portion of the cornea only, mild interstitial keratitis and keratoconus. It is not indicated in extensive ulcers, burns and deep infiltrating diseases, severe interstitial keratitis, trachoma with pannus, adherent leucoma, glaucoma, aphakia and the dystrophies. Irwin E. Gaynon.

McLaughlin, R. S. **Chemical burns of the human cornea.** Am. J. Surg. 74:373-377, Sept., 1947.

The urgent immediate treatment of a chemical burn of the eye consists of immediate and copious irrigation of the eye with tap water. This should be done at the site of the accident. No neutralizing substances are used. The patient is then brought to the dispensary where the eye is anesthetized with 0.5-percent pontocaine solution, stained, particles removed, and the eye irrigated for fifteen minutes with normal saline. The eye is stained again with fluorescein. If it stains, the eye is again irrigated for 15 minutes. If the cornea still stains, the involved epithelium is removed by denudation using a round tooth pick swab, moistened with 4-percent cocaine hydrochloride.

Petragnani, P. V. **Reiter's disease.** Riv. di Oftal. 2:51-57. Jan.-Feb., 1947.

Petragnani describes the case of a man, 30 years of age, who had Reiter's disease twice in two years. Cultures taken from urethra, blood and conjunctiva did not reveal any causative organism. Recovery occurred in eight days after local antiseptic and stringent treatment supported by three intramuscular injections of sulfoidol. In another case, local treatment and sulfonamids and salycilates were of

no avail. Finally after three weeks recovery occurred after intramuscular administration of sulfoidol.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Bitran, David. **Recovery from sympathetic ophthalmia.** Arch. chilenos de oftal. 3:318-322, Nov.-Dec., 1946.

A healthy man of 32 years sustained a penetrating corneoscleral injury, with hernia of the iris and ciliary body. Prophylactic injection of 80,000 units of penicillin did not prevent the development of sympathetic ophthalmia in the second eye, which continued to get worse even after enucleation of the injured eye. In the course of 48 days, however, the sympathetic involvement completely recovered under further use of penicillin and intensive use of sulfadiazine. The sympathetic nature of the inflammation was confirmed by a histologic study of the enucleated eye. (3 figures.)

W. H. Crisp.

Esterman, Benjamin. **Choroideremia.** Arch. Ophth. 37:716-721, June, 1947.

Choroideremia is always bilateral, occurs almost invariably in males, is usually associated with night blindness and sharply contracted visual fields, but often with relatively unimpaired central vision, and in the majority of instances occurs in persons with myopia of moderate degree. The lesion has often remained stationary.

A case of choroideremia was observed in a white man aged 29 years whose chief complaint was night blindness. Corrected visual acuity of the right eye was 20/200 and the left 20/30. Fields were reduced to a radius of five degrees in each eye. There was only a small island of choroid in each eye. The differential diagnosis between this condition and retinitis pigmentosa, gyrate atrophy, choroidal sclerosis and massive retinal gliosis is discussed. (1 colored plate.)

Poniedel, C. **Calcium deposits in the iris.** Brit. M. J. 2:691-692, Nov. 1, 1947.

Calcium deposits in the iris were an interesting and perhaps important finding in a patient who became severely ill in October, 1944. Soon afterward his vision became blurred and examination revealed a chalky deposit in the anterior chamber and retina of the right eye. More than one year later fine deposits of calcium were found in the iris. The clinical studies, which included chemical examination of the patient's blood, made it seem probable that the primary disturbance was a chronic renal disease with secondary increase of calcium in the blood and not a primary hyperparathyroidism. It was interesting to note deposits in the iris and the observance of renal calculi.

Sorsby, A., and Reed, H. **Local penicillin therapy of hypopyon formation with special reference to the use of subconjunctival injection.** Brit. J. Ophth. 31:528-551, Sept., 1947.

The treatment of 66 cases of hypopyon associated with infected corneal ulcer, iritis, glaucoma and with herpetic or neuropathic corneal lesions is presented in detail. It consisted of repeated subconjunctival injections of 50,000 units of

penicillin usually dissolved in adrenalin and novocaine solution combined with instillations of penicillin ointments and drops and with general sulphonamide therapy. The use of subconjunctival penicillin was superior to all other treatment in eyes with bacterial infection. It had little effect on the herpetic or neuropathic lesions and in the hypopyon associated with simple iritis atropine instillation alone was sufficient.

The penicillin was injected every 6 hours for 12 injections. After that an ointment of penicillin, 100,000 units to the gram, was instilled every four hours day and night until recovery.

GLAUCOMA AND OCULAR TENSION

Barkan, Otto. **Cyclodialysis, multiple or single, with air injection—an operative technique for chronic glaucoma.** California Med. 67:78-83, Aug., 1947.

The author's operation is designed to create a larger dialysis with less trauma than is possible with the ordinary technique, and, secondly, to control hemorrhage. The resulting cleft is larger and permanent. The technique is described in detail. His injection of air into the chamber has been seen to stop an iris hemorrhage. An injection, if too great, can cause a rise of intraocular tension by blocking the outflow in the angle and by producing a seclusion of the pupil. Saline solution is made to replace some of the air. Extreme miosis is a preoperative essential. Maximal miosis should be maintained postoperatively to prevent closure of the cleft and the channel outlet. He further advises permanent daily use of a miotic to assure maintenance of the opening and channel.

Francis M. Crage.

Bloomfield, S. **Lability test for chronic simple glaucoma.** Arch. Ophth. 38:368-374, Sept., 1947.

The need for a more reliable provocative test for simple glaucoma led the author to design his lability test which is based on the fact that the induction of a transient vascular congestion in the eye would tend to produce a significant elevation in tension that would be most pronounced if the normal controlling mechanisms were pathologically defective.

Basically, the lability test consists in the simultaneous application of the cold pressor test of Hines and Brown and the jugular compression test described by Schoenberg. First the tension of each eye is measured. The patient then places one open hand up to the wrist in ice water. Simultaneously, a blood pressure cuff previously placed loosely about the neck is inflated to a pressure of 50 to 60 mm. Hg. At the end of exactly one minute, the ocular tension is again recorded, with the hand still in ice water and the cervical pressure undiminished. Then the hand is withdrawn, the pressure cuff is removed, and the test is over unless a repetition is desired for purposes of accuracy. A study of its results when applied to a series of eyes with chronic simple glaucoma and to another group without that condition indicates that it is a highly reliable test. (3 figures, 3 references.)

R. W. Danielson.

Díaz Dominguez, Diego. **The etiopathogenesis of glaucoma,** Arch. Soc. oft. hisp.-amer. 7:477-507, May, 1947.

This article deals exclusively with primary chronic glaucoma. There is no experimental work which can elucidate its pathogenesis because glaucoma is fundamentally a human disease. The author identifies glaucoma with ocular hypertension and does not believe in the existence of glaucoma without hypertension. Cases of glaucoma without hypertension have been reported but in his opinion the

hypertension was not discovered because the patient's tension was not taken often enough to get a true measurement. He believes that glaucoma develops because an initial neurovegetative dystonia causes a circulatory disturbance. The result of the persistent circulatory disturbance is a venous stasis that leads to increased capillary permeability and production of exudates which block the drainage outlets. The author presents an extensive review of theories of the development of hypertension in glaucoma and especially the role played by the aqueous humor. (Bibliography.) J. Wesley McKinney.

Gát, L. **The effectiveness of a modified cyclodialysis.** Ophthalmologica 114:106-118, Aug., 1947.

This is a report from the University Eye Clinic of Debrecen (Hungary) where, during the last 25 years, glaucoma surgery has consisted chiefly of iridectomies and cyclodialyses. Blaskovics' "inverted" technique has been modified as follows. The scleral incision is made anterior to the lateral instead of the superior rectus muscle. Most of the upper-temporal quadrant of the ciliary body is dialysed. During the dialysis the globe is fixated and the bleeding tendency reduced by placing a muscle clamp tightly on the tendon of the lateral rectus. The statistically presented results are difficult to evaluate because the absolute number of operations is small, the period of postoperative observation is short, and the criteria of failure or success are not clearly stated.

The author believes that the cyclodialysis is the most promising operation for glaucoma. Its advantages are the ease of performance, the applicability to all forms of glaucoma, the feasibility of repeated cyclodialyses on the same eye, the inherent freedom from serious operative complications.

Cyclodialysis also has disadvantages. The intraocular pressure remains high during the first two or three days after the operation. The acute and some of the chronic glaucomas, therefore, require a posterior sclerotomy combined with the cyclodialysis. Severe hemorrhages may occur (incidence not given). If the absorption is slow, the essayist aspirates the chamber contents on the fourth or fifth day. The central visual acuity may be temporarily impaired by the residues of the hemorrhage or by a refractive change in the direction of greater myopia. Retinal detachment has been reported but has not occurred in the author's series.

The author believes to have shown that cyclodialysis has lived up to the prediction of its originator Heine: "Optimal effects are achieved with the smallest and least dangerous operation."

Since completing this report the author has moved the site of the operation again. The scleral incision is now made in front of the inferior rectus and the inferotemporal quadrant is dialyzed. "The results have been encouraging."

Peter C. Kronfeld.

Grant, H. W. **The diagnosis of early glaucoma.** Am. J. Ophth. 30:1276-1285, Oct., 1947. (9 figures, 1 table, 18 references.)

Gros, B. H. **Glaucoma in young persons.** Ann. d'ocul. 180:366-375, June, 1947.

In all glaucoma three factors are important: the constitutional, the environmental, and the age-time factor. The author relates the progress of 17 cases of glaucoma, mostly in young persons. These illustrate the important effects of ocular and extraocular vascular permeability in the aggravation of glaucoma. In the aged this vascular degeneration is an arteriosclerotic process, but in the young

it is a neurovegetative disequilibrium involving especially the hypothalmus. Syphilis and other diseases as well as the excessive use of stimulants, alcohol, tobacco, and especially caffein may further accelerate this constitutional degenerative tendency. Records of prolonged uncontrolled destructive emotions and the shocks and frustrations of life, singly and in combination, run through the glaucomatous histories of these 17 persons of different ages. Chas. A. Bahn.

Holst, J. C. **A statistical study of glaucoma.** Am. J. Ophth. 30:1267-1275, Oct., 1947. (2 tables.)

Kronfeld, P. C. **Contribution to the chemistry of the aqueous humor in the glaucomas.** Tr. Am. Ophth. Soc. 44:134-142, 1946.

The author presents interesting statistical studies of the protein and ascorbic acid content of the aqueous humor of normal eyes and of eyes with glaucoma of the wide-angle type. He correlates these findings with the ascorbic acid content of the blood. There is a close parallelism between the ascorbic acid content of the blood and of the aqueous and no apparent relationship between the permeability of the blood-aqueous barrier and the ascorbic acid level in the aqueous. He concludes that in the normal eye as well as in the eye affected with deep-chamber glaucoma the ascorbic acid level of the aqueous is dependent upon the blood-ascorbic acid level. C. D. F. Jensen.

Magitot, A. **The intracranial origin of glaucomatous optic atrophy.** Ann. d'ocul. 180:321-341, June, 1947.

Glaucoma and ocular hypertension are not synonymous. The field changes in primary glaucoma are reasonably explained only by postulating extraocular vascular lesions in the optic nerve and hypothalmus that are either spastic or otherwise obliterative. These lesions reduce the blood supply to specific sections of the retina until anemia temporarily or permanently prevents their function. The upper nasal quadrant is first involved in 60 percent and the lower nasal field in 20 percent. Glaucomatous field changes center around the disc and not the macula which is involved much later, if ever. The foundation of functional and structural changes that occur in glaucoma is to be found in the arrangement of the several sectors in the retina, disc, optic nerve and the chiasm as well as in their vascular supply. The vessels of the optic nerve, like those of the retina, branch dichotomously and are terminal vessels with practically no anastomoses. Hence there is no more collateral circulation in spastic or other obliterative lesions of the optic nerve than in the retina. The binasal hemianopic fields which are frequent in advanced glaucoma also occur in chiasmal lesions, especially in those of vascular origin. The mydriasis which usually accompanies glaucomas cannot be produced by fluid vitreous injections that increase the intraocular tension. The pupillary changes in glaucoma are essentially bilateral, even though but one eye is involved. Similar changes may be induced with electric shock or cardiazol treatment. These basically affect the vascularity of the hypothalamus. The hypothalamic center of Karpus and Kreidl which is apparently primarily involved affects pupillary dilatation and is very near the other autonomic centers, which are involved in lacrimation, accommodation, and indirectly in intraocular tension and glaucoma. This autonomic regulation involves not only the quantity and quality of nervous impulses but also vascularity and permeability.

It is difficult to dissociate hypothalamic and pituitary function. The relative fre-

quency of glaucoma in patients with definite evidences of pituitary disfunction has long been known. Only recently are the association of bodily neurovascular spastic and other obliterative lesions in integrated patterns being recognized. Irrespective of their bodily locations, angioneurotic edema in the skin and the chronic glaucoma of epidemic dropsy in India, have in common a dominant neurovascular factor in which apparently hypothalamic dysfunction is involved. The accepted field changes in primary glaucoma are evidence that the atrophy is descending, not ascending. This means that paracentral, peripheral and central loss of vision is not primarily intraocular, but due to vascular lesions in the optic nerve and hypothalamus. (8 figures, 61 references.) Chas. A. Bahn.

Marr, W. G. **The clinical use of diisopropyl fluorophosphate (D.F.P.) in chronic glaucoma.** Am. J. Ophth. 30:1423-1426, Nov., 1947.

Sabata, J. **A case of inborn glaucoma observed during seven years.** Lekarske listy 2:477-479, Oct. 15, 1947.

A girl of healthy parents had bilateral congenital glaucoma which was followed by great growth of the eyeballs, subluxation of the lenses and spherophakia. The child, now eight years of age, began to grow strikingly in height at the age of six years and now she displays other symptoms of Marfan's syndrome.

CRYSTALLINE LENS

Arjona, J. **Two thousand cataract operations.** Arch. soc. oft. hisp.-amer., 7:429-444, May, 1947.

This is a brief analysis of 2,000 cataract extractions performed by the author. Tabulated data are presented. His observations are also given on the behavior of certain types of cataracts with particular characteristics such as: juvenile, morgagnian, myopic, diabetic and those complicated by iridocyclitis.

J. Wesley McKinney.

Atkinson, W. S. and von Sallman, Ludwig. **Mercury in the lens.** Tr. Am. Ophth. Soc. 44:65-70, 1946.

A rose-brown, homogenous reflex was visible on the lens in a patient with chronic mercurialism. The clinical observations were supplemented with histological and histochemical studies on fixed specimens of the eyes removed at autopsy. Four control lenses were also studied histologically and histochemically. The microscopic appearance of elongated and amorphous deposits of black or dark brown pigment articles arranged with their long axes parallel to the surface of the lens is described. The control lenses did not contain such deposits. Spectrographic examination revealed that mercury existed among the trace elements in a value slightly less than five gammas. The chemical nature of the deposits was further confirmed with microchemical tests. Bellows suggests the distribution of the mercury in the lens may be explained, as in the case of copper, by the migration produced by the electric current within the eyeball. C. D. F. Jensen.

Barkan, Hans. **An evaluation of methods and results of cataract operations as performed in private and clinic practice at Stanford Hospital.** Tr. Am. Ophth. Soc. 44:71-79, 1946.

The author presents a survey of 771 cataract operations performed at Stanford Hospital during the past five years. The extracapsular method was used in 584 or 76 percent of these operations and the intracapsular in 187 or 23 percent. A vision of 20/30 or better was obtained in 83

percent of the intracapsular operations and in only 69 percent of the extracapsular. Sixty-two (10 percent) of the latter required discission. Retinal detachment followed eight and infection five extracapsular extractions and did not occur after the intracapsular procedure. There was vitreous loss in 5 of the 187 intracapsular operations and in 6 of 584 extracapsular. Barkan emphasizes the need of statistical reports of completely unselected material. Cases with poor prognosis are segregated from the body of the statistics. C. D. F. Jensen.

Buschke, Wilhelm. **Acute reversible cataract in chicken due to various nitrocompounds.** Am. J. Ophth. 30:1356-1368, Nov., 1947. (2 figures.)

Duehr, P. A., and Hogenson, C. D. **Treatment of subchoroidal hemorrhage by posterior sclerotomy.** Arch. Ophth. 38: 365-367, Sept., 1947.

Diagnosis of the expulsive type of subchoroidal hemorrhage is not difficult. The sudden severe pain, pallor, clammy perspiration and nausea associated with a rapidly hardening eyeball are characteristic. This occurred in a patient while the sutures were being tied after cataract extraction. The authors performed a sclerotomy and the knife was thrust into the wound to release the blood. This was repeated at least six times. The eye healed with normal tension and visual acuity of 2/100. R. W. Danielson.

Hoskins, L. C. **Penicillin therapy of experimental infections of the lens and vitreous with Clostridium welchii.** Arch. Ophth. 38:301-309, Sept., 1947.

In view of the failure of penicillin iontophoresis to check infection of the lens with Clostridium welchii, the present study was undertaken with direct injection of penicillin into the lens and the vitreous. Direct injection of penicillin into the lens and vitreous of rabbits controlled infections with Clostridium welchii when the therapy was instituted within three hours after the inoculation. Less favorable results were obtained when the interval between the infection and the treatment was increased to six hours. The beneficial effect in the three hour series was obtained with moderate damage to the structures of the eye. (15 references.) R. W. Danielson.

Kettesy, A. **Restoration of the chamber after intra-capsular extraction.** Brit. J. Ophth. 31:572-575, Sept., 1947.

Delayed restoration of the anterior chamber is more frequent after intracapsular extraction than after extracapsular but it is less significant because it cannot be ascribed to particles of capsule or cortex left in the wound. The easily verified and remediable causes are: delayed healing, reopening of the wound, and choridal detachment.

Occasionally the anterior chamber does not form at all and this very serious sign seems not to be appreciated.

It can occur after a perfectly normal operation with a perfectly healed wound. On the twelfth or fourteenth day the cornea becomes hazy, the tension rapidly rises and the eye becomes blind. In 20 years in which he performed 250 extractions annually, Kettesy lost two eyes from this occurrence, and chance affected a cure in a third and gave a possible explanation. Both eyes of the patient were

operated on by uneventful intracapsular procedures. On the twelfth day the tension rose and despite medical treatment, both eyes seemed lost. Cyclodialysis was attempted and by accident the spatula injured the hyaloid membrane of the vitreous. The latter immediately streamed forth, pushed back the iris and filled the anterior chamber. The procedure was repeated on the second eye with the same result. Satisfactory healing was uneventful. The cause of the rise in tension is purely mechanical. The flat iris becomes plastered against the cornea and kept there by the inelastic hyaloid membrane. The aqueous is absorbed by the vitreous and this increases the pressure so that the iris is pressed more firmly against the cornea.

Morris Kaplan.

Leoz, G. **Cataract extraction in high myopia.** Arch. Soc. oft. hisp.-amer. 7: 445-458, May, 1947.

When a cataract develops in a patient with a high degree of myopia the cataract is usually found to be one of the most complicated. Generally, there is damage in the retina, choroid and vitreous humor which makes the success of the operation very doubtful. The author recommends that whenever it is possible it is much better to perform this kind of cataract operation in two stages; a total iridectomy, followed by extracapsular extraction a month later.

J. Wesley McKinney.

Parry, T. G. W. **Post-operative security in cataract cases.** Brit. J. Ophth. 31:569-570, Sept., 1947.

To obviate expected difficulties in post-operative care of an 80-year-old somewhat unreliable patient a complete conjunctival flap was tied with a purse string suture so as to cover the entire cornea after an ordinary intracapsular extraction. The eye was bandaged and the patient walked back to bed and remained ambulatory. The suture started to give on the third day and the whole cornea was clear on the fourteenth day. The procedure seemed so satisfactory that it was repeated on 11 more patients with very good results. All patients were ambulatory after 24 hours and all healed uneventfully.

Morris Kaplan.

deRoetth, A. **Influence of the suture on complications following cataract operation.** Arch. of Ophth. 38:315-330, Sept., 1947.

Use of deep sutures in cataract operations is a great step forward in eliminating certain complications. The preplaced appositional corneo-scleral suture, combined with a conjunctival flap covering the wound, is considered the best method. A modification of the McLean suture is described which eliminates the difficulty of making the incision in the presence of a prepared conjunctival flap. One or two sutures can be used. A series of 150 unselected cases of cataract extraction with use of the Verhoeff suture method A, and a second series of 150 cases of extractions with use of the new suture are compared as to post-operative complications, degree of astigmatism and final visual results. It was found that the new suture was superior to the Kalt-Verhoeff suture in the rapid and solid closing of the wound, thus keeping low the incidence of shallow and flat chambers, wound rupture and postoperative prolapse of the iris and vitreous. (38 references.)

R. W. Danielson.

Samuels, Bernard: **Cataract complicating glaucoma.** Tr. Am. Ophth. Soc. 44: 51-60, 1946.

The author presents the sixth and last part of a survey undertaken to record all microscopic changes that can take place in the lens as a result of lesions in other

structures of the globe. He describes 31 cases of cataract that were believed to have been caused primarily by glaucoma and includes interesting observations on the pathological changes that take place in the retina, iris, and ciliary body. He is unable to shed light on the high incidence of extensive retinal hemorrhage in no less than half of the cases of primary glaucoma. He leaves the question unsettled as to whether glaucoma had led to an impediment in the venous outflow or whether an impediment in the latter led to glaucoma. He points out that malignant glaucoma, particularly when the lens is tilted into the wound, is usually caused by a subchoroidal hemorrhage. In two cases in this series postoperative malignant glaucoma was evidently caused by nonexpulsive subchoroidal hemorrhage. Two other cases of malignant postoperative glaucoma without detachment of the choroid are believed to be definitely the result of a swollen and hardened vitreous body. An extensive cyclodialysis frequently favors the more rapid development of the cataract and may lead to an insidious iritis which is hard to counteract because atropine must be used cautiously. After trephining the ciliary processes are often fixed to the scar and extensive hemorrhage is apt to follow the section which may lead to membrane formation and possibly to sympathetic ophthalmia. (10 figures) C. D. F. Jensen.

Seidenari, R. **The vortex and the posterior epithelium in cataract.** Rassegna ital. d'ottal. 16:293-311, July-Aug., 1947.

The author discusses the question of the growth of the anterior epithelium around the equator and into the posterior surface of the lens. He reports 10 cases, giving the clinical histories and a description of the microscopic changes. Especial attention is given to the general aspect and width of the posterior epithelium, the form, size and aspect of the nuclei, and the number of layers of cells. The epithelial cells passed over the equator in 82 percent of 50 cases. In the nine lenses in which this was not so five had mature or hypermature cataract and four immature. No definite conclusions can be drawn except that the overgrowth of epithelium is not characteristic of any type or age of cataract but it is most marked in complicated cataract. (4 figures.) Eugene M. Blake.

11

RETINA AND VITREOUS

Dollfus, M. A., Thiebaut, F., Daum, S., and Wolinetz, E. **Tuberous sclerosis of Bourneville.** Presse Méd. p. 380, June 4, 1947.

The authors report the case of a boy of 18 years with the characteristic tetrad of symptoms that consists of skin lesions, phakomatosis retinae, epileptic crises, and mental retardation. The skin lesions were nevi, vitiligo, and adenoma sebaceum. The epileptic attacks first appeared at the age of 15 years. The mental retardation had resulted in a mental age of 8 to 10 years and there was a simultaneous somatic retardation.

The patient had a visual acuity of 10/10 in each eye but fundus examination revealed prepapillary tumors and multiple pseudo-colobomatous atrophic areas. The lesions did not change during the three months that the patient was observed.

Phillips Thygeson.

Espildora Luque, C., and Schweitzer, A. **The ocular fundus in 78 autopsied cardiovascular patients.** Arch. chilenos de oftal. 3:297-304, Nov.-Dec., 1946.

The ophthalmoscopic examination was negative in 18 percent of the cases. In cases where the age was less than 40 years, the ocular background was negative in 32 percent; of those above 40 years

the negative finding was in 12 percent. In both groups of patients the normality of the eyeground coincided with severe lesions of the cardiovascular-renal apparatus; the renal lesion predominating in the young, and aortic, myocardiac, cerebral, or occasional renal lesions in those of greater age. In young cardiovasculars the ophthalmoscopic lesions were generally more discrete. An exception to this was in malignant angio-nephrosclerosis, which was always accompanied by frank and serious changes of the ocular background. W. H. Crisp.

Fritz, M. H., Fennessy, T. M., and Cabrera, H. **Operative technique of vitreous replacement.** Am. J. Ophth. 30:1221-1224, Oct., 1947. (2 figures, 5 references.)

Greear, J. N. **Interpretation of ophthalmoscopic findings in arterial hypertension.** Am. Practitioner 1:640-642, Aug., 1947.

The author gives a brief historical discussion of the topic and recommends the classification of retinal lesions in hypertension advocated by the Americal Ophthalmological Society.

In pathological studies the author found that cottonwool patches were the result of localized areas of serous exudate in the deeper layers of the retina, or cytoid bodies in the nerve-fiber layer. The macular star figure was composed of collections of lipoidal histiocytes usually in the outer plexiform layer. The flame-shaped hemorrhages involved the nerve fiber layer, the more punctate and round hemorrhages the deeper layers. There is a short discussion of the ophthalmoscopic findings in the various types of hypertension. (References.) Bennett W. Muir.

Hallum, A. V. **Changes in retinal arterioles associated with the hypertensions of pregnancy.** Arch. Ophth. 37:472-490, April, 1947.

This is a detailed study of the fundus changes in hypertensions of pregnancy including a review of the literature. At least 10 percent of pregnant women show some degree of late toxemia. It is stated that an examination of the eyegrounds by one experienced in their interpretation gives the most essential information concerning the management and course of the various toxemias of pregnancy. The obstetrician should do his own ophthalmoscopy, because he will often gain valuable information without extra expense and delay to the patient.

Acute hypertensive true toxemia of pregnancy is characterized by localized and generalized spastic constriction of the arterioles, the degree of which has been found to parallel closely the severity of the toxemia. The degree of spasm of the retinal arterioles indicates the degree of angiospasm in other parts of the body. The eyegrounds should be examined routinely during the early months of pregnancy to determine the status of the arterioles. Later in pregnancy, if hypertension develops, the frequent inspection of the arterioles may help determine the treatment to follow. John C. Long.

Koch, F. L. P., and Strong, P. S. **Lipemia retinalis: report of a case.** Tr. Am. Ophth. Soc. 44:187-194, 1946.

The authors report a case of lipemia retinalis in a diabetic subject. It is the sixty-sixth case of lipemia retinalis to be reported three of which unquestionably occurred in patients without diabetes. Photographs of the eyegrounds and of the serum show the contrast between the conditions present at the peak of the episode and on the twenty-first hospital day.

News items should reach the editor by the 12th of the month

DEATHS

Dr. Frederick G. Adolph Bardenheier, St. Louis, Missouri, died September 26, 1947, aged 65 years.

Dr. Edward T. Hornback, Hannibal, Missouri, died July 15, 1947, aged 83 years.

Dr. Bertil Thomelius Larson, Pontiac, Michigan, died July 20, 1947, aged 54 years.

Dr. Charles Porter Small, Chicago, Illinois, died September 25, 1947, aged 83 years.

ANNOUNCEMENTS

FLORIDA MIDWINTER SEMINAR

This year the University of Florida Midwinter Seminar in Otolaryngology and Ophthalmology will be held at the Flamingo Hotel in Miami Beach, from January 12th to 17th. The lectures in otolaryngology will be presented on the first three days and those in ophthalmology, the last three days. The registration fee is $25.

Among the outstanding ophthalmologists who will lecture are Dr. S. Judd Beach, Portland, Maine; Dr. William L. Benedict, Rochester, Minnesota; Dr. Daniel B. Kirby, New York; Dr. Peter C. Kronfeld, Chicago; and Dr. Dohrmann K. Pischel, San Francisco.

GEORGE WASHINGTON UNIVERSITY COURSE

From January 26th to 30th, The George Washington University School of Medicine, 1335 H Street, N.W., Washington 5, D.C., will conduct an intensive postgraduate course in ophthalmology.

Fundamental and practical instruction in ophthalmic problems will be presented. Among the topics to be considered are the following: anatomy of the eye, orbit, and optic pathways; congenital defects of the eye; examination of the eye; mydriatic and miotic agents; ocular findings in intracranial disease; the neuro-ophthalmologic examination; psychosomatic disorders; ocular findings in systemic diseases; preoperative and postoperative care for eye surgery; management of cataracts; diagnosis and surgical management of ocular deviations; tumors of the ocular bulb and adnexa; penetrating injuries of the eye; nonperforating eye injuries; localization and treatment of foreign bodies in the eye and orbit; lacrimal apparatus; uveitis; glaucoma; pediatric, geriatric, and tropical ophthalmology.

Among the distinguished ophthalmologists who will take part are: Dr. F. Bruce Fralick, University of Michigan; Dr. Murray F. McCaslin, University of Pittsburgh; Dr. Phillip Robb McDonald, University of Pennsylvania; Dr. Charles A. Perera, Columbia University; Dr. Raymond Pfeiffer, Columbia University; Dr. James S. Shipman, University of Pennsylvania; Dr. Isaac Samuel Tassman, University of Pennsylvania; Dr. Charles Dwight Townes, University of Louisville; Dr. Frank B. Walsh, Johns Hopkins University; Dr. Alan Woods, Johns Hopkins University.

Dr. Ernest A. W. Sheppard, professor of ophthalmology, is the faculty member in charge. The fee for the one-week course will be $50.

OREGON TO HAVE COURSE

The ninth annual spring postgraduate course in ophthalmology and otolaryngology will be held in Portland from March 21st to 26th. Another fine program has been arranged by the Oregon Academy and the University of Oregon Medical School. Dr. A. D. Ruedemann, Wayne University, Detroit, and Dr. C. Allen Dickey, University of California, San Francisco, will be among the guest speakers. There will be lectures, clinical demonstrations, and ward rounds.

Preliminary programs will be ready about February 1st. A program and further information may be obtained from Dr. Harold M. U'ren, secretary, 1735 North Wheeler Avenue, Portland 12, Oregon. In order to make the course more practical and personal, registration will be limited to 125.

A.O.S. TRANSACTIONS AVAILABLE

The American Ophthalmological Society offers back copies of its *Transactions* from its founding through 1939, with the exception of the following numbers that are not available: vol. 1, 1865, 1867, 1868; vol. 6, part 3, 1893; vol. 8, part 2, 1898; vol. 16, 1918; vol. 33, 1935; vol. 34, 1936; vol. 35, 1937. These volumes have been carefully stored and are in good condition.

Volumes 1 through 15 (years 1866 through 1917), vol. 21 (1923) and vol. 26 (1928) are unbound at $3 each. The other volumes are in the standard green binding at $5 each.

Send orders to: Dr. Maynard Wheeler, M.D., 30 West 59th Street, New York 19, New York.

MISCELLANEOUS

CHICAGO REFRESHER COURSE

The Chicago Ophthalmological Society held a one-week refresher course from December 8th to 13th. The subjects covered were office procedure, ocular motility, gonioscopy, glaucoma, ocular pathology, ophthalmoscopy, neuro-ophthalmology, perimetry, slitlamp biomicroscopy, refraction, and medical ophthalmology.

Staffs of the four Chicago medical schools and of Cook County Hospital served as instructors.

Eye hospital dedicated

The Thigpen-Cater Eye Hospital, commemorating Dr. Charles A. Thigpen and Dr. Job T. Cater, was dedicated on November 2, 1947, at Birmingham, Alabama. Dr. Alston Callahan, professor of ophthalmology, The Medical College of Alabama, has been named director of the Hospital.

Rivista di Oftalmologia

Florentine ophthalmology, more or less stagnant since the transfer of the "Bollettino d'Oculistica" to Rome and as a result of the recent war, is undergoing a reawakening. Prof. Biagio Alajmo, director of the Institute of Clinical Ophthalmology of the University of Florence, has founded a new monthly ophthalmologic journal, the "Rivista di Oftalmologia," which appeared in January, 1946, published by L. Salpietra, Florence, Italy.

The editor of the "Rivista" is ably assisted by a group of well-known Italian ophthalmologists—V. Accardi, A. Bencini, G. B. Bietti, F. Caramazza, D. Cattaneo, V. Cavara, A. Contino, Q. Di Marzio, E. Federici, R. Gallenga, L. Guglianetti, G. Lo Cascio, L. Maggiore, V. Rossi, A. Santonastaso, S. Sgrosso, A. Rubino, M. Simonelli, and U. Azzolini. The "Rivista" includes in its pages original papers, reviews, therapeutic notes, and abstracts from Italian and foreign journals.

Volume I, which the writer of this note (Charles A. Perera), has had the pleasure of reading, contains excellent papers by many prominent Italian oculists. If this volume is a portend of the future, it is safe to say that the "Rivista di Oftalmologia" will make an enviable reputation in Italian ophthalmologic literature. American ophthalmologists greet this newcomer with best wishes for its continued success.

Eye-Bank Fellowships

The Eye-Bank for Sight Restoration, Inc., has granted fellowships for research in ophthalmology to the medical schools of Harvard and Yale universities. Dr. Thomas Duane has been chosen to work at the Howe Laboratory, Harvard University Medical School, investigating the metabolism of the cornea. Dr. David Freeman, who will work at Yale University School of Medicine, will carry on experiments in tissue transplantation.

Riggs Optical Company moves

The Chicago city and general offices of the Riggs Optical Company are now located at 18 South Michigan Avenue, Chicago, where the company occupies the 4th and 5th floors.

Societies

N.S.P.B. annual meeting

The National Society for the Prevention of Blindness held its 33rd annual meeting on December 12th, in the Russell Sage Foundation Building, 130 East 22nd Street, New York.

The principal speaker was Dr. C. E. A. Winslow, editor of the *American Journal of Public Health.* Dr. Winslow's subject was "Prevention of Blindness in the Public Health Program."

Activities of the National Society for the Prevention of Blindness during the past year were reviewed by Dr. Franklin M. Foote, executive director. Mason H. Bigelow, president of the society, presided.

Reading meetings

At the 70th (Academy) meeting of the Reading (Pennsylvania) Eye, Ear, Nose, and Throat Society, the following members reported: Dr. Paul C. Craig, Dr. William J. Hertz, Dr. Isaac B. High, Dr. James E. Landis, Dr. John J. Penta, Dr. Samuel A. Phillips, Dr. Robert E. Shoemaker, and Dr. John M. Wotring.

The 71st meeting of the society was held jointly with the Berks County Medical Society. The speakers were Dr. Samuel A. Phillips of Allentown, Dr. Arthur A. Bobb of Reading, and Dr. William T. Hunt of Philadelphia.

Milwaukee program

On the scientific program of the November 25, 1947, meeting of the Milwaukee Oto-Ophthalmic Society were the following speakers: Dr. George Roncke, who discussed "Intraocular Tumors"; Dr. Wendell Jones, "Injection Therapy of Oesophageal Varices"; Dr. Charles Finn, "Case Simulating Acoustic Neuroma"; Dr. Howard B. Morter, "Otogenic Intracranial Infection"; Dr. Milton Loring, "Exophthalmos: A Case Presentation"; Dr. Claire M. Flanagan, "A Problem in Diagnosis of Laryngeal Carcinoma."

Personals

Gives Schoenberg Lecture

Dr. Peter C. Kronfeld, Chicago, delivered the first Mark J. Schoenberg Memorial Lecture on December 1, 1947, at the New York Academy of Medicine. The subject of the lecture was "The Canal of Schlemm."

Has new address

Prof. Ida Mann has resigned her appointment at Oxford University and has returned to London where her address is 87 Harley Street, London W. 1.

Receives Mackenzie medal

Mr. Eugene Wolff, F.R.C.S., London, was presented with the William Mackenzie Memorial Medal in Glasgow on October 24, 1947.

Speaks on corneal transplantation

Dr. A. E. Maumenee recently discussed "Corneal Transplantation" for the members of the department of ophthalmology, Medical College of Alabama, at the Thigpen-Cater Eye Hospital.

OCULAR LESIONS FOLLOWING THE ATOMIC BOMBING OF HIROSHIMA AND NAGASAKI*

JOHN J. FLICK, M.D.
Indianapolis, Indiana

INTRODUCTION

It seems necessary for me to relate briefly in chronological order the fortuitous series of events leading to my participation in the medical investigations at the atomic bomb areas in order to give the reader insight into the situation that confronted us and the difficulties we encountered in making a clinical study of the survivors. The atomic bomb had struck Hiroshima on August 6, 1945, and Nagasaki on August 9, 1945, three days later.

On September 7th, I was called to an interview held in Yokohama with Brig. Gen. T. F. Farrell, Col. A. W. Oughterson, Col. Stafford L. Warren and Dr. Masao Tsuzuki of Tokyo Imperial University. Dr. Tsuzuki had made an expedition to Hiroshima with some other Japanese several days before, but no American expeditions had been made until that time.

Farrell and Warren represented the Atomic Bomb Investigation Committee of the Manhattan Project. Oughterson, who was at that time deputy chief surgeon, General Headquarters, was to represent the Supreme Command. The Manhattan-Project group, of course, were interested in furthering technical studies carried over from the long train of laborious scientific experimentation and complicated industrial administrations that were partially consummated *in the first test explosion of the atomic* bomb conducted in New Mexico in July, 1945. Their survey was to comprise not only medical research but multitudes of technical observations in the realm of nuclear physics. Colonel Oughterson's task, more specialized, was to make a survey of the overall casualty picture and to organize and formulate a program for adequate study of the casualties. "They say this explosion gives off the light of ten-thousand suns!" he said to me. "If this be true there should be something for you to do."

Our party consisting of three medical officers and 16 others flew to Hiroshima on September 8th, and made the first official entry into the city of Hiroshima on the morning of September 9th. We visited the Red Cross Hospital in charge of Dr. Ken Takenchi and learned that at that time there were approximately 2,000 atomic bomb casualties in 80 hospitals in Hiroshima and surrounding area. Since most of these hospitals were very small and widely scattered over the countryside with no centralized registration, we could see an almost unsurmountable obstacle to organized study of cases. We learned that the death rate was 100 per day among those survivors and felt that any studies made would have to be instituted quickly.

Ujina Hospital was selected for the center of operations because it was located two kilometers from the center of the explosion and because it had the largest number of

* This work was performed as part of the medical researches undertaken by the Manhattan Project, under the guidance and supervision of Dr. Stafford L. Warren, then of the University of Rochester. The aid of Mrs. H. C. Wilder of the Army Institute of Pathology in interpreting the microscopic sections is also greatly appreciated.

patients and the most capable medical organization. Only 30 of the 300 doctors in Hiroshima were alive and able to work at that time. Fairly comprehensive blood studies had been made at Ujina by Dr. Nakao, but the rarity of English-speaking Japanese and our inability to use the records were very discouraging.

There were 220 patients in the hospital at that time for our study. Although all these patients were casualties of the atomic bombing in a sense, they included many types and categories that could furnish us only a small amount of useful information. Some of the patients were debilitated old people, some suffering only from malnutrition; others had thermal burns of the ordinary type sustained in the conflagration of their homes. Although it was our mission to gather statistics on the overall casualty picture including all types, our interest was unavoidably centered about the peculiar form of reaction to irradiation. Japanese records even when translated were often disappointing. Chaotic conditions were reflected in the confusing records kept of the patients. Great numbers of patients were moribund on admission. Lack of housing facilities, medical equipment and personnel, and time interfered with complete and adequate case studies. At one time there were 500 seriously ill patients cared for on the lawn in front of the Red Cross Hospital. This point was a center to which wounded were brought because special fire-fighting facilities had been set up there to keep the fire from that area.

Some of our patients were found in Ono Military Hospital, an old, made-over tuberculosis sanatorium, south of Hiroshima. Two weeks later a landslide brought on by a typhoon destroyed the entire hospital and killed nearly all the persons in it. We went through a small hospital situated in a school house containing several hundred casualties. The place was in charge of a lay nurse's assistant. She told us the doctor came every three days to attend the patients. Dozens of dead were lying among the living. Innumerable flies covered raw, granulating wounds.

At the end of the second day I had examined approximately 300 patients. I had found the usual traumatic lesions one sees in wartime but none of the corneal or lenticular syndromes I had expected to find. There were few ophthalmias among the sick and those found were of the nonspecific kind due to infection. Knowing the high degree of radioresistance of the tissues of the posterior segment I had paid little attention to ophthalmoscopic studies. Becoming interested in the blood studies and peculiar clinical picture of the late "aplastic" anemia, I felt that ophthalmology was to play a very small part in the pattern of radiation sickness or "atomic-bomb disease" as it was being called.

On the third day I was examining two moribund Japanese soldiers with bloody diarrhea, bleeding from the gums, covered from head to foot with petechiae. Their white counts were 2,000 and 900. I examined their eyegrounds. Both had extensive hemorrhagic and exudative lesions of the retina. It seemed entirely consistent with the rest of the picture. The observation seemed a minor confirmation of the findings of the clinicians and hematologists.

As I looked at these patients, I was struck by the remarkable similarity of the shape and form of the lesions in the two cases. Here were hundreds of cases of aplastic anemia! Why not make a study of them? There had never before been and perhaps never again would be such a collection of cases! Correlation of these ophthalmoscopic findings with those of the hematologists and clinicians made it evident that these characteristic fundus lesions were one of the most reliable criteria of radiation sickness. Thus we had acquired a very useful method of separating the radiation casualties from the others.

We had completed our initial survey and felt the need of equipment and personnel for a detailed and comprehensive study. We left Hiroshima on September 14th. Our expedi-

tion to Nagasaki began on September 20th when we flew to Omura. There we found the medical facilities much better than at Hiroshima. The geographic nature of the site of the explosion had resulted in far less destruction of life and property among the Japanese, leaving many able medical men to aid us in our work and to collaborate with us. There were also good buildings in which to work and a relative plenty of equipment and auxiliary personnel to help us. The large naval hospitals located in the vicinity provided excellent places in which to work. The Japanese did everything possible to aid us in carrying out our mission. It was here that a large part of the work herein described was done.

A number of English-speaking Japanese medical students from Kyushu Imperial University in Fukuoka were assigned to us as interpreters. Their work was of obviously great value in translating and interpreting the great number of case histories. At the bedside they were of greatest aid in questioning the patients and translating their answers. It was at Shinkozen Hospital in Nagasaki that my work began to assume organized form. I could see the outline of the task that lay before me. I compiled a check list of all the essential elements of my case histories and tabulated my cases in order not to forget any important data. A Japanese ophthalmologist by the name of Ikui, assistant professor of ophthalmology at Kyushu Imperial University, had been studying the cases there before I came. Through interpreters we had many discussions over the lesions. His studies were very thorough.

On the 26th of September our whole party moved its center of operations from the Shinkozen hospital in Nagasaki to the Omura Naval Hospital, 20 miles away, in which facilities for laboratory work and autopsies were excellent. In subsequent investigations extending over several months, the Omura Naval Hospital was the center, and all patients in surrounding areas were evacuated there for study and treatment. This large hospital was of excellent construction and well provided for in the way of equipment, including the comfort of linen, cooking facilities, and clean water supply. There were five wards of about 50 beds each. The patients were nearly all irradiation cases.

From a practical standpoint my work was immensely easier there due to better frame of mind of the patients and the fact that they were in hospitals beds instead of on straw mats on the floor as all the preceding cases had been. The routine of putting on and taking off a pair of army combat boots a dozen times a day and being compelled to crawl from patient to patient on my knees, examining eyegrounds in awkward positions, had become very annoying. Capable nurses were on hand to instill mydriatics to a whole ward of patients at a time. The patients soon became very much accustomed to the homatropine and seemed to enjoy having their eyes looked at, particularly those who suffered some loss of vision because of their lesions.

By means of army transportation I was able to travel around the area, visiting a number of the small hospitals, gathering case histories and doing ophthalmoscopic examinations. In this respect I had a great advantage over Japanese workers who, because of the unavailability of transportation, were compelled to remain in one hospital for their study.

I remember a visit to one hospital far up on the hillside very near the hypocenter of the explosion that will leave forever in my mind a picture of the stark misery of those wretched people. Only a jeep could have made the trip. In some places the pathway was no wider than a foot path and the wheels seemed to grasp for a footing on the sharply inclined mountainside. A stone building from which the windows, sash and all, had been blown out and from which the roof had been broken and partially blown away was the "hospital." About 20 patients were lying about on the floor upon loose straw so wet

that water came over the tops of my shoes as I stooped to examine the patients. Some were covered with loose nets but most of them were unprotected from the hordes of flies that came to feed upon their open wounds. A small Japanese man introduced himself as the doctor in attendance. He asked us in a weak though earnest voice if there were any way to help his patients, any medicines the Americans could offer. His hair was sparse and his skin pale. [K rations were brought in next day and the patients evacuated to better quarters.]

By the first of October the number of new cases of irradiation sickness coming to the hospitals was practically nil and it could be seen that further studies would have to be limited to repeated reëxaminations of the cases already under observation. On October 6, 1945, I returned to Tokyo to resume my duties with the 42nd General Hospital.

Review of the literature

From a medical standpoint the casualty picture of the survivors of the atom bombs is unique in the history of man. Experimental studies have been made in great numbers on animals by various investigators.[9,10] Medical literature is replete with reports of injuries and even death due to improper or excessive use of irradiation, but never before this time has the world seen death of human beings in large numbers from total body exposure to penetrating rays.

Concerning aplastic anemia and agranulocytosis, one finds isolated case reports of individual cases described more or less in detail,[1,7] often with special reference to the etiology (usually idiosyncrasy to some drug). Studies of the effects of whole-body irradiation even in animals have never included examination of the eyegrounds as far as the author has been able to determine.[10] Such studies have been focused on the gastro-intestinal tract and the hematopoietic system.[11,12]

Benkwith[2] describes a case which he saw in Nagasaki exhibiting epilation of the hair, and petechial hemorrhages of the skin and mucous membranes. The blood studies showed anemia and leukopenia. A beautiful colored illustration shows the hemorrhagic lesion of the retina. The reader is strongly urged to study this illustration—it is very characteristic.

Schlaegel[6] in his recent article gives a beautiful detailed account of the microscopic pathology of eyes taken at autopsy of fatal cases. The article has a comprehensive bibliography. A singularly distressing fact that has been apparent to more than one of us is that the fundamental, early research on biologic effects of irradiation was made with primitive equipment and the protocols often are not clear as to the physical properties of the energy with which the effects were brought about.[5,9] The remarkable advances made in nuclear physics are such as to make much of this early experimental work nonspecific and of little value as interpreted today.

Clinical studies

At the time of our visit to the atomic-bomb areas at Hiroshima and Nagasaki, it was anticipated that some pathologic changes would be found in the eyes of those survivors who were near the site of the explosion. It was known that a large amount of light was produced by the explosion, and it could be assumed that some detectable damage to the tissues of the eye could have resulted. To the date of the completion of this study, October 6, 1945, no primary damage to the ocular structures has been observed that could be interpreted as the result of irradiation of any sort. The president of the Nagasaki Medical College, Dr. Yamane, who himself died two weeks after the explosion from irradiation sickness, is said to have treated a number of cases of purulent conjunctivitis occurring 3 or 4 days after the blast and lasting about a week. These cases all resolved and the disease did not involve the cornea or leave any permanent sequelae. No bacteria were found in the discharge in

studies made by the Japanese at that time.[8]

No evidence of such a disease was found by us 4 to 6 weeks later, and no patient questioned by us gave a history of such a disease. A number of patients with flash burns of the face who must have been facing the exploding bomb were examined carefully with the pupil dilated using the ophthalmoscope and focal illumination. No opacities could be seen in the lens and no pathologic changes were noted in the cornea or conjunctiva. In fact, the flash burns seemed to spare the eyelids in many cases as if the tight closure of the eyes had occurred quickly enough to hide that area of skin. Some patients were seen who had lost their lashes but epilation of eyebrows was rare.

Lesions resulting from the explosion of the atomic bomb may be divided into three categories:

1. Mechanical injury from the blast.
2. Thermal injury from long-wave energy.
3. Radiational injury from gamma rays and neutrons emitted at the time of detonation.

Mechanical injury from blast

Those lesions resulting from mechanical injury differed in no way from those produced by other explosive agents, such as bullets and shells. Among those noted were penetrating injuries of the globe, leukoma of the cornea, traumatic cataract, various lid deformities including ectropion, symblepharon, ankyloblepharon, detachment of the retina, and various syndromes involving fracture of the skull and walls of the bony orbit. Many ambulatory casualties were seen on the streets wearing eye patches.

Thermal injury from long-wave energy

Effects of the enormous thermal energy released by the explosion were evidenced in the frequency of pigmented flash burns. These were of a copper color and involved only the side facing the explosion. The burned areas had straight-line borders resembling a shadow cast over the upper trunk. There were large numbers of patients exhibiting extensive facial burns of the ordinary type with much dense cicatrix. These burns in some instances had involved the conjunctiva and cornea to such an extent that the red, inflamed, lacrimating eyeball had only slight movement and seemed set in a dense mass of contracting scar.

Radiational injury

It is not in the province of this paper to describe in detail the general picture of the effects of the whole-body irradiation or "radiation sickness" as it has been called. However, a brief outline of these phenomena may help to orient the reader in interpreting the more specific findings of the ocular examinations. From 3 to 5 days after the explosion, many survivors who had been near the hypocenter became acutely ill and completely prostrate with bloody diarrhea. These individuals died within 2 or 3 days, long before our investigation began. Those may be called "acute roentgen deaths." They did not become subjects of our investigation. Accounts of the course of their illness were obtained from the Japanese local medical authorities.[3,10] It is assumed that they all received dosages of irradiation sufficient to cause necrosis of the mucosa of a large part of the gastro-intestinal tract.

Beginning about two weeks after the explosion, a strange, new syndrome appeared. Individuals who had previously been well and apparently free from all injury from the explosion fell ill in large numbers. They manifested extreme weakness, pallor, and loss of hair. Innumerable petechial hemorrhages appeared in the skin and there was ulceration and bleeding from oral mucosa. They became febrile and succumbed in large numbers to invasive pulmonary and pharyngeal infection. Examination of the blood revealed extremely low red-cell and hemoglobin values, low white blood count, particularly the granulocytes, and an extremely prolonged bleeding time with no

clot formation. The condition progressed to death. Such cases appeared in large numbers from the beginning of the third week until the end of the sixth week and brought much speculation from the Japanese as to the probable etiology. At the time of our arrival in Hiroshima, near the end of the fourth week, the death rate in that area was given as 100 per day.

The Japanese were doing numerous autopsy studies on the cases at the time of our arrival and had already demonstrated the lesions of the bone marrow, the lymphoid atrophy, the aplastic blood picture, and the diffuse manifestations of hemorrhagic diathesis.

Many of the patients from Hiroshima were evacuated to Fukuoka, Kyushu, for study and treatment in Kyushu Imperial University. Dr. Toichiro Sawada and Dr. H. Mizusima of the medical faculty there showed us the clinical records of many of these cases, the completeness and detail of which reflected their keen awareness of the situation. Dr. Kosaku Ono of the Pathological Institute has preserved beautiful specimens of autopsy material, particularly of the gastro-intestinal tract. It was in this institution that Ikui[3] made his ophthalmoscopic studies.

The physical state leading to and forming the basis of the ocular lesions I am about to describe is briefly and concisely set forth in the following quotation from Warren:[12]

"The hematopoietic system (marrow and lymph nodes) is so badly damaged by the penetrating gamma and neutron radiation as to appear aplastic on histologic examination. This damage is reflected later in leukopenia, progressive anemia, development of petechiae, prolonged bleeding time with absence of clotting with probably some actual capillary injury to all the vessels in the body. . . ."

Ocular lesions associated with irradiation

Ocular lesions associated with or secondary to irradiation were limited to the retina, as far as clinical features were concerned, and were found in 46 cases. Unfortunately accurate count was not made of all patients examined. A reasonable estimate, however, is about 400, of whom approximately 50 were from the Hiroshima area and 350 from the Nagasaki area. Even if these figures were actually known it would be difficult to compute the real incidence of the ocular lesions, since in some instances examination with the facilities available at the time left some doubt as to whether radiation reaction was actually present or not. It was felt that in many cases the ophthalmoscopic examination was useful in establishing a diagnosis of postradiation state in otherwise doubtful cases. I believe it can be stated without reservation that retinal lesions were found in 50 percent of those showing obviously demonstrable signs of whole-body irradiation, that is, epilation, leukopenia, and petechiae of the skin.

The relationship of the blood changes to the retinal lesions is emphasized in the analysis of the data obtained in the clinical examinations (table 3). Of the patients showing these retinal lesions 75 percent had one or more other clinical symptoms of irradiation at the time the study was made. Of 37 cases in which leukocyte counts were available, 28, or 75.7 percent gave figures at some time of 4,000 or below. There were 23 patients under 25 years of age and 23 patients over 25 years of age. Of the four clinical signs found to be typical of irradiation damage—petechiae, gingivitis, angina, and epilation—the group of under 25 had an average of 1.52 while the group of over 25 had an average of 1.22, a difference of about 20 percent. This may indicate a relationship of age to sensitivity to gamma irradiation. However, no correlation whatsoever could be found between the age and the degree or intensity of ocular involvement.

All of the patients in this study were within two kilometers (1.2 miles) of the hypocenter of the explosion. Of all 41 cases, where the information could be obtained,

only 8 (19.5 percent) were outside of a building at the time of the blast. In these cases it must be assumed that some intervening absorptive material, that is concrete, must have protected the majority from gamma-ray dosages that would certainly otherwise have caused them to die before our investigation began.[12] Because of this unknown amount of shielding in any given case, it appears that a correlation of the distances from the explosion with the quality and intensity of the pathologic effects is difficult to compute in spite of the fact that doses received through the air by persons at equal distances were probably the same.

TABLE 1

RELATION OF WHITE BLOOD COUNT TO DISTANCE FROM EXPLOSION

Type Lesion	Number Cases	Average W.B.C.	Average Distance
Exudate alone	10	4,666	1.15 Km.
Hemorrhage alone	14	3,458	1.08
Exudate plus hemorrhage	22	3,156	0.99

The data in Tables 1 and 2 show, however, a definite tendency for the white count to vary directly with the distance from center, and it is felt that if the many extraneous factors such as density of clothing, posture at the time of the blast, intercurrent physical disease, and nonradiational injury could have been properly evaluated the relationship could have been demonstrated more clearly.

Although the factor of sex in the development of the reaction did not seem to be prominent in the cases examined, it may be seen from Table 3 that the average white-cell count was significantly lower for the females than for the males. There is little or no relation between the sex and the ocular lesions found, qualitatively or quantitatively.

It is evident then that, in the case of any given individual at the time of our investigation, we knew only that he had received a dose of irradiation that was either sublethal for him or lethal with a longer latent period than other cases had shown. As noted in some of the case histories, serial leukocyte counts made by the Japanese before our arrival indicated that the depth of the leukocyte depression probably took place around the first week in September in the cases alive and available for our clinical appraisal at the time this survey was made.

TABLE 2

RELATION OF WHITE BLOOD COUNT TO DISTANCE FROM EXPLOSION

Distance Meters	Number of Cases	Counts Available	Average W.B.C.
0–500	10	10	2,470
500–1000	15	9	3,344
1000–1500	12	11	3,081
1500–2000	8	4	8,950

TYPES OF HEMORRHAGES OBSERVED

The lesions observed in this disease appeared in the retina and were limited to that structure and the nerve-fiber layer as it overlay the nerve head. The hemorrhages were of four types. In order of frequency of occurrence these are: flame hemorrhage, preretinal hemorrhage, "Roth"-type hemorrhage, and vitreous hemorrhage.

Flame hemorrhage is, of course, situated in the nerve-fiber layer of the retina. It is due to the rupture of capillaries in that layer and the infiltration of cellular blood elements between the nerve fibers. These lesions were very numerous, being seen in 25 (54.3 percent) of the cases. They were nearly always situated, as were all other fundus lesions described in this study, close to the nerve head, being rarely seen further than three disc diameters away. Some of the flame hemorrhages were very dense and had

TABLE 3

INCIDENCE OF SEX AND RELATION TO WHITE BLOOD COUNT

Sex	Number	Number Counts	Average W.B.C.
Male	20	16	4,262
Female	26	21	2,976

a deep maroon color, while others were a very pale red and only slightly darker than the uninvolved retinal tissue and underlying choroid. The pallor of these hemorrhages was a striking manifestation of the depletion of circulating hemoglobin. The term "flame hemorrhage" is used in this study to refer only to those lesions in which the reflexes from the internal limiting membrane revealed no change in level as they passed over the lesion. The location in the nerve-fiber layer was often strikingly demonstrated by the extension of the lesion continuously onto the disc itself. Some of these took the form of narrow, splinter shapes often being situated parallel to and very close to a large vessel.

TABLE 4

TYPES AND INCIDENCE OF RETINAL LESIONS

Lesion	Number of Cases	Percent of Total*
Exudate	30	65.2%
Flame hemorrhage	25	54.3%
Preretinal hemorrhage	11	23.9%
"Roth"-type hemorrhage	4	8.6%
Vitreous hemorrhage	2	4.3%

* These percentages do not total 100 because each eye often had more than one type of lesion.

Preretinal hemorrhage occurred in 11 (23.9 percent) of the cases. These seemed to be a gross development of the flame hemorrhage in which the blood had leaked into the subhyaloid space producing an elevated, rounded hematoma immediately adjacent to but not invading the vitreous. These lesions were often quite large and had straight-line, horizontal upper borders due to stratification of the elements of the blood. The surface of the hematoma was smooth and convex as determined by the character of the reflex from it. The surface of these blood masses was granular. The distinguishing ophthalmoscopic features of these lesions were their uniformity of color, their large size, their extremely sharp margins, and the tendency to form horizontal, straight-edged upper margins. The serum of the blood could be dimly seen above the straight edge and was usually clear enough so that underlying retinal vessels could be seen.

"Roth"-type hemorrhage. A unique type of hemorrhage observed in this study resembled nothing so much as a Roth spot except that it was larger. These lesions were noted especially in 4 (8.6 percent) of the cases. They were larger than most flame hemorrhages and were almost invariably seen overlying a large artery, a branch of the first order. The portion of the lesion toward the disc was smoothly and sharply outlined while that away from the disc was brushlike. The color was a deep maroon and the lesion showed elevation of the retinal surface. Somewhere on the lesion, usually on the distal portion, was an irregular, round, white area about one fourth of the diameter of the lesion itself. The pathogenesis of these spots could be made out from a study of the hemorrhage forming in association with the exudates (vide infra).

Vitreous hemorrhage was noted in two cases (4.3 percent). There was an infiltration of the vitreous body itself by blood which had burst through the hyaloid. The view of the fundus was always more or less obscured in this type of hemorrhage.

Exudation into the retina was a most common finding in these cases (30 or 65.2 percent). It took the form of round, snow-white, slightly elevated lesions obscuring the retinal vessels. They were usually about one-fourth disc diameter in size. These spots were always within three disc diameters of the disc and were sometimes extremely numerous, 40 or 50 being seen in a single eyeground. The spots were scattered in random fashion over the polar zone of the retina without any reference to blood vessels.

In some of the cases, however, it was noted that occasionally a lesion situated near an artery would show a fine fringe of hemorrhage about its borders, particularly its peripheral or distal border. Some were seen

in which this hemorrhage became large and came to surround the exudate. This led me to believe that such a hemorrhage about an exudate could develop into a hemorrhage of the so-called "Roth" type described above.

The morphologic variations noted in these exudates were rather marked. The most common type was, as described, round and smoothly elevated with a feathered margin indicating that it was an involvement of the nerve-fiber zone. Elongated forms were also seen and a peculiar zig-zag formation in which the extension in length was in a direction perpendicular to the direction of the nerve fibers composing the lesions. Also in these the area of exudation would not everywhere be equidistant from the disc, producing a "Z" shaped figure (fig. 1). In some cases this development became so marked that these exudates formed one or more rings or wreaths partially surrounding the disc.

Subsequent observation of the lesions showed their borders to become sharper as they absorbed in contrast to the hemorrhages in which the borders became more indefinite as absorption progressed. A late residue of an old exudate is a small waxy, yellowish, sharply outlined plaque associated with several much smaller satellite spots. In some instances rather large sharply outlined grayish speckled areas were seen surrounding a large artery. These could very well represent residual atrophy from absorption of one of the larger hemorrhages.

No changes were observed in the optic discs nor were any pathologic changes noted in the vessels themselves. Generalized retinal edema was a very common accompaniment of hemorrhages and exudates so that if edema was present a search for a local pathologic condition was more intensively pursued.

Microscopic findings

Microscopic examination of the eyeballs removed at autopsies done in Hiroshima and Nagasaki has been carried out by Mrs.

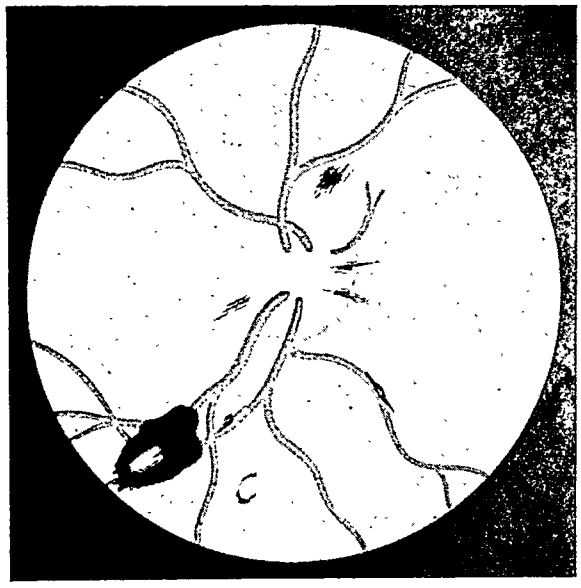

Fig. 1 (Flick). Composite drawing representing the different morphologic types of fundus lesions seen. The hemorrhages are in black and the exudates in white.

H. C. Wilder of the Army Institute of Pathology, Washington, D.C., and also by Dr. T. F. Schlaegel, Jr., of the Indiana University School of Medicine, with both of whom I have conferred personally at length on the findings. It is an unfortunate fact that none of the cases appearing in my report furnished any material for microscopic study and in none of the autopsy specimens examined critically had a clinical examination of the eyegrounds been made.

Of 18 eyes examined by Wilder, 15 showed degenerative changes in the lens; one eye showed a conjunctival hemorrhage; one eye, a retinal hemorrhage; one eye, swollen areas in the nerve-fiber layer resembling cytoid bodies; and 17 eyes showed septic choroiditis. These eyes had been removed 24 to 33 days after the explosion and none had been examined ophthalmoscopically.

Since studies by the Japanese showed that the peak of the leukocyte depression occurred about the end of the fourth week, it is entirely possible that eyes removed in the third and fourth week after the explosion would not reflect the pronounced blood changes that they would have showed

if the individual had survived another 2 or 3 weeks. This explains the absence of hemorrhage in the retina on microscopic examination and also the packing of the choroidal vessels with inflammatory cells.

Regarding the lens changes, there is little to be said at this time. I examined dozens of eyes with the pupil dilated but saw no lens opacities. At no time was my view of the fundus hampered by opacities of the media that I could localize in the lens. I have been extremely interested myself in the swollen areas in the nerve-fiber layer. (This condition is shown in figures 4, 5, and 6.)

These lesions were lenticular in shape, protruding slightly into the vitreous chamber and depressing the inner nuclear layer. The lesion itself is somewhat granular and the nerve fibers become blurred in outline as they pass through the lesion. The color of the stain is grayish pink and the center of the lesion has an amorphous appearance. These lesions could be the areas of edema seen with the ophthalmoscope as white exudates.

Schlaegel in his recent report[6] found no microscopic evidence of the retinal lesions

TABLE 5

TABULATION OF HISTORICAL DATA

No.	Name	Age and Sex	Dist. Km.	Date Onset	Manifestations*	W.B.C. Date	Location When Bombed	Eye Lesions
1	Ogawa	22 ♀	1.0	9-5	1-2-3-4-5-6	3,200	inside	Macular hemorrhage, exudative plaque

seen clinically. He, too, found the septic choroiditis and evidences of lens degeneration. His paper, which is a remarkable contribution from a documentary standpoint, contains an interesting table showing the increased thickness of the lens capsule in these eyes.

Case histories

The reports submitted in this account represent free translations of histories taken through interpreters. It was felt that a good deal of the realism of the stories told of individual experiences was lost through imperfect and sometimes impossible rendition of the Japanese idiom. The interpreter's lack of knowledge of English frequently resulted in misunderstanding.

Case 1

History. Ogawa, a Nagasaki woman, aged 22 years. This patient was in the Mitsubishi weapons factory one Km. from the center of the explosion inside a concrete building. She was dressed in a blue, one-piece suit with long trousers and Japanese sandals. She suffered no burns or wounds. One hour after the explosion she vomited. Nausea continued for two or three days with loss of appetite.

Beginning on August 13th, she had diarrhea for five days but there was no blood in the stool. Her hair began to fall on the 26th of August and she became bald. From September 1st to 7th she suffered from bleeding of the gums and tonsillitis with high fever. During that time she also had severe nose bleeds.

Since September 15th (now October 6th) she had had poor vision in the right eye. She menstruated five days before the explosion. She began to bleed again on the 25th and had been bleeding continuously at the time these studies were made.

On September 24th, the leukocyte count was 8,600, and the sedimentation rate was 50 mm. for the first hour and 64 mm. in two hours.

Eye examination. On September 21st, the eyegrounds were examined at Shinkozen Hospital and the following descriptive note written:

"Examination of the fundus of the right eye (fig. 3) reveals an appreciable amount of retinal edema generally, particularly pronounced in the macular region. The veins and arteries are full and of good color. There are no pathologic changes in the optic discs. In the foveal region is a deep-red, preretinal hemorrhage one-fourth disc diameter in size and laterally oval in shape. The lesion shows marked bulging into the vitreous and the borders are very sharply defined. Above this is a very much larger, although similar lesion, about three disc diameters in size. This lesion is elevated and

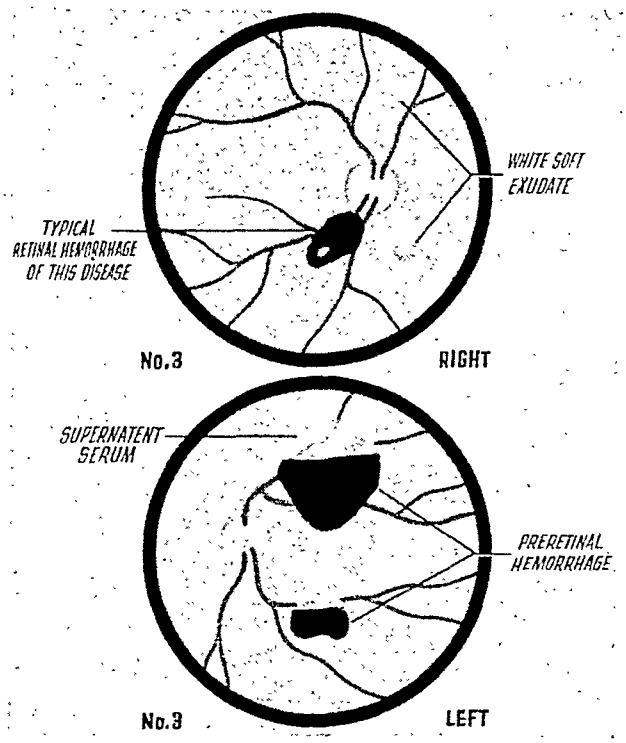

Fig. 2 (Flick). Both eyegrounds of Case 3, showing large lesions.

the lower margin is very sharp. The upper margin is horizontally straight. The lesion is situated 1 to 2 disc diameters from the papilla.

"Scattered about in the intervening retina are numerous small flame-shaped hemorrhages and several white, fluffy, elevated exudates, particularly on the nasal side. The left fundus shows no hemorrhage but numerous exudates of the soft white type."

On October 5th, 15 days later, the following note was made on reëxamination of the eye grounds: "The large preretinal hemorrhage above the macula is 2½ disc diameters in size and shows little evidence of absorption. The hemorrhage in the macula shows some evidence of absorption and has a whitish spot in the center. One small fresh exudate is present with no hemorrhage around it."

Case 2

Hirota, a Nagasaki woman, aged 19 years, had been ill since August 19th. Her only symptoms were severe weakness and poor vision in the left eye. The leukocyte count on admission was 3,300. She had been one Km. (0.6 miles) from the center of the explosion. The right eye was normal in every respect. The left eye, with pupil dilated, showed blood behind the lens with oblique illumination. The fundus could be dimly seen, and it seemed likely that there was detachment of the lower portion of the retina.

Case 3

History. Matuda, a Nagasaki woman, aged 19

years, was one Km. (0.6 miles) from the center of the explosion, inside, at the time of explosion. She became ill on September 8th and developed sore throat, fever, petechiae of the skin, and extreme weakness.

Eye examination. "The right fundus (fig. 2) showed numerous massive hemorrhagic extravasations. Below and temporal to the disc is a very large preretinal hemorrhage that has burst forth from the nerve-fiber layer and protrudes into the vitreous. The lower portion of this lesion is of a yellowish color similar to the so-called 'Roth spot' seen in sepsis. Many small, whitish, elevated, fluffy exudates are seen scattered over the intervening retina. The disc is normal. The large hemorrhage seems to cover the inferior temporal artery and vein near the disc. The left fundus (fig. 2) shows two large preretinal hemorrhages, a very large one above the disc and a smaller one below. These lesions are, respectively, 4 and 3 disc diameters in size. The upper one has an irregular lower border and a flat upper border indicating the level of the settled red cells. The surrounding retina is extremely edematous and the supernatant fluid is slightly cloudy. Numerous small white fluffy exudates are seen scattered about."

CASE 4

Yoshino, a Nagasaki man, aged 64 years, had been ill since August 29th with weakness. He had been only 100 meters (0.06 miles) from the explosion, inside a house. His leukocytes numbered 1,100. Only the right eye (fig. 3) could be examined.

"There are no changes in the optic disc. A small area 1½ disc diameters in size surrounds the inferior temporal vein and consists of a speckled, whitish gray area, as if moth-eaten. The borders are sharp and there is no elevation. There is such a spot also located above the disc in relation to the superior temporal artery and vein. Near the lower spot is a very superficial nerve-fiber layer hemorrhage. One small preretinal hemorrhage is seen just above the disc."

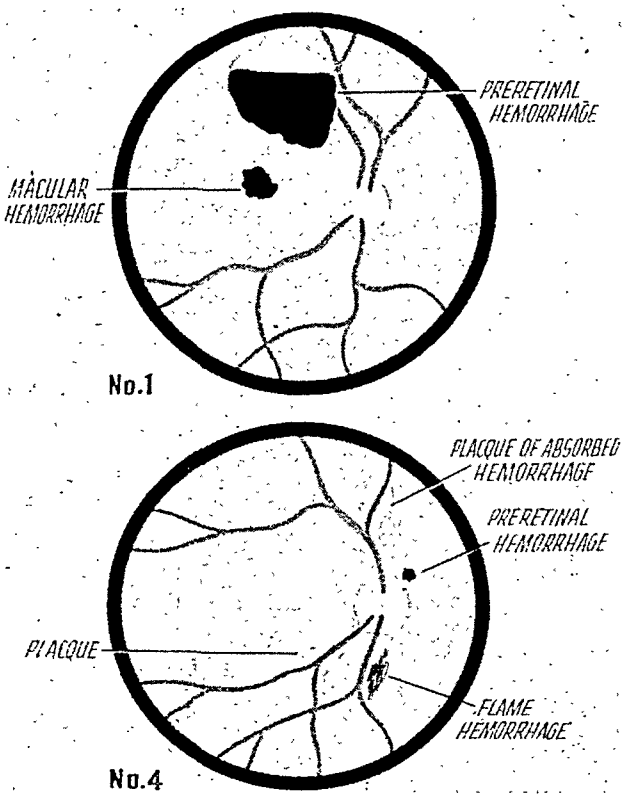

Fig. 3 (Flick). Right eyeground of Case 1, showing macular hemorrhage. Right fundus of Case 4 shows plaques of absorbed hemorrhage.

CASE 5

Miyasaki, a Nagasaki woman, aged 25 years, began her illness on September 5th. The white-cell count was 3,200. There was a moderately large globular hemorrhage of the lower portion of the right fundus.

CASE 6

Matsubayashi, a Nagasaki man, aged 49 years, had been ill since September 14th with ill-defined symptoms. The white-cell count was 7,800. The eyegrounds showed numerous white, soft exudates but no hemorrhage.

CASE 7

Tasaki, a Nagasaki woman, aged 16 years, was at the center of the explosion inside a concrete house. She had been ill since September 5th with extreme weakness. The white-cell count was 2,400. The eyegrounds showed globular hemorrhages and white, soft exudates. The doctors who had treated numbers of the cases said she would surely die.

CASE 8

Tawara, a Nagasaki man, aged 20 years, was also at the center of the explosion inside a concrete house. He became ill on August 26th with extreme prostration and weakness. His white-cell count was 3,100. The eyegrounds showed several large subhyaloid hemorrhages and some white, soft exudates.

CASE 9

Ito, a Nagasaki woman, aged 24 years, had been ill since September 7th. This patient had been 600 meters (one mile) from the center of the explosion, outside. This patient was in extremis. The white-cell count was 1,500. The eyegrounds showed large, globular preretinal hemorrhages, many flame hemorrhages and small, soft, white exudates.

CASE 10

Hashimoto, a Nagasaki woman, aged 14 years, gave no history. The vitreous of the left eye was almost entirely obscured by dense hemorrhage, the lower portion only being visible with the ophthalmoscope. In the right eye were seen a large peripapillary hemorrhage as well as flame hemor-

Fig. 4 (Flick). Lesion of nerve-fiber layer close to nervehead, showing swelling and displacement of outer retinal layers.

rhages and vitreous hemorrhages. There were many white, soft exudates but no papilledema. The leukocyte count was 4,000.

CASE 11

Hashimoto, a Nagasaki man, aged 50 years, was entirely epilated. He had been 500 meters (0.3 miles) from the center of the explosion. There was one small flame hemorrhage temporal to the right disc but no exudates. Leukocyte count was 2,400.

CASE 12

Narita, a Nagasaki woman, aged 32 years had been two Km. (1.2 miles) from the center of the explosion, indoors. There was complete epilation. She had had diarrhea for two days and had been ill since August 14th. There were numerous small white exudates and one small splinter hemorrhage.

CASE 13

Kurokawa, a Nagasaki woman, aged 31 years, had been one Km. (0.6 miles) from the center of the explosion, outdoors. She had become ill on August 18th. The white cells numbered 6,100. There was one small exudate in the left lower fundus.

CASE 14

Yokoyama, a Nagasaki woman, aged 59 years, had, at the time of the explosion, been in a wooden house one Km. (0.6 miles) from the center of the explosion. She became ill on August 9th, the day of the explosion, probably due to the fact that she suffered many primary injuries. The white-cell count was 3,600. There was one small exudate in the right upper temporal region near the disc.

CASE 15

Momoki, a Nagasaki girl, aged 14 years, became ill on September 11th, with nosebleeds and fever. She had been only 200 meters (0.12 miles) from the center of the explosion inside a wooden house. The white cells numbered 1,200. There were great numbers of small exudates scattered about the posterior pole of both eyes. There was also much general retinal edema. One flame hemorrhage extended onto the disc in the left eye.

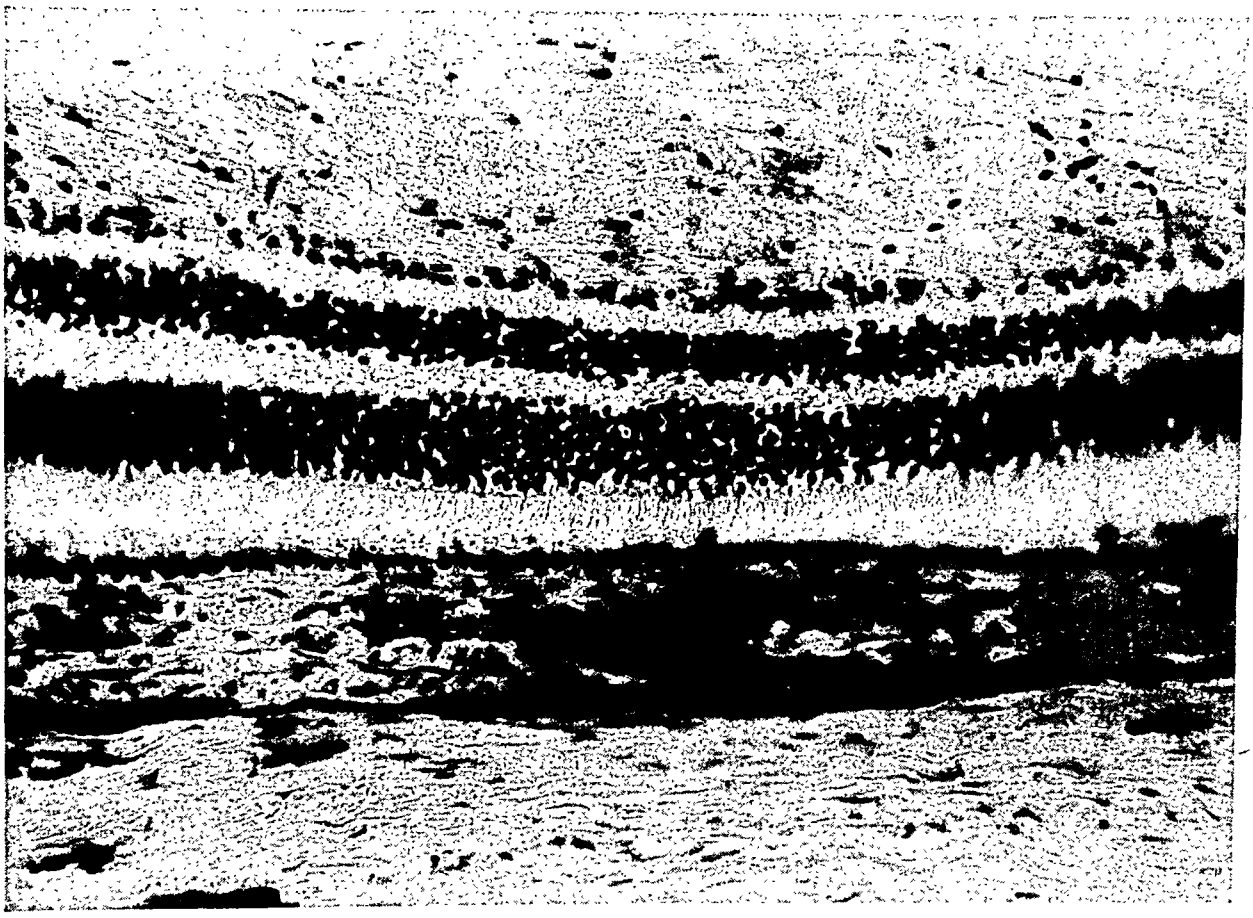

Fig. 5 (Flick). Higher-power view of same lesion as in Figure 4. The granular appearance and loss of fibrillar structure in the nerve-fiber layer in this lesion can be seen.

CASE 16

Kitagawa, a Nagasaki man, aged 67 years, had been outdoors two Km. (1.2 miles) from the center. He had been continuously ill since the explosion with febrile illness. There were no other manifestations of radiation injury. The white count was 13,800. There was a small, white exudate near the left disc, and splinter hemorrhages surrounded the right inferior temporal vein.

CASE 17

Kataoka, a Nagasaki woman, aged 25 years had been 1,500 meters from the center of the explosion, outside. She became ill on August 11th. There was generalized flash burn over neck, arms, and legs. No other evidences of radiation injury were present except the marked oral sepsis with gingivitis and hemorrhagic ulceration of the throat. The eyegrounds showed many white exudates.

CASE 18

Iwanaga, a young Nagasaki woman, aged 18 years, was inside a wooden building at the time of the blast, 1,700 meters away (1.02 miles). She lost her hair on August 25th and became quite ill on September 1st, with gingivitis, sore throat, purpuric spots on the skin, and bloody sputum. The eyegrounds showed one large typical hemorrhage.

CASE 19

Tsujimaru, a Nagasaki woman, aged 38 years was standing in the open doorway toward the blast at the time of the explosion. This was approximately 1,600 meters (one mile) from the center. Two weeks later she began to suffer from bleeding gums and pharyngitis. The left fundus showed one flame hemorrhage.

CASE 20

Sugino, a Nagasaki woman, aged 56 years, was standing in a wooden house near Urakami station, Nagasaki, 800 meters from the center (0.48 miles). There were no burns or wounds. Beginning two weeks after the explosion she became ill with headache, fever, and prostration. Many small hemorrhages of the flame type and many small exudates were found in the eyegrounds.

CASE 21

Kawano, a Nagasaki woman, aged 23 years, had been standing in a wooden house 1 Km. (0.6 miles) from the center. She gave a history of having soreness of the gums and headache for an indefinite period of time. The hair began to fall on August

17th. From August 10th to 17th, she had a temperature of 39° to 40°C. There was a small wound of the left hand and some bruises but no burns. The last menstrual period was July 1st. Examination with the ophthalmoscope revealed one small exudate in one retina, no hemorrhages.

CASE 22

Nanri, a young Nagasaki woman, aged 20 years, was sitting indoors working as a secretary in the Mitsubishi arms factory one Km. (0.6 miles) from the center. She began to notice a dizziness on September 5th. She also began to notice at that time a soreness of the gums which lasted about eight days. She had a headache and fever up to 40°C. On September 9th she began to have diarrhea with 2 to 3 soft, reddish stools per day. On September 5th: white-cell count, 500; red-cell count, 3.4 million; September 10th: white-cell count, 3,200; September 22nd: white-cell count, 4,800. The left eyeground showed one small exudate.

CASE 23

Fujihara, a Nagasaki man, aged 24 years, was a medical student at the Nagasaki Medical College located 500 meters from the center. He was inside a heavy concrete building. On August 29th, he developed a temperature up to 39°C., with angina of the throat which was diagnosed as diphtheria but persisted until September 14th. During this time the white cells numbered 12,000; at the time of this study they numbered 6,000. He also suffered a compound fracture of the left femur and lacerations of the arms, head, neck, breast, and left side of the abdomen. Eyegrounds showed two small, thin exudates but no hemorrhages. (Practically all persons in the medical-school area died.)

CASE 24

Kaneshiro, a Nagasaki man, aged 34 years, was at Ohashi, 1.2 Km. from the center. He was standing outside. There was deafness of the right ear without pain or tinnitus. Numerous minor burns were present. There were several small exudates and splinter hemorrhages in the eyegrounds.

CASE 25

Ota, a Nagasaki man, aged 67 years, was 800 meters (0.48 miles) from the center of the explosion inside the arms factory at Urakami. He was standing up outside. The eyegrounds revealed many small exudates and splinter hemorrhages.

CASE 26

Nakamura, a Nagasaki youth, aged 18 years, was also in the arms factory, standing up, 800 meters (0.48 miles) from the center. He began to lose his hair on August 29th. There was marked diffuse retinal edema but no local or focal lesions were seen.

CASE 27

Hirana, a Nagasaki man, aged 51 years, was

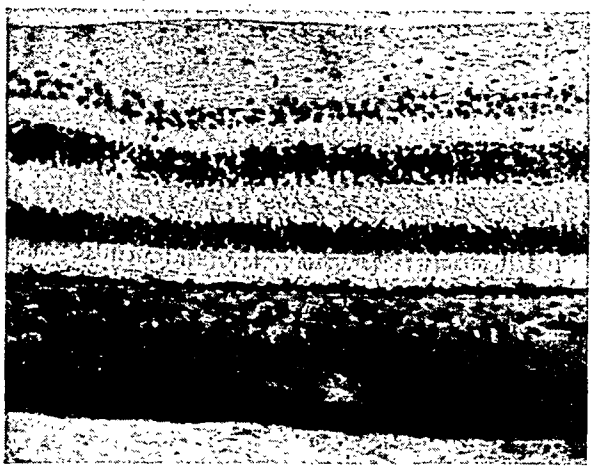

Fig. 6 (Flick). Another lesion in the same section. Note the excellent structural preservation of the retinal elements.

1,700 meters (1.02 miles) from the center, standing outside but protected by a brick wall 4 meters away. From August 20th to 30th he had diarrhea of 1 to 2 stools a day. An absorbing hemorrhage was seen in the right eye. The left eye showed a typical "Roth-type" hemorrhage with white distal portion.

CASE 28

Inaba, a Nagasaki man, aged 22 years, was at the arms factory at the time of the explosion. He was admitted to the hospital on the day of the explosion but his present illness did not begin until August 19th when his hair began to fall. He was bald for about one month when his hair began to grow back. In the meantime he had sore gums, pharyngitis, and diarrhea with black stools. The eyegrounds showed many exudates in the right fundus, nasal to the disc. There were no hemorrhages. The left fundus showed changes similar to those in the right, but there were some absorbing hemorrhages in the left.

CASE 29

Takemoto, a Nagasaki woman, aged 43 years, was at Ohashi near the arms factory. Epilation began on August 16th. She had a severe "cold" with fever up to 40°C. On August 23rd, white-cell count, 800; red-cell count: 4.04 million; Hemoglobin, 55 percent; color index, 0.68. On September 12th, white-cell count, 4,300. The left fundus showed numerous absorbing hemorrhages of the lower portion.

CASE 30

Furuta, a young Nagasaki woman, aged 18 years, was in Ohashi in a wooden house. She states that at the time of the explosion she was blinded and could not see for three days. From August 15th to 18th she had fever up to 40°C. At this time the cuts she had began to be infected. Fever recurred, September 4th to 14th, up to 40°C., and there was soreness of the gums and tonsillitis.

She also complained of nausea, increased salivation, and pain in the abdomen. There were three small exudates in the upper nasal fundus of the right eye. The left eye showed small exudates with some subsiding retinal edema.

CASE 31

Ando, a Nagasaki youth, aged 18 years, was in a wooden house. There was inability to open the mouth for a long time (tetanus?). There was diarrhea for two days without blood on August 28th and 29th. There was some infection of the right wrist reaching its height about September 1st. Examination of the eyegrounds revealed one small hemorrhage of the "Roth" type.

CASE 32

Niigaki, a Nagasaki woman, aged 25 years, was near the Mitsubishi arms factory and was injured by falling building material. She was three months' pregnant and abortion occurred on September 1st. She developed pallor and gingival bleeding on September 20th that lasted five days. On September 24th, the sedimentation rate was 140 for one hour, and 168 for two hours. The leukocyte count was 2,500. There were many flame and preretinal hemorrhages, and exudates in both eyes.

CASE 33

Okamura, a Nagasaki woman, aged 30 years, was located 500 meters (0.3 miles) from the center, inside a wooden house. On September 9th her hair began to fall out. On September 20th the white cells numbered 2,400. She had missed one menstrual period. The eyegrounds showed one flame hemorrhage.

CASE 34

Hirayama, a Nagasaki woman, aged 30 years, gave no history. There were preretinal and flame hemorrhages in the eyegrounds, as well as some exudates of the usual type.

CASE 35

Morinoki, a Nagasaki man, aged 59 years, had been 400 meters west of the Ohashi arms factory or about 1,200 meters (0.72 miles) from the center of the explosion. He was standing outside. Beginning on August 25th, there was increasing weakness, swelling, tenderness and bleeding of the gums, and fever up to 41°C. He complained of pain in the chest and some ringing in the ears. On admission to the hospital it was found he had sloughing of the anterior portion of the soft palate which seemed to result from the extension of the gingival ulceration. Ophthalmoscopic examination revealed several soft exudates and splinter hemorrhages extending to the disc. Reexamination eight days later revealed one small exudate temporal to the left disc. The hemorrhages were seen to be absorbing.

CASE 36

Kagiya, a Nagasaki man, aged 23 years, was two Km. (1.2 miles) from the center of the explosion. He had diarrhea and sore throat with nose bleeds on September 8th. A few splinter hemorrhages, found in the eyegrounds, had completely disappeared in eight days.

CASE 37

Azuma, a Nagasaki man, aged 31 years, was sitting inside the arms factory 800 meters from the explosion (0.48 miles). He began to notice dizziness and weakness on September 17th and noticed that his skin was covered with petechiae. There were also painful soreness of the gums, headache, and falling of the hair which started on August 19th. There was fever up to 40°C. and tonsillitis. The eyegrounds showed many flame and preretinal hemorrhages and also exudates. On reëxamination eight days later, hemorrhages were recorded as very numerous in both fundi. These were of the flame and preretinal type. There were a few exudates. A few typical "Roth-type" lesions were seen, related to the left inferior temporal artery. There was one exudate just temporal to the right disc. Two preretinal hemorrhages, related to the superior and inferior temporal arteries of the right fundus, were seen.

CASE 38

Kuromiya, a woman, aged 34 years, was inside a wooden house 1.5 Km. away from the center at the time of the explosion. The hair began to fall on August 22nd. The patient states she had bloody diarrhea for several days after the explosion. She had not menstruated since the explosion. On September 3rd, the white cells numbered 2,000, and the sedimentation rate was 130 for the first hour and 160 for two hours. Both eyegrounds showed exudates and hemorrhages. Reëxamination eight days later showed one exudate nasal to the left disc. There was an area of absorbed hemorrhage around the proximal part of the superior nasal artery. This had the appearance of the typical "Roth-type" hemorrhage of this disease. There were no lesions seen in the right eye.

CASE 39

Matsuo, a Nagasaki man, aged 49 years, had been at Ohashi factory 1 to 2 Km. (0.6 to 1.2 miles) from the center and had been standing outside. The hair began to fall on August 23rd. Sore throat with fever up to 39°C. came the first week in September. He also had petechial eruption in the skin and sore, painful gums. His record showed:

	Sept. 6	Sept. 8	Sept. 10	Sept. 13	Sept. 15	Sept. 20	Sept. 24
R.B.C.	3.7	3.3	2.7	2.2	2.2	2.6	3.0
W.B.C.	600	500	700	1,100	3,400	3,600	3,000
H.B.G.	65%	60.9%	50%	55%	48%	50%	58%
C. Ind.	0.89	0.91	0.9	1.2	1.0	0.96	0.96
Bl. T.	3½	12	12	10	7	6	5
Cl. T.	3.16	3.16	3.16	3.15	3.14	3.14	5

On September 27th the examination revealed many exudates and hemorrhages of all kinds. On October 5th, there were numerous exudates with sharp borders indicating absorption but no hemorrhages were seen. In the right eye, there was a lesion of the upper temporal region and, in the left eye, one below the disc.

CASE 40

Ishita, a Nagasaki man, aged 42 years had been at the Ohashi factory inside a wooden house at the time of the explosion. On August 19th he had weakness, sore gums, and falling of the hair. He was hard of hearing in the left ear. Many exudates were seen in both fundi. Reëxamination eight days later showed the exudates to be smaller, whiter, more waxy and they seemed to be broken up into numbers of smaller deposits.

CASE 41

This Hiroshima man, aged 24 years, had been 500 meters (0.3 miles) from the center of the explosion of the bomb that had fallen on Hiroshima. He was examined on September 10th and had had purpuric anemia for five days at that time. His leukocyte count at that time was 2,000. The eyegrounds showed massive retinal hemorrhage around the discs in both eyes. There were subhyaloid and nerve-fiber hemorrhages and "Roth" spots in the right eye. The hemorrhages had sharp margins indicating their preretinal location. There were many edema exudates and some swelling of the macula but no changes in the discs.

CASE 42

This Hiroshima man, aged 25 years, was at the center of the explosion. He had been ill 10 days by September 10th. The leukocyte count was 900. The eyegrounds showed large edema exudates near the discs with globular subhyaloid hemorrhages. It was the hemorrhages in this case that first suggested to me their similarity to Roth spots. There was a macular hemorrhage in one eye.

CASE 43

Yoshida, a Hiroshima man, aged 26 years was seen in Fukuoka where he had been evacuated from Hiroshima after the bombing. Patients from both areas were being studied together at the Imperial Kyushu University Hospitals. He suffered from sore gums, petechiae, and fever which had its onset about August 24th. His record showed:

Date	White-Cell Count
September 9th	2,300
September 22nd	2,700
September 29th	3,100
September 30th	6,800

The eyegrounds showed flame hemorrhages.

CASE 44

Matsumoto, a Hiroshima woman, aged 45 years, was 1.5 Km. (0.9 miles) from the center of the explosion. She had petechiae, loss of hair, sore throat, and gingivitis with fever. These entries showed:

Date	White-Cell Count
September 9th	2,500
September 22nd	2,700
September 27th	3,600
September 30th	3,800

The eyegrounds showed many exudates but no hemorrhages.

CASE 45

Iwatsu, a Nagasaki girl, aged seven years, was one Km. from the center of the explosion. She developed petechiae and epistaxis.

Date	Red Cells	White Cells	Hemoglobin
September 10th	2.3	2,800	45%
September 13th	2.1	1,200	54%
September 17th	1.5	1,200	46%

There were exudates and flame hemorrhages in the eyegrounds.

CASE 46

Imafuku, a Nagasaki man, aged 31 years, was a student in the Nagasaki Medical College, one Km. (0.6 miles) from the center. The onset of the illness was September 13th, when he developed petechiae, fever, and angina with marked painful involvement of the tongue. He was examined at Kyushu Imperial University. There was no epilation.

Date	Red Cells	White Cells	Hemoglobin
September 13th	3.6	5,500	——
September 18th	——	——	51%
September 30th	1.74	3,800	——

The retina showed flame hemorrhages.

CONCLUSION

The transient nature of the condition and the chronologically short period over which the studies were made tend to relegate to the order of indulgent speculation any definite conclusions as to the pathogenesis of these lesions. As a result of repeated examinations of the same individuals and of repeated examinations of the same lesions it seemed likely that the exudative lesions represented the milder involvement. This is borne out statistically in Table 1. It seems that those individuals showing both hemorrhage and exudation were on the average closer to the site of the explosion and had lower white-cell counts than did those with either hemorrhage or exudation alone. The witnessing of a transition from the fluffy

exudate to the "Roth"-type hemorrhage and preretinal hemorrhage was rather impressive. It would seem logical to conclude that local areas of the retina could become swollen by transudation of serum through the walls of hyperpermeable capillaries in the presence of anemia, oligocythemia, and consequent lowered oxygen tension in the blood. If this process were to become so intense as to cause tissue breakdown in the lesion itself as a result of stasis and anoxemia, the extravasation of whole blood elements could occur superimposing itself on the original lesion, coming to surround it as "the hemorrhage with the white center."

The location of these lesions near large vessels is explained by the increased intravascular pressure in vessels of larger size. Once engendered by complete vascular rhexis the bleeding is not halted or modified by the clotting mechanism since practically none exists. The tendency of the preretinal blood to settle in layers is no different from its behavior in the sedimentation test tube. The spotty localization of the retinal lesions is probably based on slight local anatomicophysiologic differences in the circulation in the fine branches of the terminal retinal vessels.

It seems safe to conclude that the ocular lesions here described are directly related to the deficiency in blood elements and in no way directly related to the action of radiant energy on the eye. The lesions were observed to disappear in those individuals recovering from the hematopoietic depression with no residual damage to the eye. It is felt that this healing occurred in all patients who survived the irradiation and that no permanent residual damage of permanent nature resulted from the retinal lesions. As to the vexatious question of radiation damage to the lens, time alone will tell.

THE ROLE OF THE DIENCEPHALON IN REGULATING OCULAR TENSION*

ERNST SCHMERL, M.D.,† AND BERNHARD STEINBERG, M.D.
Toledo, Ohio

This study is a part of an investigation of factors which influence ocular tension. In a previous publication[1] the normal range of ocular tension and rigidity was ascertained in rabbits with a Schiøtz tonometer. Average values and standard deviations were established. The purpose of this presentation is to determine the role played by the cerebral cortex and the diencephalon on ocular tension in rabbits and dogs.

Certain hypnotic drugs are assumed to have a more or less selective action on various regions of the brain. These drugs were used by other investigators to evaluate functional differences. Pick and his co-workers[2-5] determined that paraldehyde and chloral hydrate depress mostly the cerebral cortex; whereas, barbiturates act mainly upon hypothalamic centers. These observations inspired several investigations which in a sense tended to confirm Pick's findings. Barbiturates were found to be antagonistic to the analeptic effects of picrotoxin, ephedrine, and benzedrine which act on the brain stem.[6-8] Masserman's[9] work indicated that sodium amytal, a barbiturate, diminished or abolished in cats the sympathetic and emotional mimetic reactions of the hypothalamus to faradic stimulation. On the other hand, excitation of the cerebral cortex exerted no influence on the responses of the skeletal neuromuscular mechanism. Bender and O'Brien[10] found that barbiturates either decreased or altered nystagmus due to disease of the brain stem.

On the basis of these reports, paraldehyde and pentobarbital sodium (nembutal) were employed in the following experiments to differentiate the functional activity of the cerebral cortex from that of the diencephalon in relation to ocular tension. Additional data on the subject were supplied by Lowenstein and Schoenberg[11, 12] who demonstrated in their pupillographic studies the possible presence of a central sympathetic factor which is assumed to play a role in the production of primary simple glaucoma. The diencephalon includes the thalamus, the hypothalamus, and the hypophysis, the mammillary, and the pineal bodies, the trigonum habenulae, and the posterior commissure.

MATERIALS AND METHODS

Rabbits of 1 to 2 years of age and adult dogs were used. The ocular tension was determined tonometrically. In one phase of the investigation, paraldehyde was given orally (1.5 cc. per Kg. body weight) and diluted with water in proportion of 1 to 8. Pentobarbital sodium was injected intravenously (0.45 cc. per Kg. body weight). The concentration of both narcotics was sufficient to induce a moderately deep narcosis for a few hours. In another phase of the investigation, the effect of hypotonic solution was studied on narcotized animals. Immediately prior to injection of pentobarbital sodium or paraldehyde, 40 cc. of distilled water per Kg. of body weight was administered to the rabbits by mouth. The ocular tension was determined before and during narcosis at intervals of 2 to 20 minutes for two hours. The 5.5- and the 10-gm. weights were used. Care was exercised during narcosis to avoid extraneous pressure on rabbits' eyes. Narcosis was induced and the ocular tension was determined on 10 to 20 different occasions on each of the animals.

Eight normal rabbits and three dogs were employed in the experiments. In addition, three rabbits with abnormal changes were

*From Toledo Hospital Institute of Medical Research. This work was supported by a grant from the Snyder Ophthalmic Foundation.

† Research ophthalmologist of the Snyder Ophthalmic Foundation.

studied. Two of the abnormal animals had congenital hydrophthalmos. In the third animal, a secondary glaucoma was induced in the left eye with colloidal iron.

The eyes of the abnormal animals showed the following changes: In the experimentally induced glaucoma six weeks after introduction of colloidal iron, the cornea contained several superficial blood vessels, the iris was atrophied, there were several minor lens opacities, the left anterior chamber was deeper than the right, and there was a ring of white tissue, 1.5-mm. wide, inside the corneal limbus. Five months after induction of glaucoma, the left papilla was dark gray with a peripheral dark-red zone and the excavation was about two diopters.

In one of the animals with a congenital disorder, there was an increase in connective tissue between the eyeballs and the upper lids of both eyes. The corneas were cloudy and the corneal diameters were approximately 18 mm. Both anterior chambers were deep. The fundus of the right eye had a large papilla with slight peripapillary atrophy but with normal medullated fibers and without excavation. In the left eye, the papilla was larger, gray-red, with peripapillary atrophy and missing medullated fibers.

In the second rabbit both corneas were cloudy with a pannus glaucomatosus. The parenchyma showed Fuchs's "Aufhellungsstreifen." The corneal diameters were 17 mm. The irides in both eyes contained many large blood vessels. The right fundus showed a red reflex, the left was indistinct and peripapillary atrophy was present.

Results

The results of the experiments are outlined in the accompanying charts in which are shown the degree and the rate of change of tension. The curves represent average measurements of changes in tension as they were determined with the 5.5-gm. weight. Standard deviations for the above measurements were equal to ±2.5 mm. Hg; whereas, under normal conditions for a two-hour period, the deviations are ±1.5 mm. Results with the 10-gm. weight showed no variations indicating that, at least tonometrically, there was no difference in ocular rigidity in the normal and in the glaucomatous eyes (figs. 1, 2, and 3).

The ocular tension in normal and glaucomatous animals under paraldehyde showed no significant changes (fig. 1). Upon injection of pentobarbital sodium, the normal

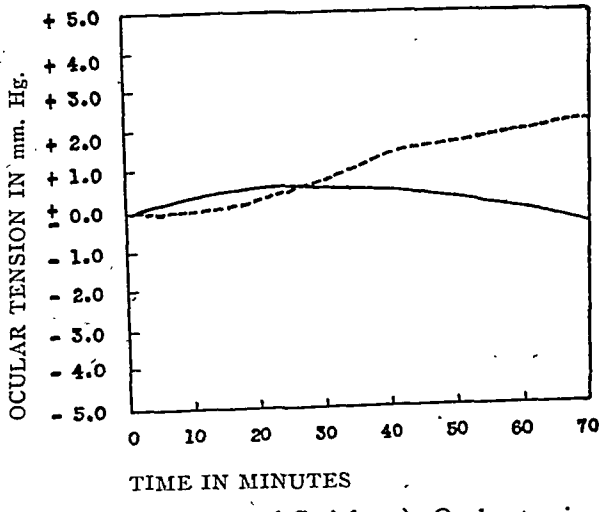

Fig. 1 (Schmerl and Steinberg). Ocular tension in normal rabbits (unbroken line represents 14 experiments) and glaucomatous animals (broken line—10 experiments) under the influence of paraldehyde. There are no significant changes in either group of animals.

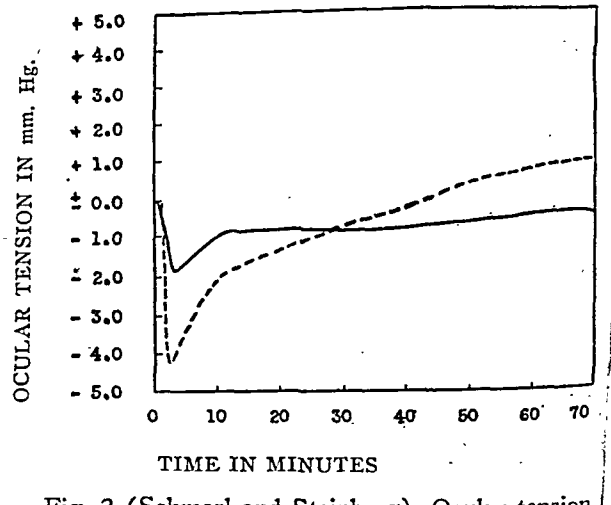

Fig. 2 (Schmerl and Steinberg). Ocular tension in normal (unbroken line—18 experiments) and glaucomatous animals (broken line—14 experiments) after injection of pentobarbital sodium. There is an immediate decrease in tension which shortly returns to normal.

and the glaucomatous animals showed an initial immediate decrease in tension which was followed by a return to normal (fig. 2).

Hypotonic solution (distilled water) was administered to normal and glaucomatous rabbits. The ocular tension showed a rapid and pronounced increase in the normal animals. The subsequent fall in tension occurred almost as rapidly. In the glaucomatous group of animals, the rise in tension was slower and less pronounced (fig. 3).

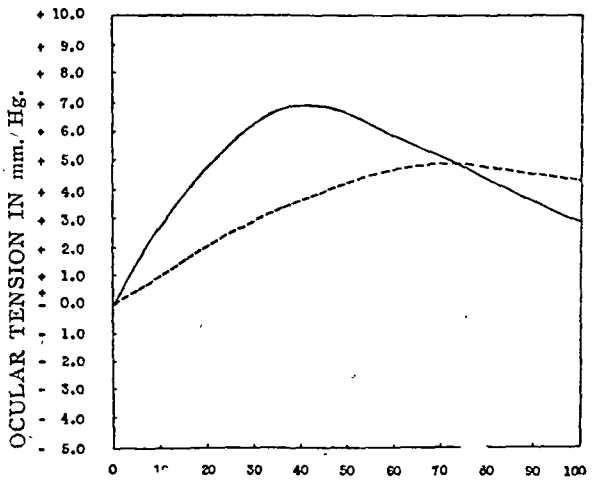

Fig. 3 (Schmerl and Steinberg). Distilled water was given orally to normal and glaucomatous rabbits and ocular tension determined in normal animals (unbroken line—16 experiments) and in glaucomatous animals (broken line—14 experiments). Note the rapidity of increase and decrease of ocular tension.

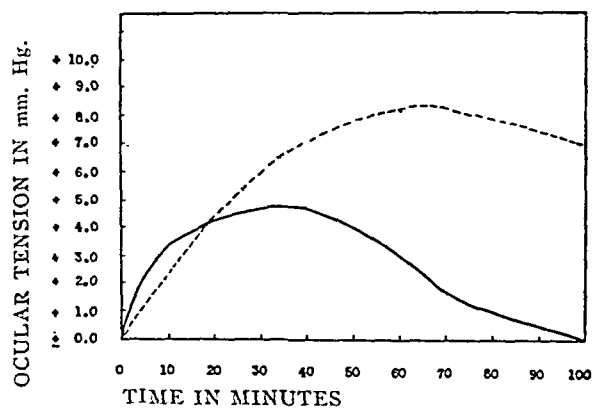

Fig. 4 (Schmerl and Steinberg). Ocular tension in normal (unbroken line—14 experiments) and glaucomatous animals (broken line—10 experiments) after introduction of distilled water and paraldehyde. The rise in ocular tension in the latter animals is rapid and pronounced. Compare with Figure 3. There is no significant change in the normal animals.

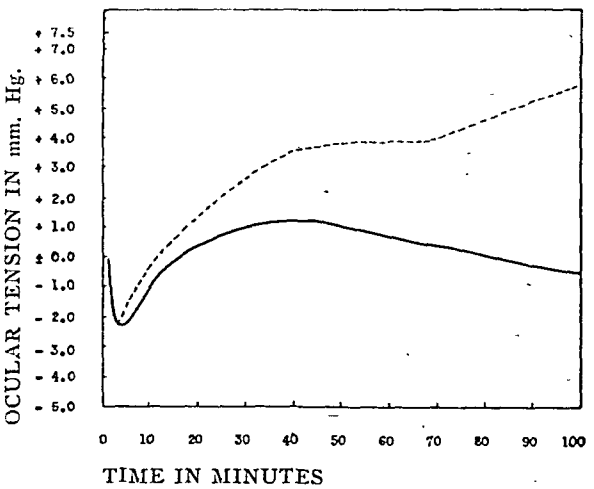

Fig. 5 (Schmerl and Steinberg). Ocular tension in normal (unbroken line—20 experiments) and in glaucomatous animals (broken line—14 experiments) with distilled water and pentobarbital sodium. The hypnotic inhibited the rise in tension in the normal and delayed it in the glaucomatous animals.

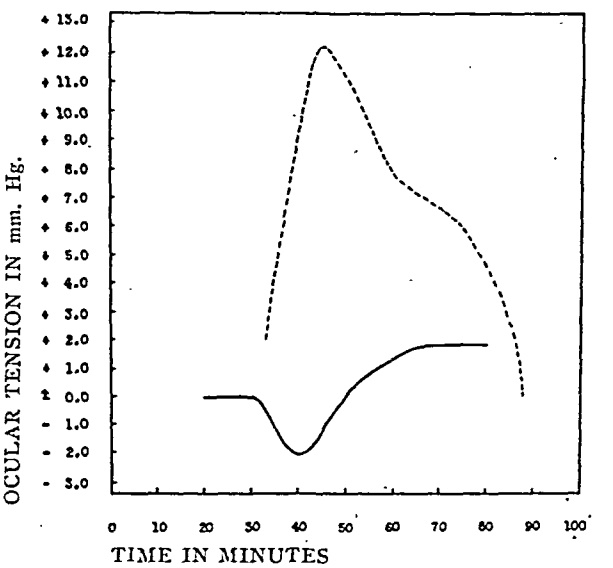

Fig. 6 (Schmerl and Steinberg). Ocular tension in a normal dog. Broken line represents tension following administration of paraldehyde and distilled water. Unbroken line represents tension following administration of pentobarbital sodium and distilled water.

Introduction of distilled water and paraldehyde into normal animals failed to change significantly the rise of the ocular tension

(fig. 4). On the other hand, in glaucomatous animals under similar conditions there occurred a considerably more rapid and pronounced rise in tension (fig. 4). The increase in tension was greater than obtained with hypotonic water alone (fig. 3).

Injection of pentobarbital sodium in animals to which distilled water had been administered showed no significant change in the ocular tension (fig. 5). Apparently pentobarbital sodium inhibited the rapid rise which occurred with distilled water alone (fig. 3). On the other hand, in glaucomatous animals after an initial delay, the tension became elevated to a degree equal to that without a hypnotic (fig. 3).

Introduction of pentobarbital sodium and of paraldehyde with distilled water in normal dogs paralleled the findings obtained in rabbits (fig. 6).

Summary and Conclusions

Paraldehyde, a hypnotic affecting primarily the cerebral cortex, produced no changes in the ocular tension of normal and glaucomatous animals. Paraldehyde also failed to inhibit the rise of tension in normal animals which were given distilled water. In glaucomatous rabbits under corresponding conditions, the rise in tension was more pronounced.

Pentobarbital sodium (nembutal), a hypnotic acting predominantly on the diencephalon, produced in normal and glaucomatous animals a slight immediate decrease in tension followed by a return to normal. There was also an inhibition of the usual rise in the ocular tension in normal animals which were given distilled water. The rise of tension in glaucomatous animals was delayed but not diminished.

It may be postulated, on the basis of these experiments performed under the conditions described, that the diencephalon contains a center or centers which exercise a regulating control of ocular tension. The experiments also suggest an instability of the diencephalic center or centers in glaucomatous animals.

CYSTIC MALIGNANT MELANOMAS OF THE UVEAL TRACT*

ROBERT E. KENNEDY, M.D.
Baltimore, Maryland

Cysts occurring in malignant melanomas of the uveal tract are chiefly of pathologic interest, but may, in themselves, present a clinical picture with a complicated diagnostic problem.

When cysts occur in ciliary body melanomas which extend behind the lens and in choroidal or iris melanomas which can be readily observed, there is no additional diagnostic problem. However, malignant melanomas projecting into the posterior chamber from the posterior surface of the iris, or from the ciliary body, may be difficult to differentiate from simple cysts. This diagnostic difficulty may be enhanced when malignant melanomas in this position become cystic. At least eight benign posterior-chamber cysts have been reported in the literature in which the eyes have been enucleated with the diagnosis of a malignant tumor.[1]

DIFFERENTIAL DIAGNOSIS

In the differential diagnosis, traumatic implantation cysts and retention or inflammatory cysts may be excluded if there is a negative history and no evidence of uveal inflammation. Developmental or spontaneous cysts of the iris stroma and pigmentary epithelium, particularly the latter, may be confused with malignant melanomas of the posterior chamber, especially since they may simulate a malignant melanoma closely, and occur in the older age groups.

Duke-Elder[2] lists the following diagnostic features of a cyst in the posterior chamber: multiplicity, tremulousness, mobility, presence of a notched margin, and, above all, translucency. However, the test of translucency by transillumination may be deceptive, since a cyst may have thick, pigmented walls and so appear solid. A tumor may undergo cystic changes with walls so thin the mass appears translucent. Thus while translucency may differentiate a cystic tumor from a solid tumor, it cannot differentiate between a benign cyst and a cystic malignant tumor. This is borne out by a patient seen by Hardy and reported by Doherty.[3] A 60-year-old white man had a black, spherical, pigmented spot on the pupillary border of the iris which was partially cystic by transillumination. Vision was normal. Because of its position, a complete removal of the mass by iridectomy was attempted. The tumor collapsed when grasped with forceps, and was excised through a wide keratome opening. A small pigment spot remained on the iris. Microscopic examination showed a malignant melanoma of the iris with cystic degeneration. The eye was later enucleated.

Diagnostic or exploratory puncture has been used to differentiate between a solid tumor and a cyst in the posterior chamber. This, however, is also unreliable, for, while an exploratory puncture may differentiate a cyst from a solid tumor, it cannot differentiate between a benign cyst and a cystic malignant tumor.

If a posterior-chamber tumor shows no evidence of cystic changes on transillumination or diagnostic puncture, it should be assumed to be solid and the eye enucleated. However, if either transillumination or diagnostic puncture indicates the possibility of cystic changes, it would appear the wiser course to remove the tumor by iridectomy, and await the pathologic report before deciding a more drastic surgical intervention.

REPORT OF A CASE

The complete clinical history and pathologic report of one case, which was studied in detail microscopically from serial sections, illustrates the type of lesions discussed.

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University.

History

V. H., a 74-year-old white man, was first seen in December, 1945, by Dr. Eldred W. Kennedy of Rochester, New York.

Over a period of five months, the patient's vision had gradually failed in the left eye. During this time there had been frequent attacks of pain accompanied by redness and lacrimation. There were no previous ocular symptoms and no history of trauma. There was a family history of malignant disease. The past history was not significant, and the physical examination was essentially normal for a patient of his age. Routine laboratory studies were noncontributory.

Eye examination

The right eye was normal, with corrected vision of 20/20. The intraocular pressure was 18 mm. Hg (Schiøtz).

The left eye had a visual acuity of 20/400, unimproved with lenses. The eye was entirely white and the cornea clear. There were no keratic precipitates, and the aqueous ray was negative. When observed obliquely with direct illumination, a small black tumor could be seen in the lower nasal quadrant which filled the posterior chamber between the iris and lens. The anterior chamber was of normal depth except at the lower nasal quadrant where the iris bulged forward at its root to touch the cornea between the 7- and 8-o'clock positions. The iris in this region appeared thinned out with separation of the stromal fibers and the iris crypts appeared very dark. A small, black-pigmented, crescent-shaped area was present in the iris stroma near, but did not extend to, the root of the iris above the tumor. The pupil was equal in size to that of the right eye, but was slightly elongated or pear-shaped, with the apex directed downward and nasally. This abnormal shape was due to stretching of the iris by the underlying tumor. The pupil dilated slightly with mydriatics, but not at the site of the tumor. The tumor was well outlined by transillumination and appeared solid. The lens was cataractous and only vague fundus details were seen. Intraocular pressure measured 23 mm. Hg (Schiøz), and the field was full by confrontation.

The mass was thought to be a tumor of the posterior chamber, probably a malignant melanoma, arising from the iris or ciliary body. While a posterior chamber cyst was considered, there was no history of trauma, and the mass appeared solid to transillumination. The patient was observed for a period of three weeks, during which time other consultants concurred in the diagnosis. Enucleation was advised and performed during December, 1945, under cyclopropane anesthesia. The patient was in good health, and there was no local recurrence 14 months later.

Pathologic examination

Macroscopic. The globe was fixed in 10-percent formalin and opened in a vertical plane. There were no lesions other than the tumor which was approximately 2 by 2 by 1 mm. It appeared as a pedunculated mass suspended from the crown of the ciliary body among the ciliary processes, and was adherent to the posterior surface of the iris.

Microscopic. Serial sections were cut from paraffin blocks and stained with hematoxylin and eosin stain, Verhoeff-van Gieson stain, Prussian-blue stain, and the Wilder reticulum stain.

Aside from senile changes the sections were normal except for the lesion to be described. On one side a tumor mass occupied the anterior portion of the ciliary body and replaced the ciliary muscle in that region (figs. 1 and 2). A large oval cyst arose from the anterior portion of the tumor and extended into one of the ciliary processes. The cyst wall was adherent to the peripheral three fourths of the iris and was composed of several layers of tumor cells covered with pigmented and nonpigmented epithelium. The cyst was lined by a flattened layer of tumor cells, and contained a large amount of serous exudate, cellular debris, and a few

pigment-laden macrophages. A bridging layer of tumor cells divided the cyst into a large and small loculus. The cyst bulged the iris forward to form a peripheral anterior synechia. Many pigment-laden macrophages were present in the iris stroma near its root. Pigmented tumor cells invaded the iris root and the trabeculum to the canal of Schlemm (fig. 3). The underlying cornea and sclera were not invaded. The tumor was made up of whorls of irregularly arranged, closely packed, spindle-shaped cells. The nuclei were large, oval, and deeply staining, and contained a delicate reticulum. Nucleoli were present in a few of the nuclei. There were

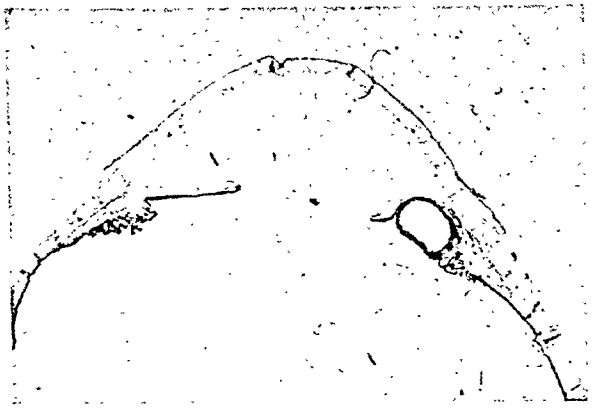

Fig. 1 (Kennedy). Posterior-chamber cystic malignant melanoma bulging iris forward to close angle. (E. W. Kennedy's case. Hematoxylin-eosin stain. Magnification, ×4.)

irregular areas of moderate pigmentation throughout the tumor, with both intra- and extracellular melanin granules. With the Wilder stain the reticulum fiber content of the tumor was marked, being more than 50 percent. The Prussian-blue iron stain was negative.

The pathologic diagnosis was cystic malignant melanoma of the ciliary body, spindle-cell type, predominantly subtype A.

Report of similar cases

There are three specimens in the Army Institute of Pathology, all of which are quite similar to the case here reported. These cases are as follows:

Case 1. Accession Number 71451 (contributed by Dr. L. Weston Oaks of Provo, Utah). Cystic malignant melanoma of the ciliary body. The patient was a 36-year-old trained nurse who is living and well six years after enucleation. The growth had been noticed four months before operation. A black mass behind the iris pushed the iris forward in the lower temporal quadrant. The iris stroma was attenuated, and the pigmentation normal. The mass appeared solid to transillumination. Corrected vision was 20/22 in the right eye, and 20/15 in the left eye. Intraocular pressure measured 13 mm. Hg

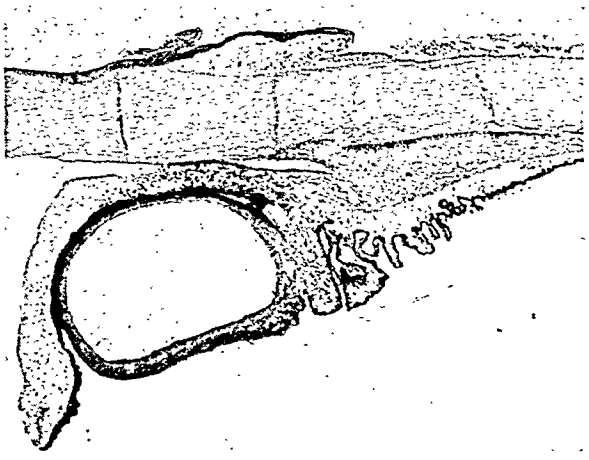

Fig. 2 (Kennedy). Higher power of Figure 1, showing extension of cystic melanoma into a ciliary process. Cyst is turned on pedicle so that section is to the side of tumor mass in ciliary body. (Hematoxylin-eosin stain. Magnification, ×10.)

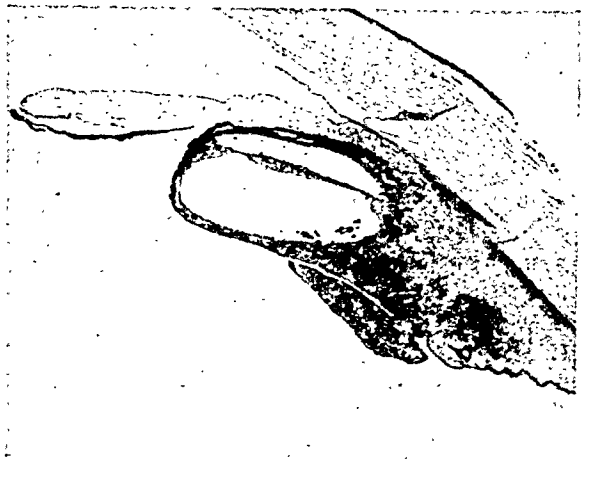

Fig. 3 (Kennedy). The same case as in Figure 2. Bilocular cyst arising from malignant melanoma of ciliary body, showing invasion of filtration angle to canal of Schlemm. (Hematoxylin-eosin stain. Magnification, ×10.)

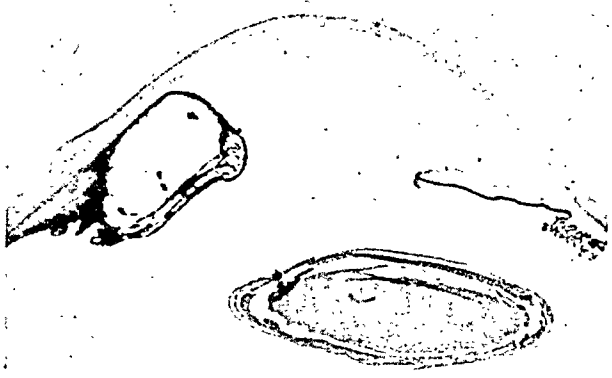

Fig. 4 (Kennedy). Posterior-chamber cystic malignant melanoma of ciliary body bulging iris forward to close angle. (Oaks's case. Hematoxylin-eosin stain. Magnification, ×4.)

(Schiøtz) in each eye, and the fundi were negative. The pathologic picture (figs. 4 and 5) was strikingly similar to the first case. The cyst was considerably larger and the adjacent wall was made up of many minute cystic spaces. The strands and islands of tumor cells within the cyst are evidence of walls of adjacent cystic areas which have broken down to coalesce.

Case 2. Accession Number 82272 (contributed by Dr. William L. Benedict of Rochester, Minnesota). Cystic malignant melanoma of the iris. The tumor involved the iris on one side and completely replaced the normal iris stroma, causing the iris to be several times its normal thickness. Bulging forward from the anterior surface of the iris into the anterior chamber, was a large cystic space, lined by tumor cells. The cell structure was made up of irregular whorls of spindle-shaped cells (fig. 6).

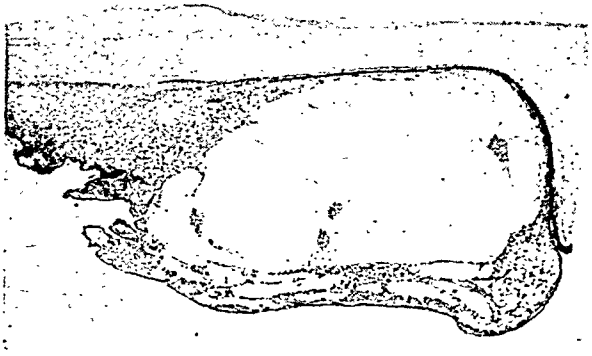

Fig. 5 (Kennedy). Higher power of Figure 4. Iris is pushed to back of cornea by cyst. Strands and islands of tumor cells within cyst are evidence of coalescence of adjacent cystic spaces. (Hematoxylin-eosin stain. Magnification ×10.)

Case 3. Accession Number 76213 (contributed by Dr. Charles C. Grace of St. Augustine, Florida). Cystic malignant melanoma of the ciliary body. The tumor extended forward into the root of the iris on one side. The anterior-chamber angle was closed off by the tumor. Many cystic spaces were present in the body of the tumor (fig. 7).

Typical cystic areas in choroidal malignant melanomas are shown in Figures 8, 9, and 10. These cases illustrate cystic malignant melanomas in various sites in the uveal tract.

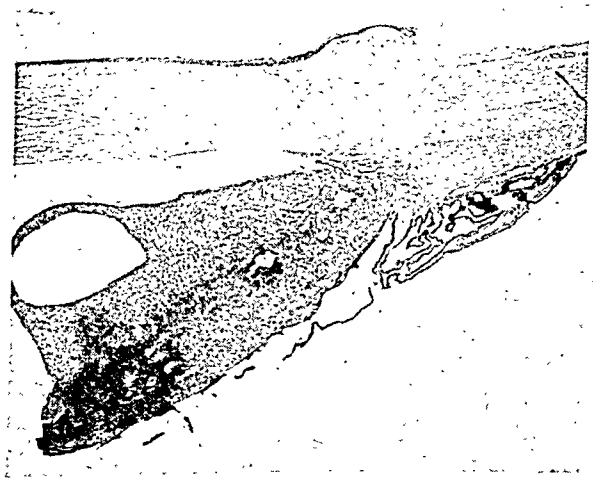

Fig. 6 (Kennedy). Cystic malignant melanoma of the iris. (Benedict's case. Hematoxylin-eosin stain. Magnification, ×10.)

Comment

Cystic areas in malignant melanomas are a degenerative change and a manifestation of tumor necrosis. Most malignant melanomas show minute focal points of necrosis, which are manifested by areas of irregularly staining cells showing pyknosis and karyolysis. The vessels of the growing tumor are large and there are no capillaries. As a result of this inadequate blood supply, there is a deficiency of nutrition. The result is death of the cells which are too far from the vessels to receive adequate nourishment. The

blood supply may also be limited by hyaline degeneration of the vessels, or by the actual compression of the vessel lumen by the growth of the tumor. The degenerated material in the focal areas of necrosis may become absorbed, forming minute cystic spaces, as shown in Figures 9 and 10.

The growth or development of the minute cysts may progress in many ways. A cyst may develop from a single area or from the coalescence of multiple cystic areas with further growth. Such cytotoxins may diffuse through the surrounding tumor tissue and may possibly have a histaminelike effect on the blood vessels in the tumor, causing an undue permeability and injury of the vessel walls which results in an extravasation of fluids into the cyst. A positive osmotic pressure in the cyst might increase its fluid content. The fact that these cysts grow by increase in their fluid content is suggested by the globular or spherical shape which they assume. This is apparent in sections showing larger cysts. In sections with small cysts, the spaces are usually more irregular in shape, indicating an earlier stage in development before growth has progressed.

Hemorrhage is another possible etiologic cause of cysts in malignant melanomas. Small hemorrhages in the tumor substance occur frequently in melanomas. Liquefaction of such a hemorrhagic area might leave a degenerative cystic space. However, the occurrence of red blood cells is very rarely seen in the cystic spaces, or the adjacent tumor tissue. In the first case, there was no evidence of old blood pigment in the tumor or cyst with the Prussian-blue stain.

Malignant melanomas are sometimes extremely vascular. Large blood-filled spaces may have only an endothelial wall between the tumor cells and blood spaces, and are sometimes lined with tumor cells in direct contact with the blood. These large blood spaces present a "pseudocystic" appearance which may be confused with true cystic spaces. An example of this is shown in Figure 11.

True areas of cystic degeneration may be

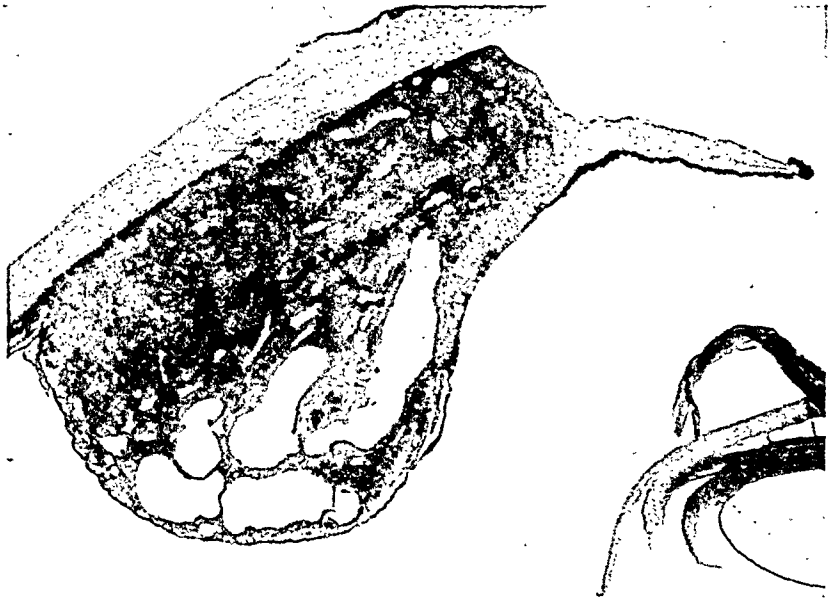

Fig. 7 (Kennedy). Multiple cystic malignant melanoma of the ciliary body invading the iris and obstructing the filtration angle. (Grace's case. Hematoxylin-eosin stain. Magnification, ×12.)

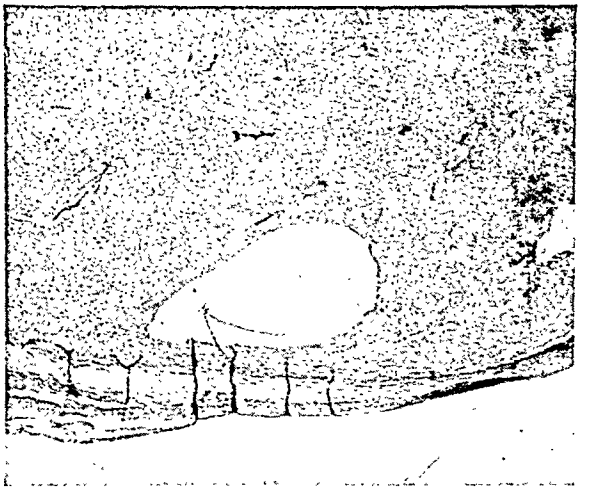

Fig. 8 (Kennedy). Typical cystic choroidal malignant melanoma. (Wilmer Pathology No. 7984. Hematoxylin-eosin stain. Magnification, ×10.)

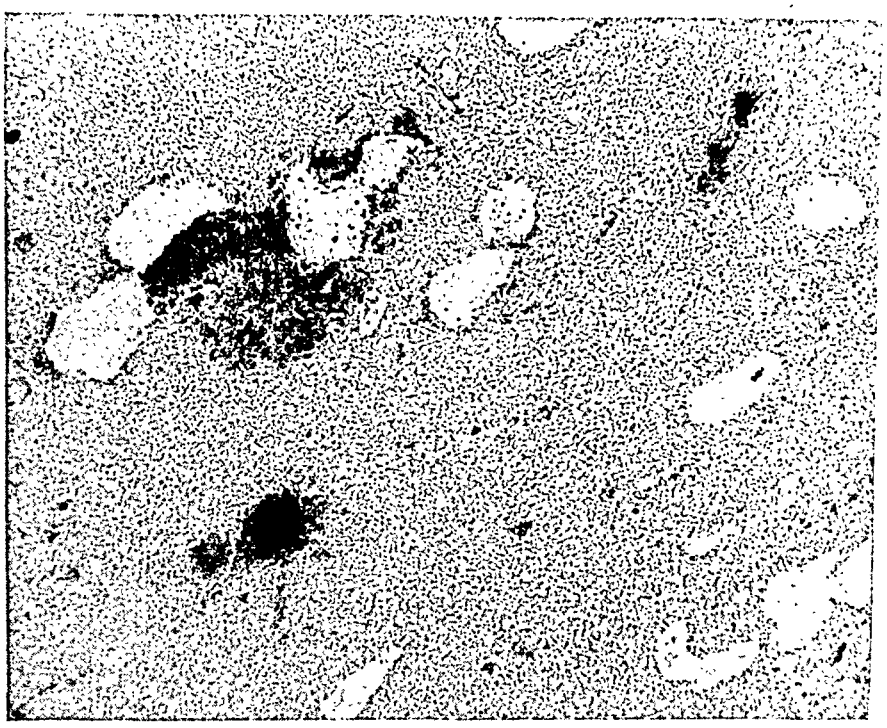

Fig. 9 (Kennedy). Focal areas of necrosis showing minute cysts. (Wilmer Pathology No. 3772. Hematoxylin-eosin stain. Magnification, ×40.)

differentiated from such blood spaces in malignant melanomas in many ways. The true cysts are usually much less numerous than the many vascular blood spaces. Red blood cells are very rarely seen in, or adjacent to, the true degenerative cysts, in contrast to the blood spaces which are usually filled. The cystic areas are usually lined by irregular cells projecting into the lumen, and many of the adjacent cells show necrosis. In contrast, the blood spaces are lined with endothelial cells, or a more regular wall of tumor cells. The cysts may show strands of tumor cells supporting islands of tumor cells as evidence of walls of adjacent cystic areas which have broken down to coalesce (fig. 5).

The Wilder stain[4] for reticulum fiber content and distribution may be used as a further point of differentiation between cystic and blood spaces. Dr. Grace's case (fig. 7), showing degenerate cystic spaces, is shown in greater magnification in Figures 12A and 12B. Figures 13A and 13B are sections of a typical vascular choroidal malignant melanoma of the same magnification. Figures 12A and 13A are stained with hematoxylin and eosin, and Figures 12B and 13B with the Wilder reticulum stain. The true cysts and the blood spaces stained with hematoxylin and eosin show a somewhat similar pic-

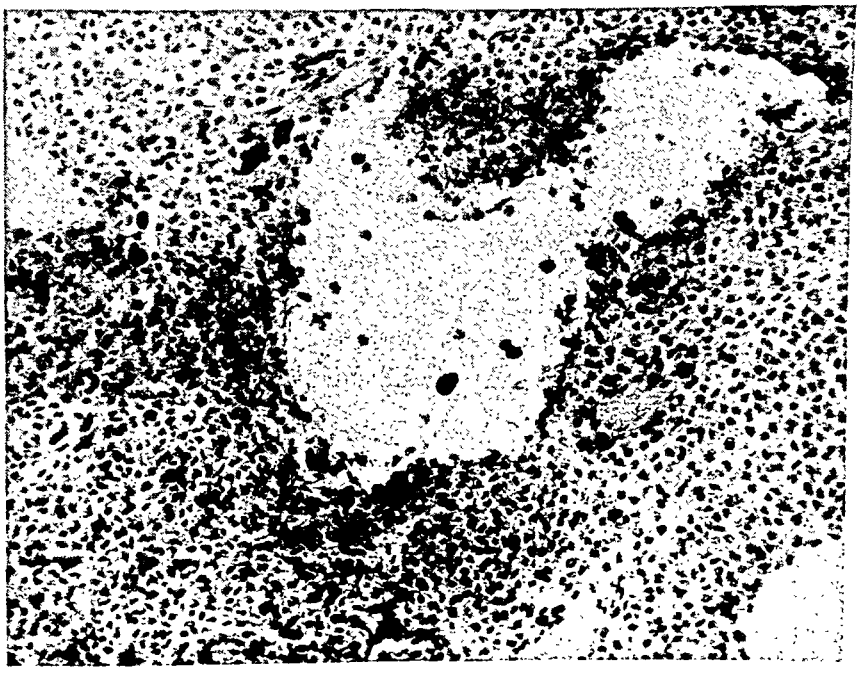

Fig. 10. (Kennedy). Higher power of Figure 9, showing irregular edges of cyst bordered by poorly staining cells. (Hematoxylin-eosin stain. Magnification, ×140.)

Fig. 11 (Kennedy). Vascular malignant melanoma of choroid giving a "pseudocystic" appearance. Blood spaces are numerous and all contain red-blood cells. (Wilmer Pathology No. 8613. Hematoxylin-eosin stain. Magnification, ×12.)

ture, but are easily differentiated with the Wilder reticulum stain. With the Wilder stain, the true cystic spaces show irregular edges relatively free from reticulum fibers, and the reticulum fibers may simulate an actual compression effect in the solid tumor away from the cysts. The blood spaces show more regular edges, with the reticulum fiber content most apparent, lining the walls and closely surrounding the blood spaces. The reticulum content around the blood spaces and vessels is also shown in relation to the blood vessels above the cystic spaces in Figure 12B.

To determine the frequency of cystic changes in malignant melanomas, a survey was made of all the routine sections of eyes containing malignant melanomas in the pathology department of the Wilmer Institute. In addition, the material from the Army Institute of Pathology was made available so that an additional group was studied. Thus a total of 440 routine sections of eyes containing malignant melanomas were ex-

Fig. 12 (Kennedy). A higher-power reproduction of Figure 7, showing degenerate cystic spaces. (Magnification, ×30.) (A) Hematoxylin-eosin stain. (B) Wilder reticulum stain. The irregular walls of the cyst are relatively free of reticulum fibers. Fibers in the solid portion of tumor give the appearance of compression. Blood vessels in the upper part of figure are clearly outlined with marked surrounding of the reticulum-fiber content in contrast to cystic spaces.

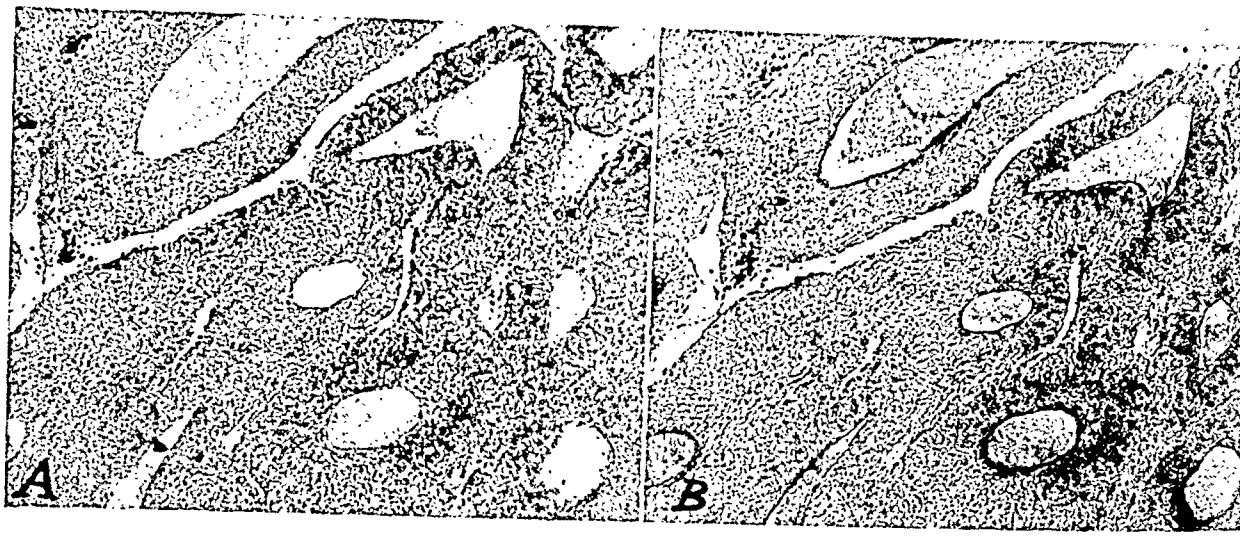

Fig. 13 (Kennedy). Blood spaces of typical vascular choroidal malignant melanoma giving a "pseudocystic" appearance. (Wilmer Pathology No. 6369. Magnification, ×30.) (A) Hematoxylin-eosin stain. (B) Wilder reticulum stain. Blood-space walls are more regular, and there is moderate adjacent reticulum-fiber content clearly outlining blood spaces.

amined (table 1). Of these, 148 sections were from the iris and ciliary body or both, and 292 were from the choroid. Thirty-seven of the 440 sections, or 8.4 percent contained cystic areas. Such a figure, 8.4 percent, can only be approximate, since the change from small focal areas of necrosis to the large, well-developed cystic formations is gradual and indefinite. Whether such changes are sufficient to be considered actually cystic depends upon the judgment of the observer. The occurrence of cystic changes was approximately equal in the iris and ciliary body (8.8 percent) and choroid (8.2 percent), so that there was no predilection for any particular site in the uvea. However, the cystic changes in malignant melanomas of the iris and ciliary body usually were larger in proportion to the size of the tumor, and were more apparent than the change in choroidal melanomas. The cystic changes in the malignant melanomas of the choroid were most apparent in those tumors which bulged freely into the vitreous cavity, or particularly those breaking through the lamina vitrea with the typical mushroom appearance. The decreased blood supply through the neck of these mushroom-shaped tumors and their uninhibited growth once they have broken through the lamina vitrea both, no doubt, aid cystic development.

TABLE 1

PERCENTAGE OF MALIGNANT-MELANOMA SPECIMENS SHOWING CYSTIC CHANGES

	Iris Ciliary Body	Choroid	Total
Total examined	148	292	440
Number showing cystic changes	13	24	37
Percentage showing cystic changes	8.8%	8.2%	8.4%

As shown in Table 2, the cystic malignant melanomas were grouped according to the cellular classification of Callender.[5] The percentages of cell-type distribution of the cystic tumors were compared to those of all malignant melanomas, as found by Callender, Wilder, and Ash[6] in a series of 500 specimens, and were found to be about the same. There was no statistically significant difference in the small series of 37 cases to indicate a preference for any cell type. No cystic malignant melanomas were placed in the necrotic group of Callender, Wilder, and Ash as being too necrotic for cellular classification. There were too few cases with

TABLE 2

CLASSIFICATION BY CELL TYPE OF CYSTIC MALIGNANT MELANOMAS: COMPARISON WITH NORMAL CELL-TYPE DISTRIBUTION

		Cystic Malignant Melanomas				All Malignant Melanomas % of Total
		Iris Ciliary Body	Choroid	Total	% of Total	
CELL TYPE	Spindle	7	9	16	43.2%	30.4%
	Fascicular	1	3	4	10.8	2.6
	Necrotic	0	0	0	0.0	9.0
	Mixed	4	11	15	40.6	55.2
	Epithelioid	1	1	2	5.4	2.8
	Total	13	24	37	100%	100%

a long enough follow-up to indicate whether there was any difference in prognosis between the cystic and noncystic groups, although with the facts available there appeared to be no difference.

CONCLUSIONS

Cystic malignant melanomas may present a diagnostic problem when they occur in the posterior chamber where their differential diagnosis from a benign uveal cyst is difficult.

The determination of translucency and the diagnostic puncture may differentiate a solid and cystic posterior-chamber mass, but cannot differentiate a benign and malignant cystic mass. Thus, they are unreliable diagnostic procedures.

When accessible, iridectomy and microscopic examination should be used to diagnose such lesions when their diagnosis is in doubt.

Large cystic spaces in malignant melanomas arise from the growth of small focal areas of tumor necrosis which are the result of inadequate nutrition.

The cystic manifestation is present in about 8 percent of all malignant melanomas of the uvea, has no predilection for the site in the uvea or the cell type, and has no apparent affect on the prognosis of malignant melanomas.

I wish to thank Mrs. H. C. Wilder for her help in making available for study the material from the Army Institute of Pathology.

Acknowledgement is made to my father, Dr. E. W. Kennedy, and to Dr. L. W. Oaks, Dr. W. L. Benedict, and Dr. C. C. Grace for permission to report their cases.

PERIPHLEBITIS RETINALIS ASSOCIATED WITH INTRACRANIAL MANIFESTATIONS

EVERETT R. VEIRS, M.D.
Temple, Texas

It has been my observation that symptoms of intracranial disease occur in patients with severe periphlebitis of the retina. Three cases are presented in which severe periphlebitis of the retina was associated with severe headaches and other signs of possible intracranial disease. A fourth case is presented, but other diseases were present in this case, which made it difficult to determine the etiology of headaches and coma. The first three patients were observed in the Army, the fourth at the Scott and White Clinic.

The ophthalmoscopic appearance of severe periphlebitis of the retina is spectacular. The veins are irregularly dilated and tortuous; the dilatation is usually marked; and sheathing of the veins may be very prominent. Often, portions of the vessels are obscured by retinal edema. New blood-vessel formation, "rete mirabile," is common. Hemorrhages and exudates are numerous, and usually fairly large and widely scattered. Large, vitreous hemorrhages are not of unusual occurrence. Glaucoma may terminate any possible useful function of the eye. It seems likely that the retinal arterioles are also, to some extent, involved, but the inflammation of the veins overshadows it.

Clinically, the term "periphlebitis" does not seem to describe the condition accurately and completely. With the markedly dilated veins and the many hemorrhages and exudates, thrombophlebitis would seem a more descriptive word. Of course, the lumens of the veins can be completely obliterated by proliferation without thrombosis.

Duke-Elder[1] states that the vast majority of the chronic cases of perivasculitis of the retina in young individuals are due to tubercle. Verhoeff and Simpson[2] found a tubercle obstructing the lumen of the central retinal vein on microscopic examination of an eye removed because of hemorrhagic glaucoma. Because the other eye had previously been affected with periphlebitis retinalis, the authors felt this gave strong support to the view that periphlebitis retinalis is tuberculous in nature.

CASE REPORTS

CASE 1

History. A 29-year-old, white officer developed severe occipital headaches and a low-grade fever on September 8, 1942. This was followed on September 15, 1942, by nausea and vomiting. On September 20, 1942, diplopia and photophobia developed and he noticed for the first time that his vision seemed diminished.

Examination on October 29, 1942, showed vision to be 20/20 and J1, both eyes. There were marked eyeground changes in both eyes, papilledema was present, the veins were irregularly dilated and tortuous, there was marked sheathing of the veins, and many hemorrhages and exudates were present. There was an intention tremor.

Labortory tests. Skin reaction to 0.01 mg. and 0.1 mg. of old tuberculin was negative. A spinal tap on December 8, 1942, showed pressure of 210 mm. of water, 150 lymphocytes were present, sugar was 78 mg. percent, total protein was 165 mg. Blood N.P.N., urea N. and creatinine were within normal limits. Widal, Kahn, blood cultures, stool examinations, sputum test for tuberculosis, agglutination for undulant fever, and smears for malaria were negative.

An X-ray film of the chest revealed Ghon's tubercle of the right lower lobe and calcification of the tracheobronchial nodes. A ventriculogram on January 24, 1943, showed no evidence of a brain-displacing mass.

Course. The patient remained relatively asymptomatic from January, 1943, to April, 1943. An afternoon temperature of about 100°F. was constant. On April 28, 1943,

the patient complained of dimness of vision. Thickness of speech, deviation of the tongue to the right, and definite weakness of the left facial muscles were noted at that time. The papilledema increased, although vision remained 20/20.

Diagnosis. A diagnosis of pneumonia, right base, was made on June 19, 1943, and the patient was given sulfadiazine. He complained of pain over the left inner thigh on June 23, 1943. Thickening of the great saphenous vein seemed to be present on palpation. On July 8, 1943, it was noted that the patient had lost ability to speak and to swallow, and he had to be fed with a tube. A complete right hemiplegia was present. A large amount of pleural fluid was aspirated on the right on July 15, July 24, and July 27, 1943. The report of a ventriculogram on August 20, 1943, was: "Diffuse, cortical atrophy of right frontal and anterior parietal areas; left ventricle enlarged; no evidences of space-consuming lesion."

By November 10, 1943, there was some return of muscle function on the right, and the patient was able to take liquids by himself. By December 10, 1943, there was a continued improvement in the general condition and the motion of the extremities continued to improve. The fundi had almost completely cleared. All the hemorrhages and exudates had disappeared and the vessels had returned to normal size, but some sheathing of the veins was still evident.

CASE 2

History. A young enlisted man, stationed outside continental United States, had been in good health until early July, 1943, at which time he complained of severe, left frontal headaches. Blurring of vision of the left eye was noticed on July 27, 1943. The blood pressure was found to be elevated at this time. The headaches continued with varying degrees of severity. An encephalogram performed on December 10, 1943, showed a possible lesion of the left frontal lobe. He was transferred to Lawson General Hospital on December 15, 1943, with the diagnoses of: (1) Tumor, type undetermined, right frontal lobe of the brain. (2) Hemorrhage, subretinal. (3) Arterial hypertension.

Examination revealed blood pressure to be 168/104 mm. Hg. Vision in the right eye was 6/200, and in the left, hand movements at one foot. There was complete detachment of the left retina. In the right eye there were the typical findings of a severe periphlebitis; that is, extreme tortuosities and dilatation of veins with sheathing, edema of the disc, new blood-vessel formation at the disc, and numerous hemorrhages and exudates.

Laboratory tests. All laboratory work, including four spinal-fluid examinations, Wassermann, blood counts, and urine analysis, indicated conditions within normal limits. The X-ray picture of the chest was reported as negative. A ventriculogram showed the left ventricle to be slightly larger than the right, but it was the opinion of the neurosurgeon that the patient did not have a space-taking mass.

The patient was transferred, so the final outcome was not known.

CASE 3

History. A 25-year-old member of the W.A.C. first complained of blurred vision in the right eye about September 15, 1943.

Examination. When first examined on September 30, 1943, the vision in the right eye was 20/50, and in the left, 20/20. Several areas of pigmentation were present in the right fundus, suggestive of old, healed choroiditis. Several areas of recent hemorrhage were present. She complained of severe, continuous headaches, beginning October 12, 1943. These headaches were not relieved by medication. On October 21, 1943, there were fresh hemorrhages noted along the course of the veins of the right eye. A diagnosis of "periphlebitis of vessels of right retina" was made.

Course. The hemorrhages in this eye increased until December 8, 1943, when the vision was reduced to light perception. Intraocular pressure remained normal. The pa-

tient continued to complain of severe headaches. All laboratory work was negative. Neurologic examination, including a ventriculogram, revealed no intracranial lesion.

The patient was transferred.

Case 4

History. A 28-year-old, white man was first seen in the clinic on January 12, 1947. He had been a known diabetic since the age of 15 years but, after he left school, very little attention had been given to dietary control.

The patient stated that he became suddenly blind in the left eye on July 4, 1946, following a blow on the face. Severe, recurrent headaches developed about this time, although there was a history of frequent, frontal headaches since 1935. In August, 1946, the patient developed severe headache, nausea, dysarthria, muscular unsteadiness, violence, and unconsciousness. Similar attacks developed in October, November, and December, 1946. The periods of unconsciousness lasted 2 or 3 days. The patient stated that he had been taking from 24 to 60 units of regular insulin a day and his urine was sugar free. He was told, during one of these hospitalizations, that his sputum was positive for M. tuberculosis. An encephalogram was advised because an intracranial lesion was suspected.

Examination. An eye examination upon admission revealed vision to be: R.E., 20/200; L.E., hand movements at one foot. In the right eye the typical findings of severe periphlebitis were present. In addition, small, "hard" exudates and small hemorrhages were seen around the macular region. There was no light reflex from the left eye.

Diagnosis. The following diagnoses were made by Dr. Ralph G. Greenlee of the medical department: (1) Diabetes mellitus. (2) Glomerulonephritis, chronic, with uremia. (3) Pulmonary tuberculosis. (4) Arterial hypertension. (5) Neuritis, peripheral.

Course. After discharge from the hospital, a competent internist to whom he was referred reported that he continued to complain of severe headaches when his diabetes was known to be under control.

Comments

The simultaneous occurrence of intracranial lesions and periphlebitis of the retinas in Case 1 does not prove a common etiology, or even a relationship. The occurrence of severe, continuous headaches in Case 2 and Case 3 does not prove intracranial involvement. Symptoms were of sufficient severity, however, that ventriculograms were believed to be indicated. In Case 4, the severe headaches and coma may have been due to hypoglycemia; however, severe headaches were present at a later date when diabetes was known to be under control. With inflammation as widespread and as severe as it is in many cases of periphlebitis retinalis, it would seem logical that the process would not end abruptly at the lamina cribrosa or optic foramina.

Summary

1. Four cases of periphlebitis retinalis, associated with severe headaches and other signs of possible intracranial disease, have been presented.

2. The cases are not presented as proof that intracranial pathologic conditions are a frequent occurrence in periphlebitis retinalis, because the series is too small. The simultaneous occurrence of periphlebitis retinalis and symptoms of intracranial disease is suggestive of a common etiology.

HISTOLOGIC STUDY OF EXPERIMENTAL CORNEAL TRANSPLANTATION*

HERBERT M. KATZIN, M.D., AND P. K. KUO, M.D.†
New York

INTRODUCTION

Although corneal transplantation has been studied since 1824, the biologic process that takes place between host and graft remains as yet incompletely understood. There have been two leading points of view, one seemingly quite different from the other. Thus Fuchs,[22] Elschnig,[14] Castroviejo,[8,9] Ascher,[2] and others believed that in corneal transplantation there is true healing, with preservation of the vitality of the graft within the tissues of the host's cornea; Salzer,[30-35] Ribbert,[29] and others, however, claimed that there is an active regenerative process on the part of the host's cornea, which eventually totally replaces the transplant. A less definite point of view seems to have been taken by others like Loehlein,[28] and Filatov,[19] although Loehlein seems to be more in favor of the regeneration theory in his later publications.

It is not our aim in this present article to go too deeply into this theoretical discussion, but chiefly to present our own histologic experimental data. We hope, however, that this data may contribute to a better understanding of the extremely interesting biologic process taking place between the host's cornea and the transplant.

HISTORICAL REVIEW

Our review of the literature on this subject is restricted to those publications on corneal transplantation that contain histologic studies, without considering the development of the different operative techniques.

In general, these studies have been done either on human eyes obtained some time after corneal transplantation, or from animal eyes which have been operated upon and subsequently enucleated for experimental purposes. The clinical material for the first type of examination has always been meager, and according to a report of Filatov,[19] up to 1935, not more than 3 or 4 clinical cases have been reported in the literature.

The first of these cases, reported by Fuchs[22] in 1901, was obtained from a 20-year-old girl with bilateral interstitial keratitis on whom a keratoplasty was performed with a donor cornea taken from a human eye enucleated because of iridocyclitis. Two-and-one-half years later, the graft turned opaque so that a second keratoplasty was undertaken; the opacified part of the cornea, removed in full thickness, was studied microscopically by Fuchs. Thus, he found that the graft healed well at the beginning but that opacification and vascularization took place later. The most anterior portion of the graft tissue remained largely unchanged except that the stroma lamellae were more wavy in appearance, with a few nuclei of wandering cells beside the fixed cells. The posterior portion of the graft presented considerable changes. Descemet's membrane appeared folded and shortened, and between the corneal lamellae there were numerous nuclei and blood vessels. The posterior surface of Descemet's membrane was covered by a layer of thick fibrous tissue, which Fuchs believed to be thick scar formation. Descemet's membrane of the host cornea, surrounding the graft, extended out behind the graft on one side, but its posterior surface was also covered by the same fibrous tissue. Fuchs drew the conclusion that the transplant preserved most of its elements even after a period of 2½ years, and no sign of replacement of the graft by the sur-

† Visiting research fellow.

rounding corneal tissue was demonstrable.

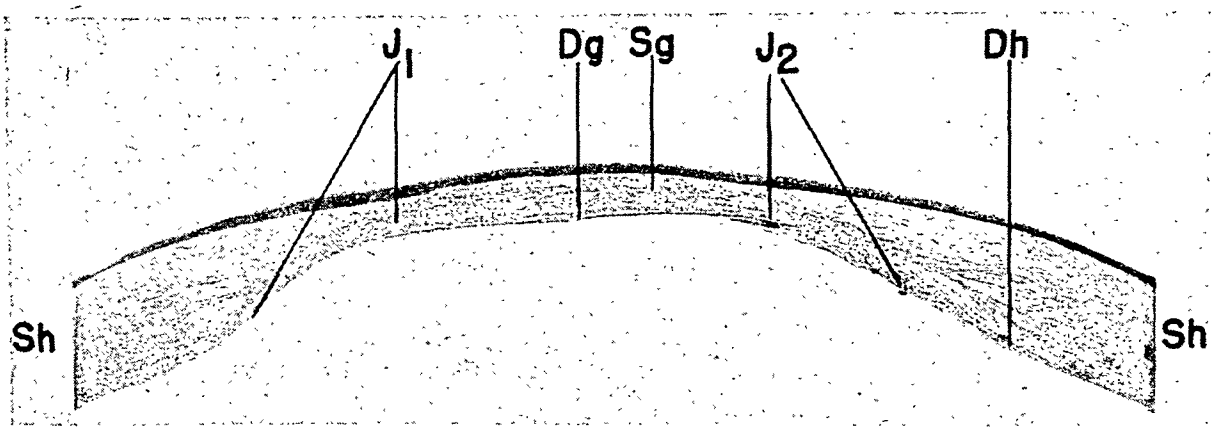
The 2nd and 3rd clinical cases examined histologically were reported by Ascher[2] in 1919. Besides material which he obtained from the removal of opaque grafts taken out in the course of a secondary transplantation, Ascher was able to report on two clinical cases with detailed histologic studies.

His first eye was from a 15-year-old girl treated for corneal fistula by partial penetrating keratoplasty. The eye was enucleated six weeks after operation because of the danger of sympathetic ophthalmia. The second case was a trachomatous corneal leukoma on which a keratoplasty had been performed. The patient died two months after the operation.

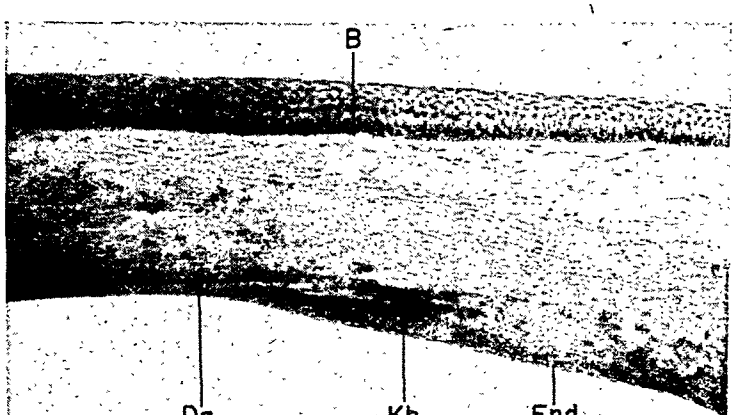
After describing the histologic findings in both instances in great detail, Ascher concluded that up to the time of enucleation in each case there was no sign of structural changes in the transplanted tissue or of its replacement by the surrounding cornea. Not only did Bowman's membrane and Descemet's membrane retain their identity, but even the epithelium at the junction did not show any definite sign of regeneration.

Sommer,[38] in 1925, enucleated an eye because of glaucoma, 15 months after a partial penetrating keratoplasty, and a histologic study of this eye was made. He found that the original tissue of the graft was essentially maintained and no replacement could have taken place.

Another case was reported by Frieberg[21] in 1927. It was a case of keratitis scrofulosa, treated by repeated keratoplastic operations. The graft was taken out 21 months after the first operation and used for histologic sections. It was found that an adhesion between Descemet's membrane of the host cornea and that of the graft had taken place. According to the opinion of the author, this adhesion might have hastened the process of healing between the graft and the surrounding cornea. As regards the fate of the stroma tissue of the graft, the author admitted the possibility of true healing, as well as that of invading growth from the host cornea.

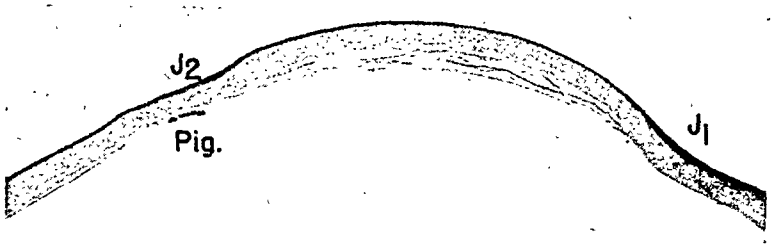


Filatov,[19] in 1935, was able to report his own clinical case in which the transplanted cornea retained its transparency for three years, until the patient's death. The transplantation was done on a leukoma that formed due to interstitial keratitis. The histologic findings were given in great detail. The epithelium over the center of the graft became thinner. Bowman's membrane of the host's leukoma was indistinct, but that of the graft remained well preserved. The stroma of the host cornea was infiltrated more under the epithelium than in its posterior portion. Some infiltration, though to a lesser degree, was also present in the tissue of the graft. At the junction, the substantia propria was scarred and contained remnants of cellular infiltration and blood vessels mostly in the anterior layers. The beginning of the transplant could be identified by the appearance of the corneal lamellae, which at a short distance from the scar acquired the arrangement of a normal cornea and preserved it along the entire length of the transplant.



Descemet's membranes of the host and graft were both present, separated from each other by scar tissue. No endothelium, either of the host or of the graft, was present. There was an iris adhesion in this specimen. In considering the pathologic changes, Filatov was rather skeptical in the interpretation of his findings. "Does the permanent transparency of the transplant signify that an actual union has taken place, or does a substitution of the transplanted cornea by regenerated corneal elements of the host occur? This question is of great pathologic interest, and cannot be answered decisively at present." Filatov, however, concluded that the transplant as such remained well preserved and was distinctly separated from the host tissue by the fibrous ring, and that Bowman's and Descemet's membranes undoubtedly belonged to the transplant.

In the same year, 1935, Thomas[42] pub-



KEY TO THE ABBREVIATIONS IN THE FIGURES

A.c.: anterior chamber;
B.: Bowman's membrane;
b.v.: blood vessels;
b.v.l.: blood vessels cut in length;
C.: cornea;

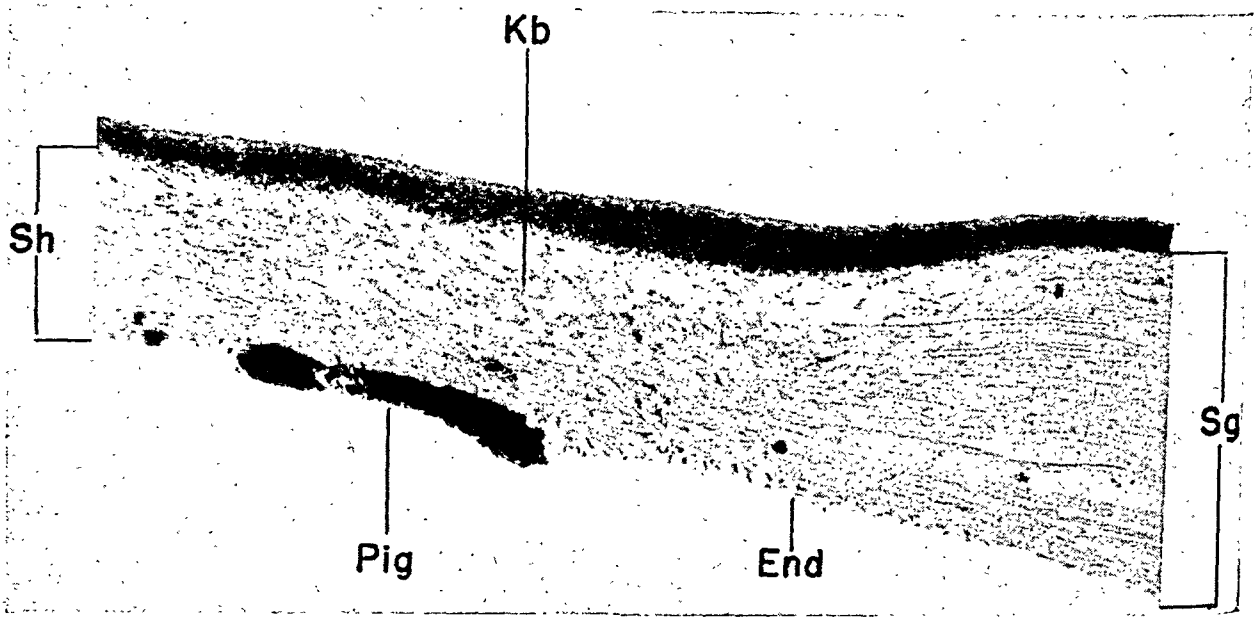
v: vacuoles.



Figs. 1a and 1b (Katzin and Kuo). 1a (above). *Section through a transparent graft 4½ months after operation.* The epithelium extends evenly over the surface of the graft and that of the host with some thickening over the junction J_1; the stroma shows parallel arrangement of its lamellae and appears thinner than that of the surrounding host; Descemet's membrane of the graft is folded at J_1, but shows brushlike extensions at J_2; the endothelium shows budlike proliferation near J_2. 1b (at right) *Section of junction J_2 of Figure 1a under high power.* The thin homogeneous acellular layer B under the epithelium shows the weakly developed Bowman's membrane; the end of Descemet's membrane of the graft Dg is seen to show brushlike extensions, radiating into a group of keratoblasts Kb in the stroma of the junction; some thickening of the endothelium is noted.

Figs. 2a and 2b (Katzin and Kuo). 2a (at left). *Section through a translucent graft 21 days after operation.* The epithelium has an even surface but shows variations in thickness. The stroma lamellae of the graft appear slightly wavy and loose. Pigment adhesion on posterior surface at Junction J_2. 2b (below). *Section of junction J_2 of Figure 2a under high power.* Note the abundance of keratoblasts in the stroma tissue.

lished his data on the histology of two successful corneal grafts in man. The specimens —one six months, the other three weeks after the corneal transplantation—were obtained after the patients' deaths. Both grafts were successful in a clinical sense. The microscopic examination of the case six months after operation revealed good union of the graft edge with the host cornea. The epithelium appeared slightly thickened at the margin of the graft. Bowman's membrane was present but was separated in some places from the epithelium by a thin layer of fibrous tissue with long flattened nuclei. In the stroma of the graft, the fibers were found regular and well defined throughout, without signs of vascularization. The original host cornea was characterized by an increased number of nuclei which were interrupted by the scar formation at the margin of the graft. The nuclei did not seem to invade the graft to any appreciable distance. Some capillaries with cellular infiltration around them were also found at the junction between the host and the graft. The whole graft stroma appeared thicker than that of the host. No sign of newly formed Descemet's membrane was noted. The ends of Descemet's membrane of the graft and the host cornea did not meet. The former were folded. Behind Descemet's membrane of the graft, there was new tissue formation extending the whole length of the graft. The thin layer of fibrous tissue consisted of fibers regularly dispersed in parallel fashion with nuclei that were long, thin, and flat and with pointed ends. This, the author believed, was not incompatible with a graft that was clinically transparent.

The case of three weeks' duration manifested a histologic picture which in the regularity of the lamellar arrangement and

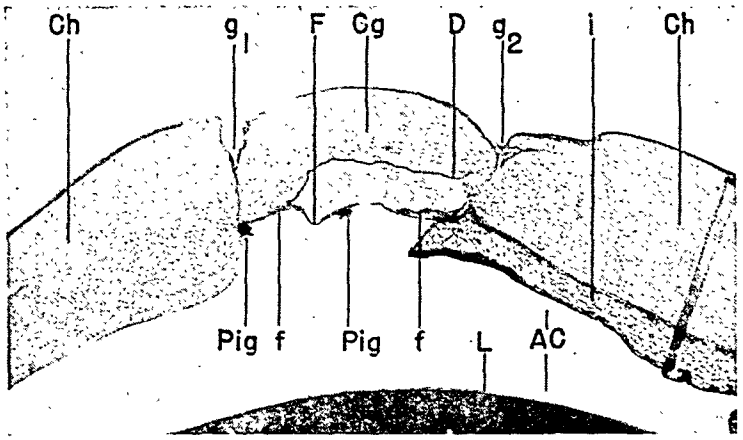


Fig. 3 (Katzin and Kuo). *Section through an edematous graft three days after operation.* The epithelium is proliferating into the wounds g_1, g_2. The stroma tissues of both the host and the graft appear markedly edematous. Descemet's membrane D of the graft is wrinkled. Fibrinous membrane F is seen behind it. Pigment adhesions and iris adhesions are present.

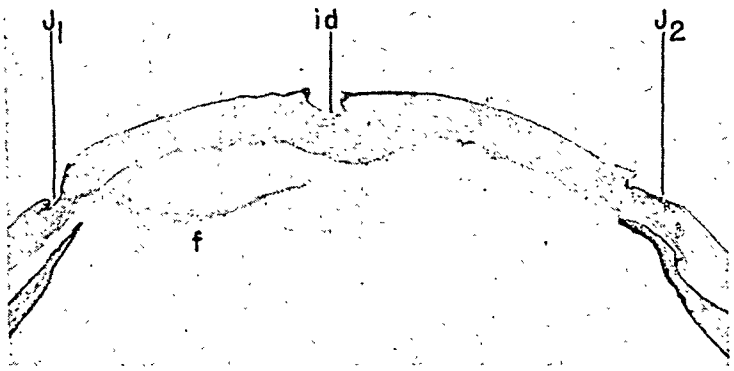

Fig. 4a (Katzin and Kuo). *Section through an edematous graft four days after operation.* The epithelium of the graft shows variation in thickness, peeling off in places, and proliferating over the suture indentation (id) at the center. The stroma appears edematous, its structure loose. Fibrinous mass f is seen in the anterior chamber.

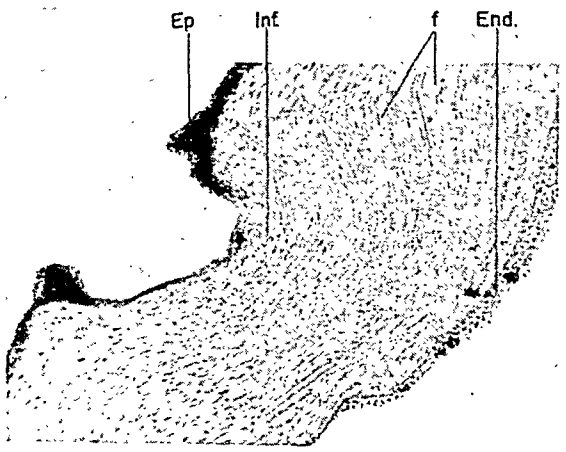

Fig. 4b (Katzin and Kuo). *Section through the indentation (id) of Figure 4a.* The proliferated epithelium over the edges of the indentation and the wide interlamellar spaces filled with fibrinous fluid f are well illustrated. Some cellular infiltration Inf. is seen in the stroma beneath the indentation.

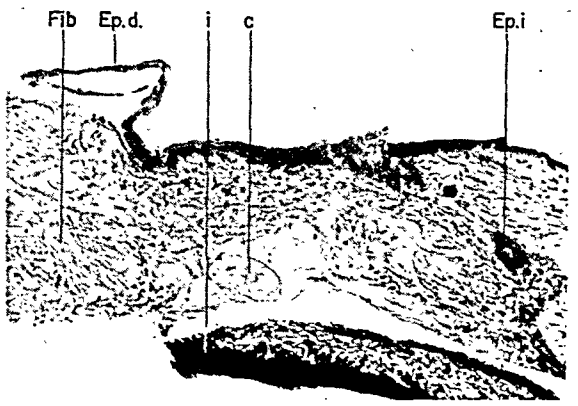

Fig. 4c (Katzin and Kuo). *Section through junction J_2 of Figure 4a.* Epithelium Ep.i is seen lying in the stroma tissue between the host and the graft and partially peeling off Ep.d in its total thickness over the surface of the graft. Numerous fibroblasts are present in the stroma.

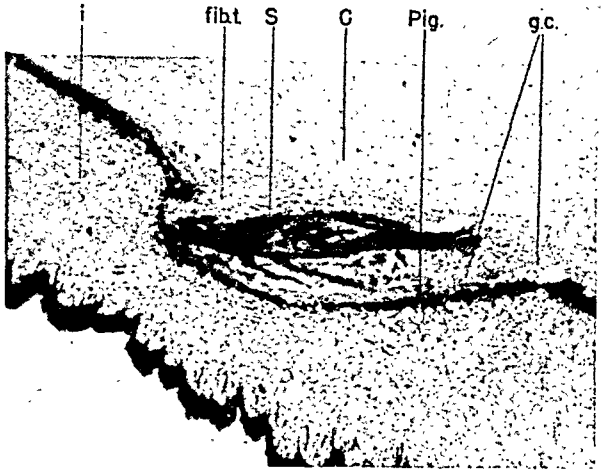

Fig. 5 (Katzin and Kuo). *Section through the adhesion between cornea and iris.* A silk suture S is embedded between cornea and iris and is surrounded by giant cells g.c. and fibrous layer fib.t.

nuclear content of the graft stroma was very normal in appearance. Marginal scar tissue was also present. The epithelium was continuous throughout. Bowman's membrane of the graft was also of the same thickness as in the donor cornea. There was tissue formation behind the graft of the same nature as in the previous case.

The descriptions by this author seem to show his preference for the theory of true healing, although he did not make any definite comment in this connection.

Castroviejo,[9] in 1937, included in his detailed histologic reports one case of microscopic examination of an opaque human cornea three months after a heteroplastic

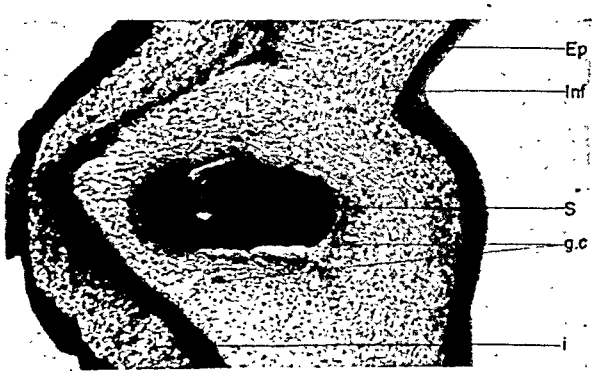

Fig. 6 (Katzin and Kuo). *Section through an adhesion between cornea and iris.* A suture S is embedded in the corneal tissue and is encapsulated by giant cells and a fibrous tissue layer as in Figure 5.

transplantation with the cornea of a monkey (macaccus rhesus). The microscopic examination revealed, "in the central part of the cornea, a necrotic area outlined on one side by blood vessels and lymphocytic infiltration, on the other side there was a perforation through which the lens capsule, lens matter, and vitreous were extruding. A dense lymphocytic infiltration along the entire surface of the cornea between the epithelium and the stroma was also seen. In the necrotic central plug or graft, there were many giant cells."

Subsequent histologic examinations of clinical cases were found in articles by Velter[44] in 1940, Babel[3] in 1945, and by Fieandt[16] in 1946. Velter published, in 1940, 18 corneal transplants; 15 of these were ob-

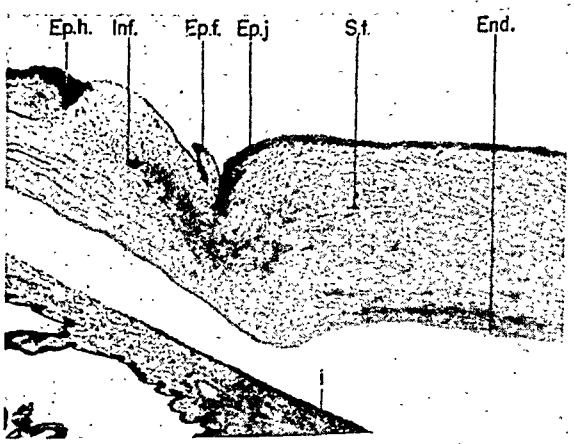

Fig. 7 (Katzin and Kuo). *Section through an opaque graft 22 days after operation.* A typical angular junction between the host and graft is noted, due to the effect of a tight suture. The epithelium is varied in thickness and presents a peculiar fold Ep.f. at the junction. Note the irregular pattern of the scar formation.

tained surgically when secondary transplants were used to replace the primary opaque ones. Three were obtained from eyes enucleated for glaucoma. The epithelium was usually thickened, sometimes vacuolated. Bowman's membrane was usually normal. The substantia propria showed only insignificant changes. Descemet's membrane was found preserved in over half of the cases and was usually detached and curled. The endothelium was absent in all cases. The demarcation between the transplant and the

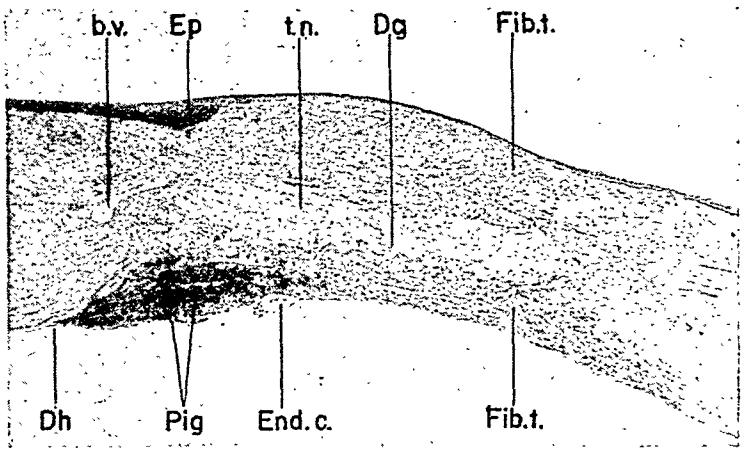

Fig. 8a (Katzin and Kuo). *Section through an opaque graft one month after operation.* The epithelium is thickened over the junction but thinner over the graft. Anterior and posterior fibrous tissue layers are present; wrinkled Descemet's membrane, necrotic tissue area t.n., pigment granules, and an endothelial cystic formation End.c. are seen in the part of the graft. Vascularization at the junctions and Y-shaped Descemet's membrane of the host are clearly illustrated.

scar was very sharp in all cases. Membranes were found developed behind the graft in 7 out of 18 cases; in 6, they originated in the corneal scar. The iris, when adherent to the transplant, did not contribute to the formation of the connective tissue invading the transplant. The author seems to be in favor of the true healing theory.

Babel,[3] in 1945, after presenting his 11 cases of transplanted corneas, ranging from four days to five years after operation, claimed to have substantiated the experimental findings of Bonnefon and Lacoste. The graft tissue, including Bowman's membrane, stroma lamellae, and Descemet's membrane, remained intact and was not replaced by the surrounding corneal tissue. The author mentioned, however, that the stroma tissues of the graft showed a marked degree of swelling, pyknosis of the nuclei, and so forth, as if they would subsequently disappear and be replaced by the surrounding elements. The epithelium may manifest signs of proliferation, overgrowing the wound edge and preventing the proper union between the host and the grafted cornea.

Fieandt's[16] case was the enucleated eye of a patient with interstitial keratitis, treated by corneal transplantation with subsequent development of an anterior chamber cyst. The histologic picture, the author believed, supported the view of true healing of the graft, because the transplanted area contained all the corneal layer. Bowman's membrane was found in the transplant, but was partially absent in the surrounding cornea and completely absent at the margin of the transplant.

Although the clinical histologic data is limited, experimental histologic reports are so much more numerous and elaborate, that we will simply summarize.

Salzer's[30-35] work along these lines seemed to be most comprehensive. His publications appeared between 1898 and 1945. According to this author, the fate of the transplanted cornea is that of gradual replacement by the host corneal tissue, in which the epithelial cells of the host cornea play the main role in the process of regeneration. Thus Salzer[30]

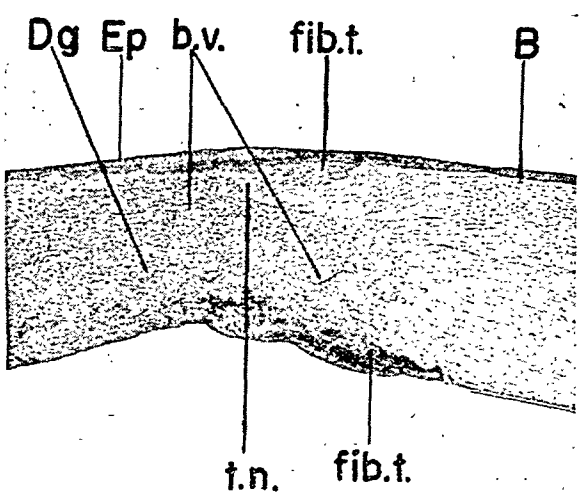

Fig. 8b (Katzin and Kuo). *Section through the same opaque cornea as Figure 8a.* The epithelium is thickened over the graft. The fibrous stroma of the graft is seen vascularized. A ring of Descemet's membrane Dg. is present. The necrotic area t.n. is seen more anteriorly than in previous figure.

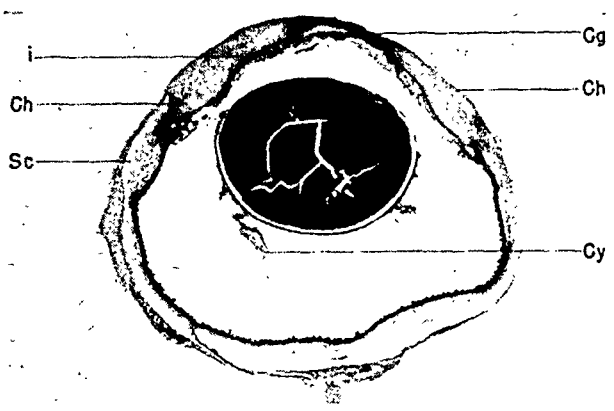

Fig. 9a (Katzin and Kuo). *Section through an eyeball of an opaque graft one month and 24 days after operation.* Total anterior synechia is noted. The graft tissue is totally cicatrized; edema is present in the host cornea as well as in the sclera.

said, in 1908, "The fact that heteroplastic operations have been performed with success, even in those cases where heteroplastic material from animal corneas from different species were used, is from the scientific point of view enough proof that there can be no true transplantation in the operation of keratoplasty, but rather that the graft heals only as a dead tissue or foreign body."

In order to show the regenerative power of the cornea, amplifying the results of Ribbert,[29] Salzer carried out the following experiment: He cut a pocket in the cornea of a rabbit and used different materials for implantation: egg membrane, a flap of guinea-pig's cornea, or a flap of the cornea of a rabbit. Two months later he carried out histologic examinations of these specimens and found profound changes in all parts of the implanted tissue. Although Salzer claimed on the basis of his results that regenerated tissue actually invaded the implanted material, he was rather skeptical in drawing any definite conclusions and suggested that further experiments with different materials and different staining methods should be pursued to bring more light to this problem.

In 1910, Salzer[32] carried on another series of experiments in which he implanted a flap of formalinized horse cornea in the cornea of a rabbit and found that the implant actually "healed." The microscopic examination three months after the implantation showed that, although the whole implant was still recognizable, the margins appeared to be absorbed and replaced by invading regenerating tissue. Subsequent observations found that in one specimen, the implant had entirely disappeared after a period of about 15 months, clinically as well as histologically.

In the same year, Salzer[31] made another interesting observation, based on the results obtained by Nielson and Angelucci, on the filling in of a large defect in the rabbit's cornea produced with a trephine. It was found that the hole was eventually filled up with newly formed corneal tissue which, in the course of a few weeks or months, resulted in almost normal transparency. The whole process took place on the basis of a fibrinous clot which initially bridged the hole

Fig. 9b (Katzin and Kuo). *Part of the section of Figure 9a through the cornea of the host and the adherent iris.* Note the total denudation of the epithelium; the stromal edema and the total anterior synechia of the iris.

and was subsequently organized. The whole regenerative process was not accompanied by any sign of vascularization whatsoever.

In the year 1921, Salzer[33] discussed the significance of this regenerative capacity of the cornea from the clinical point of view. The corneal defect in cases of perforation due to blennorrhea neonatorum is often filled with regenerated corneal tissue so completely, that only insignificant opacity remains. A unique case of Elschnig, reported by Ascher, was cited of a 12-year-old boy whose one eye suffered from deep keratitis. The cornea of this eye was trephined without receiving a graft. After seven years, the defect was replaced by completely transparent corneal tissue. The surrounding cornea also became transparent, leaving only a very fine ring surrounding the regenerated tissue.

In the course of his studies, Salzer[33] found that the regenerative process of the cornea is associated with the activity of the keratoblasts, which seemed to be most abundant in the subepithelial layer of the cornea. On the basis of this observation, together with additional microscopic evidence, Salzer believed that the keratoblasts are of epithelial origin. He performed homo (rabbit cornea to rabbit) as well as hetero (horse cornea to rabbit) implantations and obtained histologic preparations which substantiated his view regarding the origin of the keratoblast.

The more recent work of Salzer,[34] in 1937, may be summed up as follows: In higher animals, transplanted tissue does not remain intact for a long time, but soon undergoes slow degeneration. At the same time, as a result of the natural regenerative tendency of the wound regions, newly formed tissue elements from the surrounding host tissue enter into this substance and gradually replace it, provided there is no infection or inflammation in which case a cicatricial mass will result. Regeneration of corneal wounds originates from the spindle cells lying directly below the corneal epithelium, called keratoblasts, which enter into and replace the transplanted corneal disc. The fixed

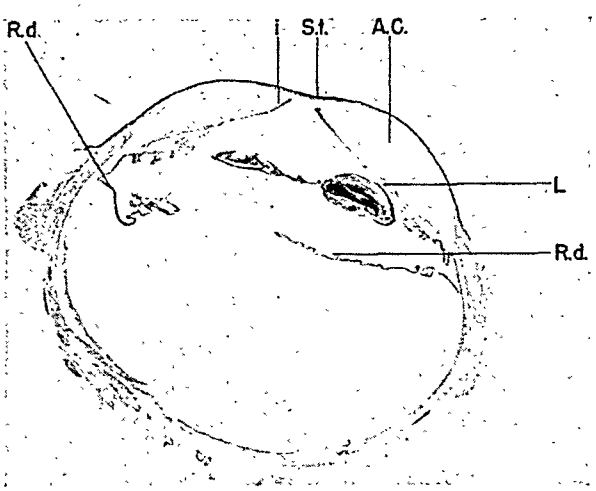

Fig. 10a (Katzin and Kuo). *Section through a hypotonic eyeball, which has lost its graft and healed (2½ months after operation).* Note the total detachment of the retina and the slight invagination over the healed corneal scar S.t. The lens has been largely extruded, and the margins of the iris are adherent anteriorly.

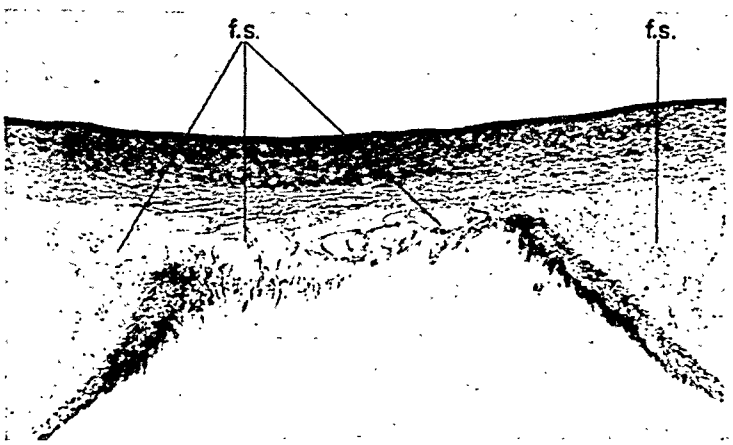

Fig. 10b (Katzin and Kuo). *Section through the central portion of the healed corneal scar of Figure 10a,* showing the fibroblastic synctium f.s. connecting the iris tissue with the posterior surface of the healed cornea. The stromal lamellae are in fairly parallel arrangement.

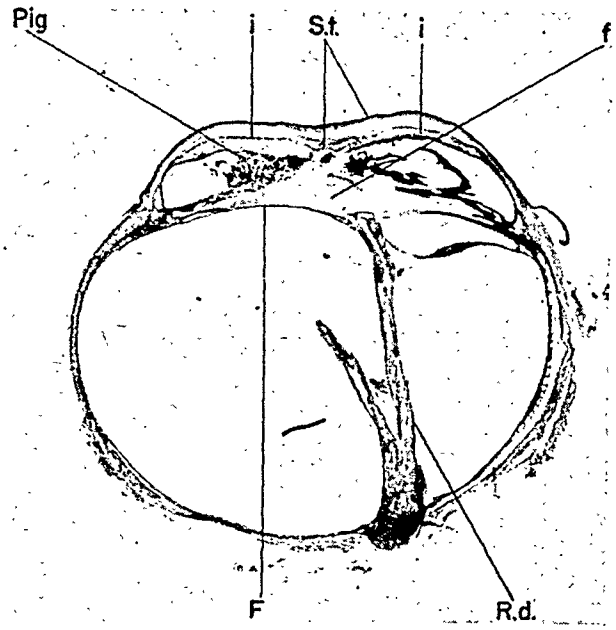

Fig. 11a (Katzin and Kuo). *Section through a hypotonic eyeball, which has lost its graft and healed (3 months and 2 days after operation).* Note the absence of the lens and the total detachment of the retina. The healed corneal scar appears also slightly invaginated as in Figure 10a.

corneal cells do not take part in the regenerative process. That the replacement of corneal graft tissue must originate from the epithelial layer is consistent with the new embryologic conception that does not hold firmly to the specificity of the germinal layers. It is of no consequence whether one uses discs from the same species or from widely different ones, for even dead materials kept in preserving fluids have been

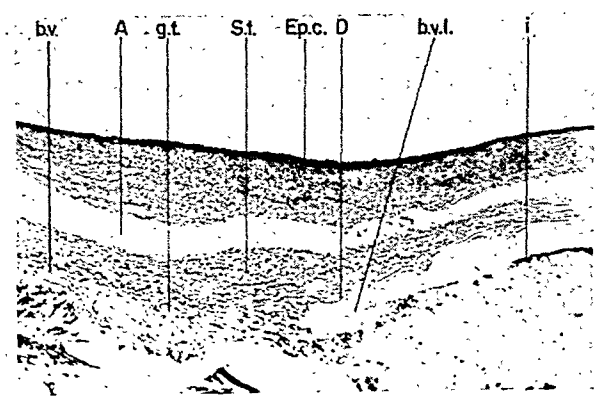

Fig. 11b (Katzin and Kuo). *Section through the invaginated portion of the healed corneal scar of Figure 11a.* Note the cornification of the epithelial surface and the presence of the granulation tissue between the corneal scar and iris tissue.

successfully transplanted. For a successful transplantation, it is necessary that the leukoma should contain well-preserved corneal elements from which regeneration may proceed. Total adherent vascular leukoma forms an unsuitable bed for transplantation.

Salzer's[35] publication, in 1941, dealt with the results of studies in comparative histology and embryology, as well as tissue cultures. All seemed to point to the same conclusion, that the cornea is epithelial in origin, development, and regeneration.

In 1910, Loehlein[28] published his histologic report of a rabbit cornea three months after transplantation. There was thickening of the epithelium as well as penetration of the epithelium into the stroma. No sharp demarcation existed between the graft and the host cornea. No changes in Bowman's and Descemet's membranes of the host were noted. A slight degree of vascularization prevailed in the marginal region between the host and the graft.

Bonnefon and Lacoste,[7] in 1913, based on 200 partial lamellar keratoplasties in animals and histologic studies on the specimens ranging from 10 hours to five months after operation, concluded that the only elements preserved up to five months were the epithelium, the lamellae of the corneal stroma, and a few corneal corpuscles. Most of the corpuscles were regenerated (immigrant fibroblasts) and in time the stroma of the cornea was probably also replaced slowly by new stroma.

Forster,[20] in 1923, prepared a review of keratoplastic surgery and reported his own experiments on the subject. He concluded that a successful graft from another species is a biologic impossibility because it is inconsistent with the biologic law of tissue specificity.

Castroviejo,[8] in 1932, carried out a detailed histologic examination on normal rabbit corneas on which partial penetrating keratoplasty had been performed. The transparent grafts showed no signs of replacement by the host. In 1937, Castroviejo[9] made

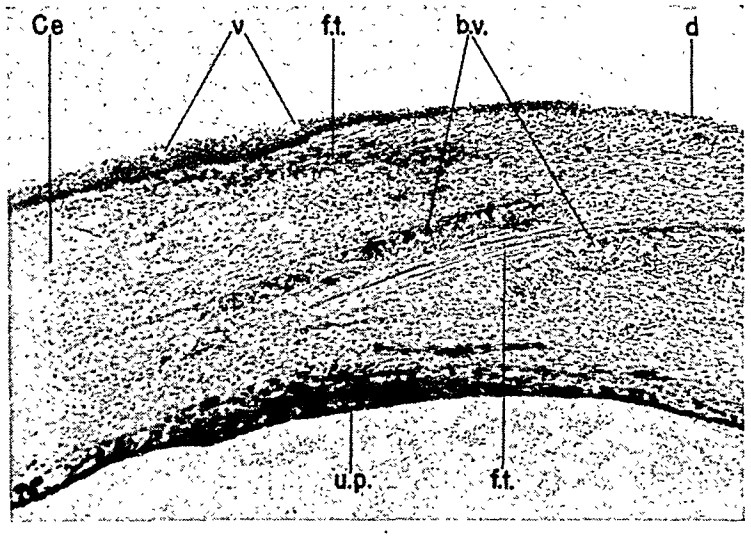

Fig. 12 (Katzin and Kuo). *Section through a formalinized opaque graft two months and 21 days after operation.* The epithelium is vacuolated; the stroma tissue is scarred with cellular infiltration, vascularization, and edema. The iris pigment is adherent and interwoven with the corneal stromal tissue.

another series of histologic studies based upon some 300 partial penetrating keratoplasties on normal and pathologic corneas of different species of animals and on 80 keratoplasties of the same type on human beings. His results appeared to show that the transparent corneal graft retained its individuality and preserved its own cellular elements. There is no evidence of a gradual replacement of this type of graft by the tissue of the host. He mentioned as the main causes of nebulosity and opacification of a graft:

1. Poor coaptation of the margins of the implanted segment into the cornea of the host.
2. Postoperative infection.
3. Incarceration of intraocular structures with subsequent development of connective tissue behind the graft.
4. Vascularization of the graft always associated with infiltration of the stroma by wandering cells.

Thomas,[39] in 1931, published a case of experimental corneal transplantation in a rabbit to replace a central opacity. His histologic study revealed that the opaque graft was densely nucleated and contained many connective tissue cells with spindle-shaped nuclei. A second series of three cases also of Thomas's[40] reported in the same year, showed that the degree of clarity of the graft was closely associated with the extent to which the iris was adherent.

In 1934, Thomas[41] performed transplantations on rabbits, using devitalized grafts heated in olive oil at 100°C. for a few seconds, and obtained good healing. There was some degree of thinning of the graft tissue and a linear scar was formed around

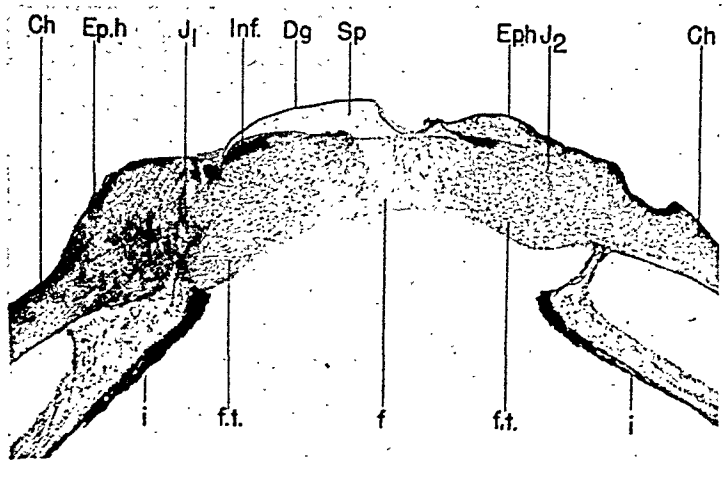

Fig. 13 (Katzin and Kuo). *Section through an opaque graft (frozen and dehydrated) 16 days after operation.* The entire tissue of the graft has been lost except for Descemet's membrane which can be seen on the anterior surface. Partly organized fibrin fills in the gap, which is beginning to be covered with epithelium. Note the polymorphonuclear infiltration in the stroma tissue near the junctions.

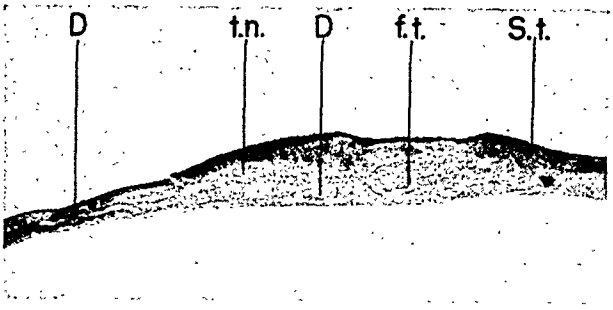

Fig. 14 (Katzin and Kuo). *Section through an opaque graft (frozen and dehydrated) 26 days after operation.* The epithelium appears uneven over the graft. Note the anterior and posterior layers of fibrous tissues with necrotic tissue in between. Descemet's membrane of the graft is wrinkled.

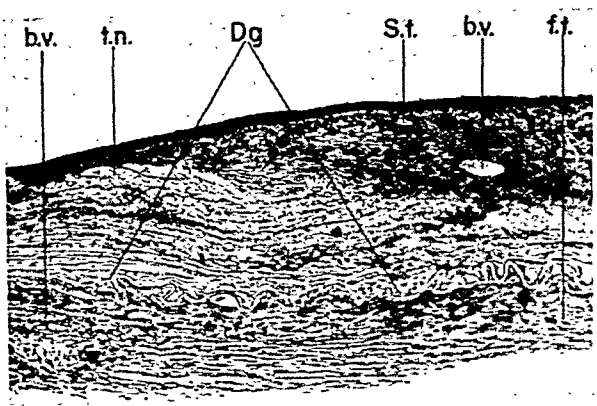
the graft. The reaction of the eye was minimal and the graft tissue remained avascular. Because of the thickening and contracture of the heated graft tissue, the posterior portion was cut off before being implanted so that the transplant actually consisted only of the epithelium and the anterior layers of stroma. Nevertheless, the graft took well. The author concluded that union between the graft and the host cornea could only have taken place by virtue of regenerative activity on the part of the surrounding corneal tissue.

In 1936, Thomas[43] carried out experiments on heterogeneous corneal grafts on six rabbits, using human cornea on one, and cats' corneas on the remaining five. It was found that the heterogeneous grafts could also unite with the host's cornea, but unlike



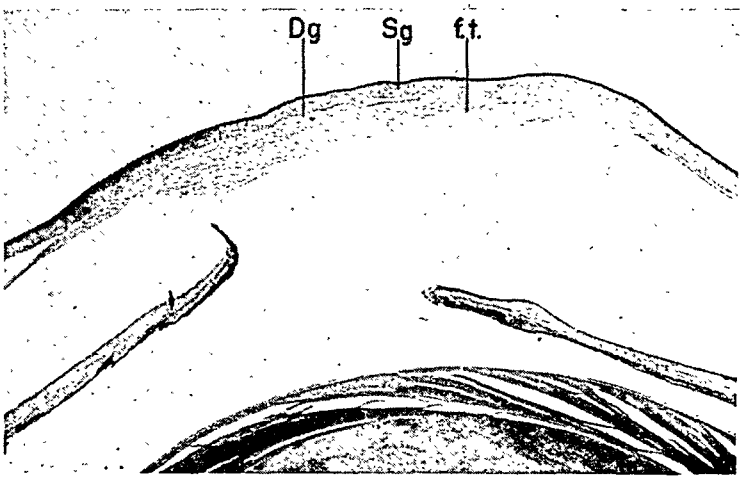


Fig. 15 (Katzin and Kuo). *Section through an opaque graft (frozen and dehydrated) one month and 11 days after operation.* Histologic details are seen in this picture similar to Figure 14, with the addition of blood vessels.

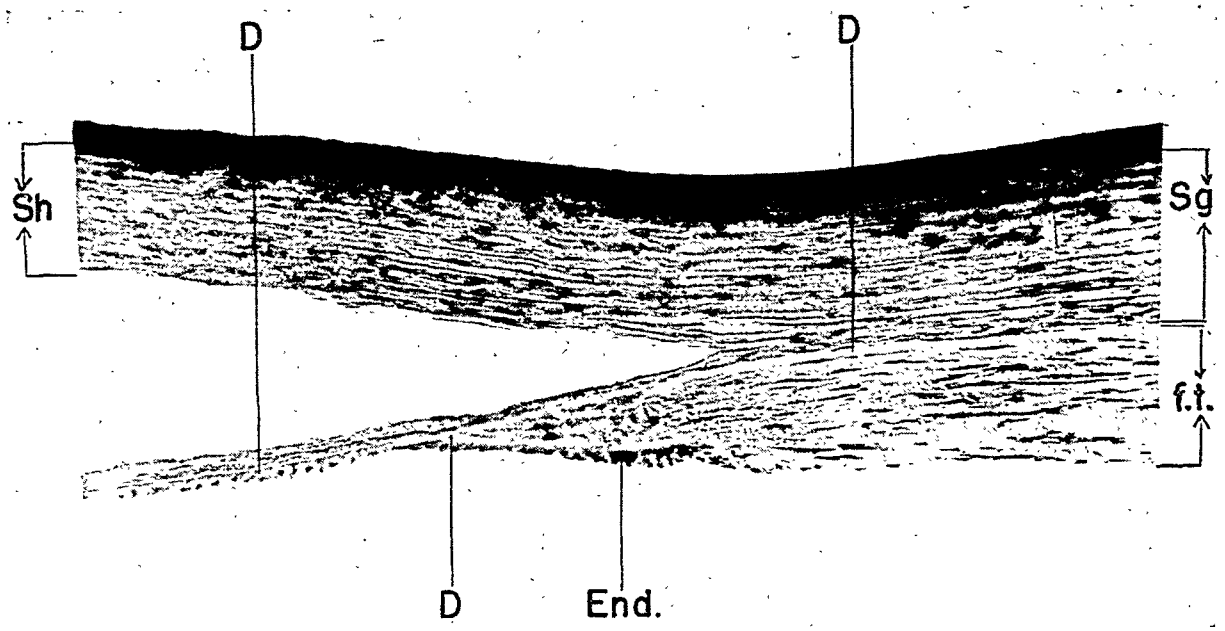

successful homogeneous grafts, they did not remain transparent, but became vascularized. After a period of 3 years and 10 months in one specimen, the graft was composed of tissue derived from the host cornea, but Descemet's membrane remained. The original stroma of the graft was retained to some extent, in the form of isolated fibers, subepithelially, and a homogeneous mass in its posterior portion where no blood vessels were present. This finding seemed to warrant the conception that the tissue was tolerated but largely ostracized by the recipient eye.

Kiyama[27] in 1934 claimed to have proved the theory of true healing of a transplant from a histologic as well as immunologic point of view. It was first shown that tissue-juice of the chicken embryo hastened the process of corneal epithelial regeneration of an artificial defect in a rabbit's cornea, and that the addition of a mixture of tissue juice and secondary aqueous promoted the healing of the graft in its bed. Subsequent histologic examination revealed that all layers of the graft tissue were well perserved. His immunologic experiment showed that a corneal transplant taken from a rabbit immunized against vaccine virus, retained its immunity after being transplanted. Kiyama concluded, therefore, that a cornea can be transplanted without dying and that true keratoplasty exists.

Scherschewskaya,[36] in 1940, carried out 37 experimental keratoplasties on rabbits with formalinized transplants. Of these, 12 healed, with retained transparency in three cases. Of five keratoplasties on human beings, one remained clear. Detailed histologic data were presented both for opaque and clear grafts. No conclusive interpretation was given for the histologic pictures, except that the formalinized grafts can actually heal and become transparent, thus substantiating the experimental data of Salzer to the fullest extent.

Deutman,[12] in 1940, used formalinized cornea for keratoplastic operations on five

Figs. 16a and 16b (Katzin and Kuo). 16a (right). *Section of an opaque graft (frozen and dehydrated) six months after operation.* Note how the necrotic tissue of the graft has been organized into fibrous tissue. 16b (below). *Section through the junction between host and graft of Figure 16a.* Note the Y-shaped extension of the host's Descemet's membrane and the thickening of the endothelium.

normal rabbit eyes. All the transplants clinically observed during the period from 3 to 11 months, postoperatively, remained opaque, due to connective-tissue formation behind the graft. From the histologic pictures, the author had the impression that the formalinized transplant was surrounded by the neighboring corneal tissue in an attempt at encapsulation.

Sena,[37] in 1941, reported two cases of experimental keratoplasty on rabbits with subsequent histologic examination. The author concluded that the histology showed definitely the maintenance of cellular autonomy on the part of the transplants.

Wiener and Rosenbaum,[46] in 1941, published their experimental data on 22 formalinized heterogeneous and homogenous corneal transplantations, five of which were formalinized dog cornea to rabbit and 17 were chemically fixed rabbit cornea to rabbits. The heterogenous transplants caused more reactions in the eye than the homogenous transplants, where 8 out of 9 healed, and three of these showed definited signs of clearing. From the histologic sections it was seen that the epithelium and the endothelium of the graft had been derived from the corresponding layers of the host. Descemet's membrane, on the other hand, was probably the remnant of the donor material. Regarding the fate of the stroma

of the graft, the authors believed that there was some true replacement taking place.

Imre,[23] in 1942, reported clinical and histologic experiments with corneal grafts on more than 20 eyes. No detailed reports are available.

Bashoff,[5] in 1946, described 30 cases of keratoplasty. Results of formalinized and autografts were compared. Of the former, the results were negligible to bad. In the autografts, 13 good results were obtained out of a total of 17 cases.

Comment on the literature

From the foregoing review of the literature, it is evident that the controversy between the leading points of view, regarding the biologic process taking place between the graft and the host cornea, has been going on for 5 or 6 decades and, in spite of the numerous publications, clinical as well as experimental, as reviewed above, no solution has yet been reached.

In general the conception of true healing has been built chiefly upon these arguments:

1. The original graft tissue remains unchanged, especially Bowman's and Descemet's membranes. The graft stroma does not totally disappear even 2½ years after operation, as reported by Fuchs,[22] and three years, as reported by Filatov.[19] Only the epithelium and endothelium seem to have been replaced.

2. The biologic principle of the individual specificity of tissue is inconsistent with the conception of active regeneration of the cornea. So said Forster,[20] "Transplantation from another species is a biological impossibility." The repeated failures reported in the literature of heterogeneous transplants seem to speak in favor of this conception.

3. The fact that devitalized transplants seldom succeed in taking and even more seldom remain transparent proved that, in order for a transplant to heal, the preservation of its vitality is necessary.

4. Immunologic experiments by Kiyama[21] have shown that the transplant retains its acquired immunity against vaccine virus even after it has healed to the donor tissue, so that any replacement of the donor tissue can be excluded.

5. That the transplant possesses unusual vitality is demonstrated clinically by its therapeutic effect in promoting the process of clearing and absorption of opacity in the vicinity of the graft as shown by the so-called "amelioration" treatment of Filatov,[17] and by the healing effect on serpiginous ulcers, as reported by Chechik-Kunina.[10]

6. The clinical experience of Elschnig[14] and Filatov,[19] which emphasizes the importance of normal surrounding corneal tissue for the maintenance of nutrition of the transplant, is but another evidence that the transplanted cornea actually possesses its own vitality.

The proponents of the regeneration theory, on the other hand, base their data chiefly on the experimental results of Salzer.[30–35] They believe that corneal tissue, like most other tissues of the body, possesses the power of regeneration by virtue of which the transplant is replaced eventually by the regenerated corneal tissue from the surrounding host. Thus the transplant does not retain its own structure, but merely acts as a dead foreign body, which is absorbed and disappears within the tissue of the host. They support their theory by the following data:

1. Implanted egg membrane and heterogeneous corneal tissue from a guinea pig placed in a pocket in a rabbit's cornea were found histologically to be invaded by the regenerated corneal tissue from the surrounding host.

2. Formalinized horse cornea implanted in the same manner first healed and then disappeared 15 months after implantation so completely that no trace was demonstrable, either clinically or histologically.

3. Corneal wounds uncovered by any

graft tissue when left alone can regenerate in the region of the gap with newly formed corneal tissue which is almost indistinguishable from normal cornea histologically.

Besides successful grafting with formalinized corneal tissue in animal experiments, as shown by Scherschewskaya,[36] and Wiener and Rosenbaum,[46] clinically transparent transplants have also been obtained in human beings with formalinized grafts by Scherschewskaya. Thus she said, "The healing of formalinized discs with preservation of their functional capacity can only be explained from the point of view of hidden regeneration or, in other words, by the role of the transplant as a carcass." But even more precise are the remarks of Wiener or Rosenbaum,[46] "If there is a true replacement, it is an extremely orderly one, and yet this must be the modus operandi, for surely one cannot conceive that dead tissue, such as formalinized cornea undoubtedly is, could be revitalized."

5. The reported success of heteroplastic transplantations on animals, as one finds in the literature (and clinically the case of lamellar keratoplasty by Von Hippel,[45] in 1888, using a dog cornea for a man where a graft actually "healed" with some degree of transparency) alone tends to disprove the theory of the biologic specificity of the corneal tissue. As Salzer says, "Since we are always dealing with the healing of a dead tissue, or a tissue which is sooner or later going to disappear, and not dealing with a true transplantation, it is absolutely indifferent (except from the mechanical and technical point of view) whether the graft is taken from the same species or from a widely different one."

Methods and Materials

Before we express our opinions on the subject, we wish to present our own experimental data in this connection for reference.

The material to be presented was obtained from a study of over 200 corneal transplantations on rabbits, and over 100 histologic sections of operated eyes. The technical methods of transplantation are presented elsewhere in the publications of one of the authors (H. M. K.).[24-26] Some of the operations were done with the use of sutures and some were done with fibrin as an adhesive to cement the graft in place. The rabbits were killed after a variable period of time up to nine months after operation, and the eyes were fixed in formalin and stained with hematoxylin and eosin. Some of the donor eyes were preserved in saline, some in other buffered physiologic solutions, some in merthiolate, and some in a moist chamber. Several transplants were obtained from formalinized eyes and some grafts were preserved by freezing and dehydrating at very low temperatures.[25] The sections were selected as typical of certain types of tissue reactions of interest to the ophthalmologist. The data on these sections will be found in Table 1 and the descriptions of the figures in Table 2.

Discussion of the Histologic Findings

Epithelium. The epithelium of the host grows rapidly into the wound at the margin of the graft and is the first cellular repair mechanism. In early sections epithelial cells can be seen lying between the stroma of the host and the graft.

Ordinarily these epithelial cells disappear later. There has been some controversy as to whether they are transformed into keratoblasts. It is our belief that the epithelium of the graft is lost within the first three days after transplantation and this is replaced by the growth of the host's epithelium.

The epithelium tends to fill in uneven surfaces and will be thicker in some places than in others in order to maintain a smooth optical surface. When the intraocular pressure is normal, the epithelium presents a fairly normal appearance after transplantation. When there is glaucoma, the cells become vacuolated, swollen, and cornified.

Bowman's membrane. In the rabbit, Bow-

DATA ON HISTOLOGIC SECTIONS OF CORNEAL TRANSPLANTS IN RABBITS

Slide No.	Case No.	Fig. No.	Time Elapsed after Operation	Preservation of Donor Eye	Sutures Used	Diameter of Disc	Postoperative Course	Clinical Result
315 O.S.	1	1a 1b	4½ months	4 hrs. in saline at +2° C.	fibrin	6 mm.	Slightly hazy on 12th day, then clearing, no synechia	Clear
323 O.S.	2	2a 2b	8 months 21 days	2 hrs. in saline at +2° C.	fibrin	4.5 mm.	Uneventful except for anterior synechia, at 6 o'clock, detached on atropinization	Translucent
347 O.S.	3	3	3 days	4 days in 1.1% $NaHCO_3$ Sol. at +2° C.	fibrin	4.5 mm.	Graft found edematous, anterior synechia	Opaque Edematous
305 O.D.	4	4a 4b 4c	4 days	4 hrs. in 1/20,000 Merthiolate at room temperature	silk	5.5 mm.	Anterior synechia	Edematous sl. cloudy
305 O.D.	5	5	4 days	4 hrs. in 1/20,000 Merthiolate at room temperature	silk	5.5 mm.	Anterior synechia	Edematous sl. cloudy
305 O.D.	5	6	4 days	4 hrs. in 1/20,000 Methiolate at room temperature	silk	5.5 mm.	Anterior synechia	Edematous sl. cloudy
344 O.S.	6	7	22 days	3 hrs. in saline at +2° C.	fibrin and silk	4.5 mm.	Suture too tight, graft surface hazy, showing marks of suture	Opaque
351 O.S.	7	8a 8b	1 month	½ hr. in saline at room temperature	fibrin	5 mm.	Anterior synechia	Opaque
325 O.D.	8	9a 9b	1 month 25 days	Graft removed and replaced in situ	fibrin	5.5 mm.	Graft not well fixed iris prolapsed	Opaque Edematous
395 O.D.	9	10a 10b	2½ months	From freshly enucleated eyeball	fibrin	4.75 mm.	Graft put upside down during operation, lost, lens protruded	Opaque
361 O.S.	10	11a 11b	3 months 2 days	2 hrs. in moist chamber at +2° C.	fibrin	4.5 mm.	Graft lost, corneal tissue shrank, narrowing the gap	Opaque
310 O.D.	11	12	2 months 21 days	Formalinized	silk	5 mm. sq.	Anterior synechia formed, marked inflammation, cornea ectatic	Opaque
23 O.D.	12	13	16 days	Frozen and dehydrated	silk	4.75 mm.	Severe iritis, graft edematous, vascularized	Opaque
30 O.S.	13	14	26 days	Frozen and dehydrated	silk	5 mm.	Graft healed with anterior synechia	Opaque
21 O.D.	14	15	1 month 11 days	Frozen and dehydrated	silk	5 mm.	Disc healed with anterior synechia, opaque on 7th day	Opaque
26 O.D.	15	16a 16b	6 months	Frozen and dehydrated	silk	4.75 mm.	Iris prolapse, graft at first edematous	Opaque

man's membrane is very poorly developed and some authors state that it is entirely absent.[10] Our studies tend to show that it is present, although in a very weakly developed form. We are led to this conclusion by the fact that a thin homogenous acellular layer can be seen underlying the epithelium, and that the epithelium peels off without great difficulty. However, in the rabbit this membrane is not a true membrane as it is in the human being.

Stroma. Shortly after transplantation a considerable amount of edema occurs in the stroma not only of the graft and host cornea but of the entire sclera as well. This edema is undoubtedly due to absorption of anterior-chamber fluid through the cut margins, and it subsides as the cut stroma becomes covered over with epithelial and endothelial cells. A considerable amount of early edema is still consistent with a perfectly transparent graft. The cornea also becomes markedly edematous in the presence of increased intraocular pressure, which usually results from exten-

TABLE 2

A TABULATED DESCRIPTION OF THE FIGURES

Fig.	Epithelium	Stroma	Descemet's Membrane	Endothelium	Iris Adhesions
1a 1b	Thickened, especially over junctions	Thinner than host with normal arrangement of lamellae	Y-shaped branch uniting with host's on one end, well preserved	Proliferated at junction, single layer elsewhere	None
2a 2b	Thinner over graft, thickened over junctions	Normal thickness structure loose, lamellae wavy	Only partly preserved no union with host	Intact	Pigment adhesion
3	Thin in middle, thicker near wound edges	Edematous, lamellae normal structure	Intact, wavy, fibrinous membrane behind, no union with host	Intact, partly proliferated	Pigment and anterior synechia
4a 4b 4c	Thin, peeled off toward edges; proliferated around central suture indentation; epithelial ingrowth into stroma at junction	Suture indentation in middle; edematous, lamellae wavy; fibroblastic repair	Partly preserved, reduced in thickness	Intact, partly proliferated at junction	Anterior synechia
5	Embedded suture between iris and cornea, showing giant cells and signs of fibrous encapsulation				Anterior synechia
6	Embedded suture in corneal stroma, showing same as above				Anterior synechia
7	Proliferated over wound edge, epithelial fold	Scar tissue. Cellular infiltration	Entirely absent	Intact	None
8a 8b	Variations in thickness	Anterior and posterior fibrous tissue layers with necrotic area in between	Well preserved, curled and embedded between fibrous layers	Intact, partly proliferated	Pigment adhesion
9a 9b	Totally lost	Totally cicatrized (edema of host cornea and sclera)	Entirely absent	Absent	Total anterior synechia
10a 10b	Intact, normal in thickness, darkly stained	Cicatrized with compact fibrous tissue	Absent	Absent	Synechia with fibrous syncytium
11a 11b	Cornified with variations in thickness	Irregular compact scar tissue	Partly preserved	Absent	Synechia with granulation tissue formation
12	Vacuolated and partly lost	Vascularized, infiltrated, edematous and scarred	Absent	Absent	Total anterior synechia with pigment proliferation
13	Absen	Partly organized fibrinous mass	Curled, pushed onto anterior surface	Absent	Iris adhesions at junctions
14	Uneven and irregular	Anterior and posterior fibrous tissue layers with necrotic area in between	Well preserved, curled and embedded between fibrous layers	Intact	None
15	Uneven and irregular	Anterior and posterior fibrous tissue layers with necrotic area in between	Well preserved, curled and embedded between fibrous layers	Intact	None
16a 16b	Uneven and irregular	Anterior and posterior fibrous tissue layers	Well preserved, curled and embedded between fibrous layers	Intact	None

sive anterior synechias. It is interesting to note in this connection that the sclera also becomes markedly edematous.

As is well known, the parallel arrangement of corneal lamellae is essential to transparency, and a pathologic process that interferes with this arrangement will impair transparency. Cellular infiltration due to infection, vascularization, increased intraocular pressure, and synechias, will all prejudice the transparency of the graft. If the graft tissue is unacceptable to the host, the stroma will be replaced by fibrous tissue, which will not have the regular parallel arrangement. This fibrous tissue tends to form beneath the epithelium and in front of the endothelium.

The reaction of the stroma to suture material is illustrated and consists of partial encapsulation with giant cells and the ingrowth of connective-tissue cells.

At the margin of the graft, keratoblasts grow in to heal the graft in position and these tend to form a parallel arrangement, so

that histologically the line of demarcation is hard to see in perfectly transparent grafts. Fibroblasts or keratoblasts are found at the junction long after the wound has apparently healed.

Synechias have a deleterious effect on the graft. If complete, they cause secondary glaucoma; if incomplete, they leave pigment deposits in the healing margin of the graft. They also serve as the origin for vascularization and scar-tissue formation. In marked cases they form the basis for granulation tissue.

Descemet's membrane. This membrane is well developed in rabbits and has a tendency to be regenerated, presumably by the endothelium. In the case of a perfectly fitting graft, Descemet's membrane can heal end to end, otherwise it tends to have several brush-like or Y-shaped extensions. In the grafts that degenerate or are replaced by fibrous tissue, Descemet's membrane can be seen usually in coiled or wrinkled state and is the last structure to be absorbed.

Endothelium. This layer covers the internal surface in all instances and is probably derived from the host. We have no definite knowledge as to the fate of the endothelium of the graft except that injury to the endothelium will increase the amount of postoperative edema. In some instances, the endothelial proliferation produces cystlike formations.

General discussion

We have learned several important factors in corneal transplantation from our study and we are able to infer others. In order for a corneal graft to remain clear and heal properly, it must be obtained from fresh viable cornea of the same species. The occasional reports that clear grafts have been obtained from transplantations of variously preserved corneas or from other species of animals are probably the result of laying down of fibrous tissue by the host cornea in parallel arrangement during the healing process. The epithelium and probably the endothelium are replaced in the graft by the appropriate cell layers from the host. The healing that takes place at the stromal level involves the ingrowth of a great number of fibroblasts or keratoblasts from the host. We are not sure as to the fate of the stroma cells in the central part of the graft. But in view of the fact that bodily tissue cells are normally replaced from time to time in the course of their metabolism, we believe that this also occurs in the cornea and that, over a period of years, the stromal cells replace the donor cells so that eventually the host takes over. However, the graft must be performed under such circumstances that it is surrounded by a sufficient number of normal corneal cells, and the transplanted cornea must be sufficiently viable so that a large proportion of its structure does not need to be replaced rapidly. When rapid replacement occurs the resultant membrane is translucent or opaque and often blood vessels find their way through the surrounding cornea to the site of the graft. Thus, our frozen and dehydrated grafts were sufficiently acceptable to remain in place and allow rapid replacement, but the latter process rendered the grafts opaque.

Anterior synechias are very prejudicial to the success of the graft. They form the basis for vascularization, fibrosis, glaucoma, and iridocyclitis. Uveitis is very much more prone to occur in human grafts, where the eye is not normal to begin with, than it is in the rabbit. Anterior synechias can be avoided by careful coaptation of the wound margins and through thorough dilatation of the pupil.

We really do not agree entirely with either extreme point of view as to the biologic process taking place in corneal transplantation. From the preceding discussion, it can be seen that our views agree in part with each. It is not necessary to regard one theory as completely exclusive of the other.

SUMMARY AND CONCLUSIONS

The literature on the histology of corneal transplantation, both human and experimental, is summarized, together with a discussion of the evidence in favor of true healing versus replacement of the graft.

Our experimental studies are presented, with sections showing normal healing as well as operative complications. Since corneal tissue is unique in its properties of transplantability, considerable emphasis is placed on this phase.

The authors believe that, in successful cases, the cellular elements of the transplant are replaced by the host, and that the intercellular structures of the graft are accepted and persist.

EFFECTS OF PRACTICE AND THE CONSISTENCY OF REPEATED MEASUREMENTS OF ACCOMMODATION AND VERGENCE*

JOSEF BROZEK, ERNST SIMONSON, WILFRED J. BUSHARD,† AND JOHN H. PETERSON†
Minneapolis, Minnesota

INTRODUCTION

This laboratory has been interested for some time in the problem of standardization and methodologic evaluation of physiologic procedures and measurements.[1] The knowledge of their variability is essential for the interpretation of the significance of experimentally induced changes. In the clinical practice, the knowledge of the magnitude of "chance" variations in repeated measurements is important from the point of view of the confidence with which we can appraise the presence or absence of functional abnormalities in patients, trends of deterioration or of spontaneous improvement, and the effects of therapy.

Appropriate statistical methods of analysis of the repeatability of the measurements were developed (see Appendix) and analyses of several physiologic functions and biochemical characteristics were made.[2-5] In a recent series of investigations on visual fatigue, several routine ophthalmic methods were used together with other visual tests, the measurements being made before and after the completion of strenuous visual work. The values taken before the start of the work period are suitable for an analysis of the variability of measurements obtained on normal subjects in repeated determinations under well-defined, standard conditions.

In this paper we shall deal only with the ophthalmic tests of accommodation and motor function. There is very little information on the effect of repeated administration of these tests and of the repeatability (consistency) of the scores. This is rather surprising, for one would expect that variations of a method which is used in clinical routine would be known. Obviously, the variability of measurements in normal subjects is important for the interpretation of changes in patients, particularly in the consideration of borderline cases.

METHODS

Measurements were made of accommodation and vergence. Current clinical methods were used.

The accommodation near point was determined by the Prince rule, manufactured by the American Optical Company. The rule was supported on the infraorbital bony rim. The subject was asked to fixate a short line of letters, 0.031 inches in height; at 14 inches the height of these letters corresponds to the size of symbols at the "14/21" line in tests of the acuity for near vision. The letters were printed on dull-white cards, placed in a metal carrier which slides along the rule. The illumination at the level of the card was about 5 foot-candles, about one half of the value recommended by Berens and Zuckerman;[6] the illumination was constant throughout the whole experimental series. The card was brought toward the eye from the range of clear vision to the point at which the letters started to become blurred, and the reading was recorded. Three consecutive measurements were made using the dominant eye; the score is the average of the three determinations and indicates the accommodation near point, in centimeters. The true accommodation near point should be determined as the distance from the anterior focus of the eye, located about 14 mm. in front of the cornea, to the

* This work has been supported in part by a grant from the Verd-A-Ray Corporation, Toledo, Ohio. From the Laboratory of Physiological Hygiene, University of Minnesota.

† Department of Ophthalmology, University of Minnesota.

point of blurring. The correction is essential when the power of accommodation is expressed in terms of diopters; to compute the latter, the reading (in cm.) obtained on the rule is corrected for the distance of the anterior focal point from the cornea and divided into 100.

The convergence near point was also obtained by the Prince rule, this time held against the bridge of the nose, in midplane. A white circular target, 2 mm. in diameter, taken from a Berens perimetry set, was brought in from the distance of clear vision to the point of binocular diplopia. The distance, in millimeters, from the bridge of the nose to the point at which the break in fixation occurred, served as a score. Three consecutive readings were made and averaged.

Values for abduction (prism divergence), adduction (prism convergence), and positive vertical divergence (prism supravergence) were obtained by the Risley rotating prism, held in front of one eye, while the subject was fixating with both eyes a spot of light six meters distant. The prism strength was increased until the "breaking point" was reached at which the light spot was seen double. A strain was imposed in the direction of abduction, adduction, and positive vertical divergence. The instrument readings were recorded in prism diopters. Each measurement was obtained in triplicate; the score is the average of the three successive determinations.

Subjects

The subjects were six men in the age group of 20 to 30 years, who had served in the laboratory for the year preceding the visual research as full-time experimental subjects in nutritional investigations. They were physically normal, intelligent, and coöperative, with no significant ophthalmic defects, well accustomed and adjusted to the routine of laboratory work and testing.

The visual characteristics (table 1) were well within the normal range, except for the accommodation near point.

TABLE 1

Characterization of the group at the start of the experimental work

Function	Subject Number						Mean	Standard Deviation	Normal Average	Normal Range	Desirable Values
	1	2	3	4	5	6					
Abduction, in diopters	4.3	8.0	5.7	10.0	5.3	5.3	6.43	2.14	6	3 to 8	High
Adduction, in diopters	7.7	5.3	15.7	18.3	16.3	10.0	12.22	5.28	12	(6 to 16)	High
Vertical divergence, in diopters	2.7	2.8	2.7	3.0	2.0	2.3	2.58	0.37	2.5		High
Accommodation near point, in diopters	6.9	6.8	8.4	9.3	6.8	9.9	8.02	1.39	(10.5)	(8.3 to 12.6)	High
Convergence near point, in centimeters	7.7	6.7	4.8	6.3	2.0	6.2	5.62	2.00	6.4	up to 8.0	Low

N =6 subjects, average age 23 years; range, 22 to 25 years. The "normal" values were obtained directly or by interpolation from Berens.[6]

The average accommodation value for the group is eight diopters which is near the subnormal range for the age group. In Duane's table the average-normal value of accommodation for 23 years of age is 10.5D., with the normal-minimum at 8.3D. Following Berens's statement that accommodation may be considered normal if it is not more than 3D. below the mean for the subject's age,[6] we arrive at 7.5 D. as the lower limit of normality.

The value is affected by a number of factors, environmental (illumination intensity on the test object), technical (speed at which the test object approaches the eyes), and subjective (criterion of blurring). The somewhat lower illumination level and the fact that the subjects were encouraged to report the very first sign of blurring may well be the major reasons for the low accommodation values in subjects whose ocu-

lar equipment was clinically considered as a "good normal."

Effects of practice

In a number of variables used in testing different aspects of "fitness" in man the repeated performance leads to an improvement in the test scores. Such an improvement represents an effect of "practice." Practice consists of small modifications in the "work method" of the subject and, in tests involving discrimination, a change in the sensory criterion of identity or difference. Practice does not necessarily bring about an "improvement" in performance but simply a change in the score, not related to any organic, physiologic, or structural alterations. Practice should not be confused with "training" in which a true increase in the functional capacity takes place.

The factor of practice, when present to a significant degree, considerably complicates the experimental design in which provision has to be made for an adequate and sometimes prolonged practice period. The test scores have to be brought up to a relatively stable practice plateau before the start of the experiment proper or other measures of control must be provided. In patients, the practice effects may produce an erroneous impression of improvement.

What is the effect of practice on the ophthalmic tests described above? The tests were administered before and after two hours of strenuous visual work, in a series of 18 testing sessions, with three testing days per week. The effects of practice on the prework test scores will be studied by comparing the means of Trials 1 through 3 with the mean of Trials 4 through 6, and 16 through 18. The individual scores obtained in the testing sessions compared will be considered as paired variates, Y′ and Y″.

TABLE 2

Average scores of the first, second, and sixth set of three successive testing sessions; the mean differences ($\bar{d}$); and the F tests of their statistical significance

Function	Means			Differences		F-tests	
	1st Set	2nd Set	6th Set	2nd vs. 1st	6th vs. 1st	2nd vs. 1st	6th vs. 1st
Abduction, in diopters	5.81	5.40	5.02	−0.41	−0.79	0.70	2.86
Adduction, in diopters	14.96	15.60	12.55	+0.64	−2.31	0.21	2.34
Vertical divergence, in diopters	2.68	2.70	2.50	+0.02	−0.18	0.04	1.33
Accommodation near point, in diopters	7.94	8.14	7.93	+0.20	−0.01	0.58	0.00
Convergence near point, in centimeters	5.43	4.51	3.75	−0.92	−1.68	8.10*	17.35**

For 1 and (18−1)=17 degrees of freedom, the value of the F ratio at the 5% level of significance is 4.45, at the 1% level it is 8.40. The level of significance has been indicated by one and two asterisks, repectively.

With six subjects, each tested on three days in each series, we have 18 values of d, defined as the difference between the paired values, $d = Y'' - Y'$. The F-test of the statistical significance of the mean difference, d, can be expressed in a simple form:

$$F = \frac{(\sum d)^2/n}{\frac{\sum d^2 - (\sum d)^2/n}{n-1}}$$

where n is the number of differences.

The mean differences—that is, the differences between the average scores obtained in the three sets of testing sessions—and the F test of their statistical significance are given in Table 2.

All changes accompanying repeated administrations of the tests are slight and have no statistical significance except for the change of the convergence near point

which shows a significant improvement on 4th, 5th, and 6th testing; this trend is even more marked in the 16th, 17th, and 18th testing session.

Consistency of repeated measurements

When a test has been repeated under standard conditions on a group of n individuals, I, in a series of k testing trials, D, the consistency of the measurements can be characterized in terms of:

1. The amount of the *intraindividual variation,* measured as $S.D._{wI}$, the average *standard deviation* of the scores *within individuals.* It should be noted that the use of $S.D._{wI}$ for characterizations of the repeatability of a measurement is legitimate only when the mean scores of a group of subjects, tested in a series of repeated testing trials, do not show a systematic trend.

2. The magnitude of the *random variation,* expressed either in the form of the *standard deviation* of the *random* components of the scores, $S.D._R$, or of a *consistency* coefficient, r_C. Neither the $S.D._R$ nor the r_C are affected by the changes in the trial means of the group as a whole.

The derivation of these concepts and the computational formulas are given in the Appendix.

The two types of criteria of consistency, the $S.D._{wI}$ and the $S.D._R$ on the one hand, and the consistency coefficient, r_C, on the other hand, have each some advantages and some limitations.

The concept of intraindividual variation may be readily understood and the term $S.D._{wI}$ indicates the magnitude of the variation in the repeated measurements directly, in terms of the units used in the test. However, the $S.D._{wI}$ values are, as a rule, not commensurable from test to test and do not yield a criterion in terms of which the consistency of different tests could be compared. The evaluation of a given absolute value of $S.D._{wI}$ as a criterion of consistency remains, therefore, impressionistic and the validity of the judgment depends on the breadth of clinical and research experience of the experimenter who is making such a judgment. He actually compares the obtained value with an impression obtained from measuring a large number of subjects and evaluates the given magnitude of the "error of measurement" in reference to the range of "normal" variation or to the differences between "normal" subjects and patients.

The use of the standard deviation of the random components of the scores, $S.D._R$, is subject to similar limitations. It is not a value in terms of which different tests can be directly compared. It becomes much more useful when related to the amount of interindividual variation, measured as the "variance within days" (Appendix, Formula 7).

From this is a short step to the second type of a criterion of consistency, r_C; this modified coefficient of intraclass correlation is an index which may be used directly for comparison of different tests and is closely related to the ordinary product-moment coefficient of correlation computed when only two repeated trials are available. The term r_C depends on two factors (Appendix, Formula 8): (1) the variation between individuals (reflected in V_{wD}) and the random variation (indicated by V_R). In the present experiment, efforts were made in advance to secure a highly homogeneous group of "normal" subjects. Thus the variation between individuals has been decreased and the obtained r_C values are underestimates of the consistency which could be expected in a relatively unselected group of subjects, particularly if patients would be included in the sample.

For the purpose of evaluating the consistency of the battery of ophthalmic measurements on repetition we shall use a set of data obtained in the third series of testing sessions, each series consisting of six trials. At this time the technique of the experimenters and the manner of response of the subjects can be considered as ideally stabilized, and the analysis should be expected

to yield the highest measure of consistency obtainable under standard conditions of over-all physical fitness, nutritional status, activity, and illumination. The interval between test sessions was 2 to 3 days. The original data are given in Table 3, A to E. Variances basic to the evaluation of consistency of repeated measurements are presented in Table 4, the consistency criteria in Table 5.

In terms of $S.D._{wI}$, the tests on repetition appear to yield values of acceptable consistency; that is, the intraindividual variability is relatively small as compared to the extent of the normal range and, more importantly, to the differences between normals and patients. Sometimes efforts are made to provide a criterion suitable for comparing the consistency of different tests by expressing $S.D._{wI}$ as percentage of the grand mean of the n.k scores. This is a hazardous procedure and the figures in Table

TABLE 4

VARIANCES BASIC TO EVALUATION OF CONSISTENCY OF REPEATED MEASUREMENTS

Function	V_{wI}	V_R	V_{wD}
Abduction	0.77	0.63	1.57
Adduction	11.90	9.40	49.60
Vertical divergence	0.08	0.07	0.18
Accommodation near point	0.42	0.30	1.25
Convergence near point	0.60	0.40	1.90

V_{wI} = variance between daily scores within individuals; V_R = random variance; V_{wD} = variance between individual scores within days.

SUMMARY

1. Measurements of ocular accommodation and vergence were made in six subjects under standard conditions.

2. The measurements were repeated at intervals of 2 to 3 days in a series of 18 testing sessions.

3. Two preliminary trials were sufficient in the majority of the routine ophthalmic tests used to stabilize the scores at a plateau.

4. The measurements provide reasonably

TABLE 5

CONSISTENCY OF REPEATED MEASUREMENTS. ABSOLUTE VALUES OF $S.D._{wI}$ AS AN INDEX OF DAY-TO-DAY VARIABILITY; $S.D._{wI}$ EXPRESSED AS PERCENTAGE OF THE MEAN ($\bar{Y}$); AND r_C, THE COEFFICIENT OF CONSISTENCY

Function	Mean ($\bar{Y}$)	$S.D._{wI}$	$\frac{S.D._{wI} \times 100}{\bar{Y}}$	r_C
Abduction	4.96 D.	0.88 D.	17.8%	0.60
Adduction	13.30 D.	3.45 D.	25.9%	0.81
Vertical divergence	2.48 D.	0.28 D.	11.3%	0.61
Accommodation near point	7.90 D.	0.65 D.	8.2%	0.76
Convergence near point	3.97 mm.	0.78 mm.	19.6%	0.79

3 should be accepted with reservation and interpreted with caution.

The r_C values vary from 0.60 to 0.81; in a reasonably heterogeneous group of subjects, values of r_C below 0.70 would be regarded as indicating a low consistency of the scores on repeated testing, $0.71 \leqq r_C \leqq 0.80$ would be interpreted as an index of moderately high consistency. Thus in the present test battery only the measurements of adduction, accommodation near point, and convergence near point appear to have the desired degree of reliability on repeated testing. However, it should be realized that the interindividual variability in our group was small; the r_C values are spuriously low. For a definite judgement as to the consistency of these tests similar investigations should be carried out on larger samples and on clinical material.

constant characteristics of the individual subjects.

STATISTICAL APPENDIX

The day-to-day variation in the scores of a group of n individuals tested on k days can be expressed as the average *standard deviation of the scores within individuals:*

$$(1) \qquad S.D._{wI} = \sqrt{\frac{\sum_{1}^{n} \frac{\sum_{1}^{k} (Y_I - \bar{Y}_I)^2}{k-1}}{n}}$$

We obtain the variances of the scores of each individual,

$$\frac{\sum_{1}^{k} (Y_I - \bar{Y}_I)^2}{k-1},$$

where Y_I is a score of an individual, I, on

a given trial, $\bar{Y}_I$ the mean of his scores on the k trials, D; we sum the intraindividual variances for all n individuals, average for an individual by dividing the numerator through n, and take the square root.*

Under certain conditions there may be present a continuous trend in the average scores obtained by a group of subjects in successive trials, resulting from a continued practice. In other situations, there may be significant shifts in the level of the mean score resulting from factors which affect the group as a whole; for example, change in environmental illumination. In such cases the value $S.D._{wI}$ will be large and would yield an underestimate of the reliability of the given test method.

The effect of "trend," both continuous and reflected in the shifts of the group means, is removed when we use the second criterion of consistency of repeated measurement, the random variance, V_R. If $\bar{Y}_I$ = mean of the k scores for a given individual, $\bar{Y}_D$ = mean of the n scores for a given day (or trial), $\bar{Y}$ = the grand mean of the n.k scores, then the *expected value* ($\hat{Y}$) of the score for a given individual and day will be obtained as follows:[7]

$$(2) \qquad Y=\bar{Y}+(\bar{Y}_I-\bar{Y})+(\bar{Y}_D-\bar{Y})$$

The grand mean, ($\bar{Y}$), indicating the general level of the scores, is adjusted for the average level of the scores of the given individual by adding the component ($\bar{Y}_I - \bar{Y}$) and for the average level of the scores on a given day by adding the component ($\bar{Y}_D - \bar{Y}$).

The actual score (Y) may then be regarded as a sum of the expected score ($\hat{Y}$) and a random component (R):

$$(3) \qquad Y=\hat{Y}+R$$

Therefore,

$$(4) \qquad R=Y-\hat{Y}$$

Substituting for Y from Equation 2 we obtain:

$$(4a) \qquad R=Y-[\bar{Y}+(\bar{Y}_I-\bar{Y})+(\bar{Y}_D-\bar{Y})]$$

After removing the brackets

$$(4b) \qquad R=Y-\bar{Y}-(\bar{Y}_I-\bar{Y})-(\bar{Y}_D-\bar{Y})$$

In a table of n.k scores, there are (n-1) (k-1) independent estimates of R, as both the individual and trial means were used in computing the R values; (k-1) (n-1) is the number of the "degrees of freedom" which will be used as denominator in computing V_R.

The *random variance* is then defined as:

$$(5) \qquad V_R=\frac{\sum_1^{nk} R^2}{(n-1)\,(k-1)}$$

$$(5a) \qquad V_R=\frac{\sum_1^{nk} [Y-\bar{Y}-(\bar{Y}_I-\bar{Y})-(\bar{Y}_D-\bar{Y})]^2}{(n-1)\,(k-1)}$$

In order to evaluate the magnitude of V_R we compare it with the differences between individuals. Ideally we should like to use the variance (= standard deviation squared) of the scores in a large, representative sample of individuals for whom the test will be used. Such a variance value is a stable characteristic of each test and would provide a criterion in terms of which different tests could be legitimately compared. Unfortunately this datum is known only for a very few physiologic functions.

Our best substitute is the value V_{wD}, the *"within days" variance,* which represents the interindividual variance obtained for each day (or trial) and averaged:

$$(6) \qquad V_{wD}=\frac{\sum_1^{k} \frac{\sum_1^{n}(Y_D-\bar{Y}_D)^2}{n-1}}{k}$$

We obtain the variances of the scores on each of the k days,

$$\frac{\sum_1^{n} (Y_D-\bar{Y}_D)^2}{n-1},$$

* In this and other cases the standard deviation is obtained as the square root of the sample variance, thus $S.D._{wI}=\sqrt{V_{wI}}$ and $S.D._R=\sqrt{V_R}$.

where Y_D is an individual score on a given day, $\overline{Y}_D$ the mean of the scores of the n individuals measured on that day; sum for all k trials, and average for a trial by dividing by k.

In evaluating the magnitude of the random variance, V_R, we may express it as the percentage of V_{wD}

$$V_R\% = \frac{V_R}{V_{wD}} \times 100 \tag{7}$$

Also we may express it in a form of a consistency coefficient

$$r_C = 1 - \frac{V_R}{V_{wD}} \tag{8}$$

Equation 8 may be written also as

$$r_C = \frac{V_{wD} - V_R}{V_{wD}} \tag{8a}$$

It is evident that when $V_R = O$, $r_C = 1.0$; the closer V_R approaches the value of V_{wD}, the closer r_C approaches zero.

For a rapid computation of the values needed for the characterization of the reliability of a test we may apply formulas which use the scores directly, without computing the deviations from the grand mean. The formulas 1, 6, and 8 may be written as follows:

$$S.D._{wI} = \sqrt{\frac{\sum_1^{nk}(Y^2) - \frac{\sum_1^{n}(T_I^2)}{k}}{n(k-1)}} \tag{9}$$

$$V_{wD} = \frac{\sum_1^{nk}(Y^2) - \frac{\sum_1^{k}(T_D^2)}{n}}{k(n-1)} \tag{10}$$

$$V_R = \frac{\sum_1^{nk}(Y^2) - \frac{\sum_1^{n}(T_I^2)}{k} - \frac{\sum_1^{k}(T_D^2)}{n} + \frac{(GT^2)}{nk}}{(n-1)\quad\quad(k-1)} \tag{11}$$

where Y = any score, n = number of individuals, k = number of days (trials), $T_I = \sum_1^k Y_I$ = total for an individual, $T_D = \sum_1^n Y_D$ = total for a day, $GT = \sum_1^{nk} Y$ = grand total.

Stadium South Tower (14).

NOTES ON THE HISTORY OF OPHTHALMOLOGY IN CANADA*

J. A. MacMillan, M.D.†
Montreal, Quebec

Colonial medical history

A glimpse into the early medical history of Canada is, I think, important before entering into the history of ophthalmology which did not exist as a specialty until many years later. According to Freedman,[1] in a recent paper on "The History of Medical Licensure in Canada," the early medical practice in Canada, under the French régime, was influenced by the medical practice in France, where all trades were controlled by guilds and membership in a guild was a certificate of competency. Surgery was controlled by the barber surgeons. They did traumatic surgery but most of their work consisted of blood-letting, and of opening boils and abscesses. Medicine was practiced by physicians who were graduates of medical schools and were licensed by examination.

A few surgeons came to Canada with the French military forces. Colonists had to be induced to come to Canada, and one of the promises in this inducement was that, if a man came to Canada and followed a trade for 6 or 8 years, he would, on his return to France, be admitted into the guild of the trade or profession he had followed. This resulted in many colonists taking up surgery and the number of charlatans and quacks soon exceeded the number of qualified men. To overcome this deplorable state, the Intendant Bigot, in 1750, passed the first piece of medical legislation in Canada.

The bill enumerated the harmful acts of the charlatans and strangers of unknown ability. Such persons were forbidden to practice under the penalty of a fine with forfeiture of their drugs and instruments, and those who wished to practice medicine were obliged to pass an examination before a representative of the Intendant and the King's Surgeon.

Early medical education

Thirteen years later New France fell to the British and at first, under British rule, there was no control of practice, so that conditions reverted to the old order.

In 1788, however, a medical act was passed in an attempt to relieve chaos in the practice of medicine. This act forbade the practice of unlicensed practitioners under a penalty of 20-pounds fine for the first offense; 50 pounds for the second offense, and 100 pounds and three months in prison for subsequent offenses.

The prerequisites to the study of medicine were examinations in the mother tongue and in Latin. Medical education required a certificate from a recognized university or a five-year apprenticeship with a practicing physician in the province.

Canada was divided into Lower and Upper Canada in 1791. The first legislation affecting the Province of Quebec alone was in 1831, and it is interesting that this act provided for penalties against American practitioners who crossed the border into Canada to see patients.

In 1823, the Montreal Medical Institution was formed by a group of men who taught students in the wards of the Montreal General Hospital, which had opened four years previously. Then, in 1829, the Montreal Medical Institution became the Medical Faculty of McGill University, the first university medical faculty in Canada.

Howard, first ophthalmologist in Canada

It was not until many years later that

* Read at the Centennial Meeting of the Section of Ophthalmology, New York Academy of Medicine, New York, March 17, 1947.

† Professor of Ophthalmology, chairman of the department of ophthalmology, McGill University; ophthalmologist-in-chief, Royal Victoria Hospital.

ophthalmology was practiced as a specialty in Canada, and the first man to limit his practice to it was Henry Howard, M.D., M.R.C.S., London. He was born at Nenagh, Tipperary, Ireland, December 1, 1815, where he was educated.

Dr. Howard studied his profession in Dublin, attending lectures in the College of Surgeons and the University of Trinity College. His early studies in Dublin were under the guidance of one of the most learned and successful European practitioners of ophthalmology—Arthur Jacob, professor of anatomy and physiology in the Royal College of Surgeons of Ireland, and one of the surgeons of the City of Dublin Hospital. Jacob made many contributions to medicine among which was *A Treatise on the Inflammations of the Eyeball,* published in 1849.

After practicing in Dublin and County of Leatrim for a time, Dr. Howard immigrated to Canada in 1841. For a short period he resided on Amherst Island, in Upper Canada, then at Kingston, and finally he took up residence in Montreal. Here, he was offered an opportunity for which he had always longed—to devote his whole time to eye and ear surgery.

Publishes textbook

In the preface to his book on *The Anatomy, Physiology, and Pathology of the Eye,* it is stated that he had for the past four years, as the surgeon to the Montreal Eye and Ear Institution, devoted his labors exclusively to the treatment of disease incident to these organs. This book, published in 1850, by Armour and Ramsay, Montreal, and John Churchill, London, was an octavo of 517 pages. It is a very good textbook for the time, and it is not simply a compilation of work done by previous authors but it also includes his own conclusions based on his studies and practical experience.

From the *Montreal Directory of 1847,* it was learned that the Institution for the Treatment of Diseases of the Eye and Ear, conducted by Surgeon Howard, M.D., and the Rev. W. A. Adamson, secretary and treasurer, was situated in the Hay Market. Subscribers of one pound per annum had the privilege of recommending poor patients to the institution. This institution was separate from Dr. Howard's house; but, in 1849, the address of the institution was 6 St. François Xavier Street, which was also his domicile. This address appears in the foreword of his book.

In 1861, he was appointed medical superintendent of a lunatic asylum at St. Johns, Quebec. The last year in which the Montreal Eye and Ear Institution was listed in the *Montreal Directory* was 1860, and Dr. Howard's name does not appear in the directory thereafter. This would conform to his appointment to the mental hospital.

From here on, as he left the field of ophthalmology, his later life does not concern us, except to mention that his tenure of office was a successful one. When confederation placed the insane under provincial management and the asylum at St. Johns was closed and the patients were moved to St. Jean de Dieu Asylum, near Montreal, Dr. Howard then became government inspector, a position which he held until his death in 1887.

Writings of Dr. Howard

Among many articles written by Dr. Howard was one on "On the Observations on the Curability of Opacities of the Cornea Treated by Prussic-Acid Vapor," a method of treatment suggested by a Dr. Bigger. He mentions six cases cured by this method. The article was published in the *British-American Medical and Surgical Journal, 1846-47.*

In the same journal, in the same year, there was a paper by Howard on "The Physiology of the Muscles of the Eye with Some New Views on Their Action." He emphasized in this paper that the inferior oblique and the superior oblique muscles are involuntary or reflective and that the rectus muscles are voluntary in their action. And in the same journal, same year, is an-

other paper by Dr. Howard on the "Physiology of the Fifth Pair of Nerves, But More Particularly the Ophthalmic Branch." He believed that the effect produced on the eye by belladonna was through its action on the fifth pair of nerves.

In 1850, he reported a case of traumatic cataract in which the lens was absorbed by the aqueous. Outside the subject of ophthalmology, in 1871, he published a pamphlet on a "Treatise on the Howard System of Ventilation." In this it is proposed to "expel foul air as fast as generated and admit pure air as fast without sensible draught on the person." The pamphlet contains 13 pages and at the end, under caution, is the warning that "any person found using one of Howard's expellers or ventilators without the patent stamp being on it would be prosecuted with the full rigor of the law. The prices can be learned from the maker on application." Dr. Howard was a highly esteemed member of the medical profession.

Early 19th century oculist

Perhaps the first well-trained oculist of his time to go to Upper Canada was Dr. Samuel John Stratford, M.R.C.S., London. He was a graduate of St. Georges and Westminster Hospitals in London, and was a pupil of William Charles Bell, and also of Dr. Guthrie at his infirmary. He wrote *A Manual of the Anatomy, Physiology and Diseases of the Eye and Its Appendages,* published in 1828, by Longman and others. It is a work of 190 pages, well written, and although it covers the diseases and their treatment, as well as the anatomy and physiology of the eye, optics and refraction are not included. He was commissioned assistant surgeon in the 72nd Regiment Scotch Highlanders but later he disposed of his commission and came to Canada, and for a time practiced in Bye-Town, now Ottawa, in 1831.

Later, Dr. Stratford moved to Woodstock, Upper Canada, where he remained for 20 years in general practice. In 1868, he went to New Zealand. There is no mention of restriction of his practice to diseases of the eye. He probably was influenced by his father, Dr. John Stratford, who was also an M.R.C.S., London, and who came to Canada in 1833. At Brockville, he issued the following professional card: "Dr. Stratford, Surgeon, Accoucher and Oculist; 30 years a member of the Royal College of Surgeons, London; 20 years in his Majesty's Military Service in that capacity, and many years in extensive private practice. Dr. Stratford has extended his practice to the diseases of females and children with more than ordinary success in their treatment."

Rosebrugh, Toronto ophthalmologist

According to Dr. P. J. F. Houston,[2] Abner M. Rosebrugh was the "Father of Ophthalmology" in Toronto, since he was the first to limit his practice to diseases of the eye and ear. Born in Branchton, in Upper Canada, in 1835, he studied at Rolfe's School of Medicine and started practice at Preston.

Since he had no special training, Dr. Rosebrugh studied first on animals and then decided to go into the specialty. He did postgraduate work in New York and London and started practicing in Toronto, in 1863. He endeavored to get the endorsement of the medical practitioners of the city but it was not unanimous. Nevertheless, his office was soon filled with special cases so that with the help of a few business men an Eye and Ear Hospital was opened on Adelaide Street, where he gave years of service to the poor of Toronto and the surrounding country.

Invents an ophthalmoscope

He was an ingenious man and invented among other things a demonstrating ophthalmoscope and a modification of it by means of which photographs of the fundus could be taken. This was in 1865, and a description of the instrument is included in his course of lectures delivered before the

ophthalmic class of the Toronto School of Medicine. These lectures were published in the *Canadian Medical Journal,* in 1866, under the headings of "The Optical Defects of the Eye and Their Treatment by the Scientific Use of Spectacles," and also "On the Ophthalmoscope." The lectures show that Dr. Rosebrugh had a good knowledge of optics but that refraction at that time consisted of prescribing spheres because he mentions that cylinders were prescribed for astigmatism but he himself had only seen one case of astigmatism.

Early teacher of ophthalmology

In 1867, Dr. Rosebrugh was joined in the practice by his brother-in-law, Dr. Richard Andrew Reeve, who became one of the most outstanding oculists in Canada. Dr. Reeve was born in Toronto, in 1842, was educated at Toronto University, and followed his medical studies at Queen's University, Kingston, being graduated in 1865. He was a demonstrator in anatomy the next year and in chemistry the following year. He then decided to practice ophthalmology and joined Dr. Rosebrugh at the Eye and Ear Infirmary in Toronto.

In 1872, he became ophthalmic and aural surgeon to the Toronto General Hospital, and, in 1887, he was appointed professor of ophthalmology and otology at the University of Toronto, retiring in 1915. He was made dean of the Faculty of Medicine in 1896, and held that position for 12 years. In 1906, he was president of the British Medical Association when that society met in Toronto.

Dr. Reeve was a leader, not alone in his special field but also in medical and university circles. The high regard in which he was held was not only because of his character and dignity but also because of his wide clinical knowledge. In addition to a series of papers and addresses, Dr. Reeve, by his lectures and clinics, did his share in the training of successive generations of medical students.

Dr. Reeve was succeeded in the chair of ophthalmology at Toronto University by Dr. James Metcalfe MacCallum, who held the chair until 1929. Dr. MacCallum in turn was succeeded by Dr. William Lowry and later by Dr. Walter Wright. Many other Toronto oculists contributed their share in the teaching of ophthalmology, and of these, perhaps Dr. George Herbert Burnham and Dr. George Stirling Ryerson should be especially mentioned.

Influence of Desjardins

The first well-trained ophthalmologist among our French-speaking confreres was Dr. Louis Edward Desjardins who was born in 1837, at Terrebonne, Quebec. He was graduated from L'Ecole de Médecine et de Chirurgie de Montréal, in 1864, and after practicing general medicine for seven years went to Europe to specialize in ophthalmology. He worked in London under Bowman and Critchett, and in Paris under de Wecker, Galezowski, de Sichel, and Meyer, and returned to Montreal in 1873. He founded the Nazareth Ophthalmic Institute where he practiced ophthalmology for over 30 years.

In history of Medical Faculty University of Montreal

In 1882, he was named professor of ophthalmology at L'Ecole de Médecine et de Chirurgie de Montréal, and oculist to the Hotel Dieu, where he lectured until his last illness. He played a very important role in the history of L'Ecole de Médecine et de Chirurgie de Montréal, which today is the Medical Faculty of the University of Montreal.

This school originated in 1843, ostensibly to meet the needs of the French-Canadian student public but undoubtedly also as a protest against what was then considered the monopoly of teaching privileges and of appointments at the Montreal General Hospital by those in authority at McGill University.

Its first teachers were all English-speaking. The legislature of the Province of Que-

bec passed an act under which lectures were to be given in French and English and authority was given for certificates to be awarded to its graduates to practice medicine. The latter privilege was cancelled two years later, in 1847, that is 100 years ago this year, on the incorporation of the College of Physicians and Surgeons of the Province of Quebec, which gave licenses only to those holding a university degree. In the emergency, an agreement was reached with McGill University under which all the lectures were to be given at L'Ecole de Médecine et de Chirurgie, in the French language only, and the students who completed this course at this school were to be admitted to the final year at McGill, which would entitle them to a degree from McGill University. This arrangement lasted until 1850.

The school then applied to Laval University in Quebec for affiliation, but this failed and, in 1867, it became affiliated with Victoria University of Cobourg, Ontario, a Protestant institution.

New troubles arose; so, in 1877, Laval University of Quebec came forward with new proposals backed by the Roman Catholic Church. This caused a break-up in the school; some students going to Laval and others continuing with L'Ecole.

During the years, a serious misunderstanding arose which threatened L'Ecole for it found itself barred by the church from attendance at the Hotel Dieu, which was deeply regretted by the nuns, and its members and students were excommunicated on the grounds of disobedience to authority and association with a Protestant university.

The painful situation was saved by the direct intervention of the Pope, before whom matters were laid by Dr. Desjardins in person, representing L'Ecole. He said, "I will go to Rome to obtain justice for L'Ecole even if I have to remain there."

Founds medical journals

Dr. Desjardins was one of the founders of *L'Union Médicale* and some years later of the *Gazette Médicale*. He published a certain number of scientific works on cataract, glaucoma, affections of the lids, and refraction, and he was interested in ocular research among the deaf mutes. He devoted his leisure to music. He was the "Father of Ophthalmology" in French-speaking Montreal.

Among his successors were several very able ophthalmologists, all of whom were trained in France, and all of whom included diseases of the ear, nose, and throat in their practice. Dr. A. A. Foucher,[3] who succeeded him at the University of Montreal and was chief of the department at the Notre Dame Hospital, published a textbook on *Maladies des Yeux et des Oreille,* in 1894. The part on the eye consists of 243 pages. Dr. Rudolfe Boulet and Dr. Albert LaSalle deserve special mention. They were charming men who served long and well, as did Dr. J. N. Roy, who is still living.

Buller, first modern ophthalmologist

Dr. Frank Buller was the first modern ophthalmologist to establish himself in Canada, and the following history of his life is taken from a biography written by Dr. W. Gordon M. Byers.[4]

Dr. Buller's father, who was a descendant of an old Devonshire family, immigrated to America in 1831, and Frank Buller was born near Cobourg, Ontario, in 1844. He was educated in a local school, except for three years when the family moved to Iowa, and at Peterborough, Ontario, where he attended a grammar school.

During the summer months he learned dispensing in the office of Dr. Burnham, a leading practitioner of his day. Dr. Buller was graduated from Rolfe's Medical School in Toronto, in 1868, and after a year of general practice in Michigan, he went to Europe for special work in connection with the eye and ear. He remained there for about seven years. He first went to von Graefe's clinic in Berlin, and although von Graefe died in 1870, Dr. Buller had been in contact with and was inspired by him. During the Franco-Prussian war, Dr. Buller

served as a volunteer assistant in a German military hospital, and at the expiration of the war he returned to Berlin where he worked under Virchow in general pathology, and in physiologic optics under Helmholtz.

House surgeon at Moorfields

In 1872, he went to London, and after passing his examination for membership in the Royal College of Surgeons, he was appointed a house surgeon at the Royal London Ophthalmic (Moorfields) Hospital. Here he was under Bowman, Critchett, and Hutchinson, and worked with Nettleship and Gunn. He had gained a mastery of the ophthalmoscope in Berlin, and from him his English confreres learned the full use of the direct method of examination. During his service here he introduced the protective shield since known as the "Buller's shield." He began practice in Montreal, in 1876. In doing so he was influenced by two Canadians whom he had learned to know in London, Dr. F. J. Sheperd and Dr. William Osler.

Friendship with Osler

It is interesting to know that Osler himself had intended going into eye work and to locate in Montreal. Cushing,[5] in his *Life of Osler,* quotes the correspondence between the dean of McGill medical faculty, Dr. R. Palmer Howard, and Osler. In this the dean informed Osler that there were three candidates in the field with better chances and he advised him to abandon the field of ophthalmology and to cultivate the whole field of medicine and surgery, paying special attention to practical physiology. Osler was disappointed at the blighting of his prospects as an ophthalmic surgeon but accepted the inevitable with good grace.

That there was no ill feeling between Osler and Buller over this incident is shown by the fact that they remained close friends. In fact, Osler had an office in Buller's house on his return to Montreal. One cannot even dare to speculate on what ophthalmology would have gained and general medicine would have lost had Osler's original hopes been realized. But to return to Buller.

Establishes ophthalmic clinic

He was given permission to establish an ophthalmic clinic at the Montreal General Hospital, where at that time the entire clinical teaching of the McGill Medical School was carried on. At first the older men were unwilling to relinquish their ophthalmic cases but, in a short time, Dr. Buller's superior training and knowledge settled the question.

In 1883, he was appointed to the first chair of ophthalmology at McGill University and, in 1895, he resigned his position at the Montreal General Hospital to take charge of the ophthalmic clinic at the new Royal Victoria Hospital, which post he held until his death in 1905.

Dr. Buller was the most outstanding man in our special field in Canada, and his practice extended from one end of the country to the other. He had a good working knowledge of French and a mastery of German so that he kept abreast with the literature on ophthalmology.

In spite of his busy practice he found time to make 76 contributions to the literature. Included in these papers are descriptions of a protective bandage for the eye, an improved trial frame, a double needle for discission of secondary cataract, a temporary ligation of the canaliculi to prevent wound infection in operation of the eye, a modification of the Mule's operation, and skin grafting in ophthalmic surgery.

Stirling succeeds Buller

Dr. Buller's successor to the chair of ophthalmology at McGill University and chief of the ophthalmic department of the Royal Victoria Hospital was Dr. John W. Stirling. Dr. Stirling was a native of Halifax, Nova Scotia, where he received his early education. He was graduated in medicine from the University of Edinburgh in 1884, and afterward was a pupil of Argyll-Robertson. He continued his studies in Vi-

enna, Berlin, and London, and returned to Canada, in 1887, and took up practice in Montreal.

Dr. Stirling was an excellent ophthalmologist, a good teacher, and made many useful contributions to ophthalmic literature. I personally owe much to him as he was my first teacher and chief in ophthalmology. Dr. Stirling was succeeded by Dr. W. Gordon M. Byers, who was followed by Dr. Fred T. Tooke, who in turn was succeeded by the late Dr. S. Hanford McKee, at the university; all three men were outstanding in our special field and all were known personally to many of the men here tonight.

Trachoma in Canada

While in this period of the history of ophthalmology in Canada, I should like to digress and to mention that the scarcity of trachoma in clinical and private practice has always impressed me. Trachoma was a fairly common ocular disease, chiefly at ports of entrance in Canada, about the middle of the 19th century.

Howard in his textbook, in 1850, states that he had cured upward of 200 cases in the previous four years. The disease declined until about 1898, when an organized movement to settle Jews in Canada, increased its incidence. Moreover, in 1897, the United States government declared trachoma to be a menacing disease and closed the Atlantic ports to trachomatous immigrants; but they left the Canadian border open and many cases found entrance to the United States in this way.

To overcome this, in 1901, the United States government kept a close watch on the Canadian border, resulting in a large number of trachoma cases being left in Canada. As a result, in 1902, the Canadian government amended its immigration act to exclude immigrants and visitors suffering from loathsome, dangerous, and infectious diseases. These regulations became increasingly effective until, in 1927, exclusion became absolute. Dr. Gordon Byers took a very active part in obtaining this legislation, and the above information is taken from a paper by him on trachoma.[6] Today, trachoma is an extremely rare disease in Canada, except among some Indian settlements in western Canada.

Training of new generation

I have, of necessity, chosen only a few of the men who played an important role in the development of our specialty in Canada. Many others deserve special mention and in a more comprehensive paper their names would be included.

It is quite apparent that the history of ophthalmology is no more than the history of the lives and accomplishments of the men who practiced it and of the institutions in which their work was done or to which they were attached.

As a general rule, those who have contributed most to the subject are the ones who have had the best preliminary training. In order that the men of the future will obtain good preliminary training, much responsibility is thrown upon the present generation of teachers and practitioners.

Teachers of undergraduate students in medicine should try to make the subject so attractive that many of the students will be impressed and decide upon ophthalmology as their vocation. If they decide early, they can concentrate their studies along these lines and avoid loss of the time spent in indecision. I think the day is past for men to enter the field of ophthalmology through general practice.

Preliminary to medical studies some knowledge of the classics, especially Latin, is essential, and a reading knowledge of at least two modern languages, perhaps French and German, and in the future even Russian or Spanish, is necessary for those who wish to go far in the subject.

Training facilities in Canada

The need for trained ophthalmologists is great, but at the present time such training is not available for all those who apply.

Our training facilities in Canada are

limited because of our small and scattered population. I think the best we can possibly do is to turn out 10 well-trained men each year and this has to be done at university centers.

Until the war, our university training had been limited to undergraduate work where the object was to graduate good general practitioners with a knowledge of diseases of the eye encountered in general practice. A few internes on eye services in hospitals throughout the country, whose duties were limited to eye work only, were carried along for one or perhaps two years and then they continued their training in other centers either in the United States or in Europe. During and since the war, these opportunities for training in centers outside of Canada no longer exist so that we have had, fortunately, to fall back on our own resources.

At McGill University we have started a four years' diploma course—one year of basic studies, two years of internship and one year of research, requiring a thesis. A similar course has just been started in the University of Toronto, where for the first time in Canada a half-time director of ophthalmology has been appointed. In our course at McGill University, the diploma student must spend at least two of his four years with us, the other two may be spent at some other recognized center. This is done to give the student a broader view in his training. I think this is a good plan and I should like to see it become more widespread so that there may be interchange of internes among the various training centers.

I should like particularly to thank Dr. W. W. Francis, librarian, Osler Library, McGill University, and Miss Edith Gordon, medical librarian, McGill University, for their assistance in obtaining much information.

CONCERNING CHOROIDITIS PROLIFERANS*

CHEN YEN, M.D.
Shanghai, China

In his book *Diseases of the Eyeground,* Adalbert Fuchs describes a disease under the name of choroiditis proliferans. This rare disease is characterized by many newly formed strands of connective tissue lying on the inner surface of the choroid over which run retinal vessels. The retina itself is relatively uninvolved. The choroid shows some shifting of pigment. The strands of the connective tissue are characterized by a tendonlike shiny color and delicate stripes. Adalbert Fuchs considers these strands of connective tissue to be the result of exudates occurring chiefly in the choroid. This characteristic picture seems to develop especially after reattachment of a detached retina. Even after reattachment of an ordinary serous retinal detachment, delicate strands of connective tissue seem to form now and then on the inner surface of the choroid. Fuchs shows such strands in Figure 5 of Table 37, and describes it as follows:

"The detached retina of a woman of 20 had reattached after some time spontaneously and, as usual in such cases, the vision was very poor due to the long duration of the detachment. The patient could count fingers at 1½ meters. The area of the reattachment could be recognized clearly because of the sharp demarcation and one could see several thin, branching and very white strands of connective tissue which were lying beneath the retinal vessels. In this case, however, the picture was not dominated by the white stripes but by the pigmentary disturbances which always develop after reattachments."

Recently I saw a similar picture in a young man who was operated successfully for a detached retina.

CASE 1

A short distance from the postoperative scars which could be easily seen as partly black, partly white lesions, a white, straight, delicate strand of connective tissue extended downward from above. Apparently a deposit of fibrin had become organized here.

In rare cases the formation of subretinal strands is so widespread that it dominates the picture, just as the formation of preretinal strands dominates the picture of retinitis proliferans. Such a picture is shown by Adalbert Fuchs in Figure 7 of Table 25, and described as follows:

"A boy of 16, showing a positive Wassermann test, developed a bilateral impairment of vision three years ago. Both fundi presented approximately the same picture. The discs were somewhat pale, the retinal vessels narrow. In addition to some pigment atrophy in several places there were broad, shiny white strands of connective tissue underneath the retina partially encircling the disc and branching in many places with a fringelike ending. In some places these bands had the width of one disc diameter."

Fuchs assumed that choroiditis exudativa interna might precede the formation of this abundant connective-tissue formation. I have had a case in my department, which I am inclined to consider as such an instance of choroiditis proliferans:

CASE 2

History. A merchant, aged 27 years, noted, 10 years ago, failing vision in his right eye which could not be improved with glasses. There was a dustlike shadow before his eye. After three years, the vision became very poor and a Japanese oculist diagnosed a retinal detachment. The left eye was normal at that time, but later became just as poor as the right eye. Three years ago, an oculist diagnosed bilateral detachment of the

* From Tung-Chi University, Department of Ophthalmology, Dr. Chen Yen, Director. Translated by Dr. Arthur Koeppl, 4554 North Broadway, Chicago, Illinois.

Fig. 1 (Yen). In the right eye, there was a small cataracta polaris anterior. In both eyes, there were numerous shiny, white strands in the neighborhood of the discs and in the peripheries which were crossed by retinal vessels.

retina. The patient did not receive any treatment.

Findings. Wassermann blood test was negative. Right vision was hand movements at one meter; left vision, 1/60. Right visual fields showed remnants, temporal and above; left visual fields were grossly normal.

In the right eye, there was a small cataracta polaris anterior. In both eyes, there were tiny opacities in the vitreous. The fundus findings were similar in the two eyes (figs. 1 and 2). The borders of the discs were sharp and the color normal. The retinal vessels were normal. There were numerous shiny, white strands in the neighborhood of the discs and in the peripheries which were crossed by retinal vessels. These strands were fairly straight with an occasional kneelike curve. In some places the strands originated from a single round spot. In the left eye the connective tissue between macula and disc occupied a large area with a fringelike appearance temporally, while the sharp nasal edge partly encircled the disc.

Comment. As happens so often in China it was very difficult to get an exact history.

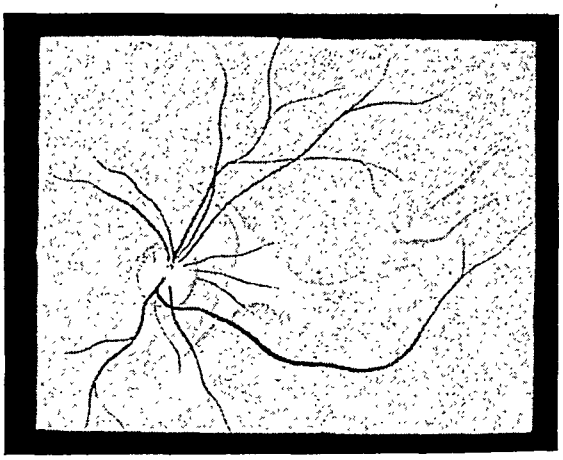

Fig. 2 (Yen). In the left eye, the connective tissue between macula and disc occupied a large area with a fringelike appearance temporally, while the sharp nasal edge partly encircled the disc.

Be that as it is, the result—a bilateral retinal detachment—was before us. The fundus, however, did not present the picture usually seen after reattachment of an ordinary serous detachment. There were no characteristic pigmentary disturbances and no sharp borders. This case was probably one of Harada's disease. This disease, extremely rare in Europe, is characterized by a bilateral detachment of the retina with iridocyclitis. After some time, when the retina reattaches again, the fundus appears depigmented and shows some isolated pigment proliferations. The vision usually improves. The condition is often associated with loss and graying of the hair and with auditory disturbances.

In our case we could not find any evidence of a previous iridocyclitis or of a systemic disease. The history of a bilateral retinal detachment with spontaneous reattachment and the appearance of the fundi suggest strongly the end result of Harada's disease.

CONCLUSION. Choroiditis proliferans seems to be the end result of an exudative, inflammatory detachment of the retina. A hemorrhagic origin can be ruled out almost with certainty. It is a well-defined clinical picture.

Tung-Chi University.

LYMPHOCYTOMA OF THE ORBIT SUCCESSFULLY TREATED BY ROENTGEN IRRADIATION*

Report of a case

Stefan Van Wien, M.D.
Chicago, Illinois

Lymphatic tumors of the orbit are either manifestations of a constitutional involvement of the lymphatic system or an independent local hyperplasia of lymphatic tissue. Although constitutional involvement usually occurs bilaterally, local hyperplasia almost invariably involves one orbit only. Birch-Hirschfeld, in his discussion of localized lymphatic tumors of the orbit, stresses that they comprise a heterogeneous group with transitions from undeniable forms of lymphosarcoma through benign tumors to a peculiar type which he calls "pseudotumor," and which actually are the result of chronic inflammation.

The lymphocytoma of the orbit represents an example of a benign lymphatic tumor. Histologically, it is a homogeneous mass, made up of lymphoid tissue that may show fibrous bands but is void of a well-developed reticulum. Since this condition is not seen too frequently, a brief report on such a case seems justified as an addition to the literature.

Report of case

History. A 67-year-old white woman was seen for the first time on October 31, 1946. She had noted a painless swelling in the region of the left upper lid that had gradually increased in size over a period of three years. At no time was there evidence of inflammation. The patient did not recall enlarged glands or swellings elsewhere on her body. Several ophthalmologists who were consulted advised an expectant and conservative attitude. There was no spontaneous complaint of diplopia; when questioned specifically she admitted occasional double vision.

Ophthalmological examination. The uncorrected visual acuity was: R.E., 20/50; L.E., 20/40. Vision in both eyes was improved to 20/20 by a +2D. sph.

There was an apparent ptosis of the left upper lid, and the left palpebral fissure was almost completely closed. The globe was proptosed and displaced downward and outward. The elevation of the upper lid was moderately limited. The globe could be freely rotated in all directions. Tests for diplopia suggested exotropia and left hypotropia. However, the two images were rather close together, and their distance did not alter in the cardinal directions. No chemosis of the conjunctiva bulbi was noted. Behind the left upper lid a fairly distinctly outlined mass could be palpated. The lid was freely movable over this mass. It was about 2.5-cm. long with a 1-cm. diameter, rather firm in consistency, and gave the impression of having a lobulated surface. The tumor seemed in no way connected with either the tear gland or the orbital walls.

Two small fleshy tumors could be observed in the subconjunctival tissue of the left globe. These tumors were flat, measured about 4 mm. in size, and were situated about 10 mm. above the limbus. They did not seem to be closely attached either to the conjunctiva or the sclera.

The eyegrounds were essentially normal.

Physical examination, as reported by the patient's own physician, was in no way remarkable. In particular, there was no increase in the size of the spleen, and no enlarged lymph nodes were noted.

Laboratory data. Red blood count: 4,560,000. Hemoglobin concentration: 14.8 gm. (88.8 percent). Color index: 98.

* From the Department of Ophthalmology, Northwestern University Medical School.

White blood count: 5,900, with 57-percent segmental, 2-percent eosinophilic, 1-percent basophilic cells, 34-percent small lymphocytes, and 6-percent monocytes.

Roentgenographic examination of the skull, including special films of the orbits and optical foramina, showed no evidence of increased intracranial pressure. There was no evidence of abnormal intracranial calcification. The petrous bones presented a normal appearance. The bones of the orbit showed no evidence of destruction or absorption and presented a normal orbital contour. The sphenoidal fissures also were normal. There was slight increase in the soft-tissue density in the left orbit when compared with the right.

Biopsy. One of the subconjunctival tumors was removed for biopsy on November 11, 1946. The report from the Department of Pathology, Mt. Sinai Hospital, was as follows: "Sections show accumulations of small round cells. There is no difference in the size of the cells, and no mitoses could be found. This picture is compatible with a so-called benign lymphocytoma, although a low-grade malignancy cannot be excluded with absolute certainty on a purely histologic basis (see fig. 1).

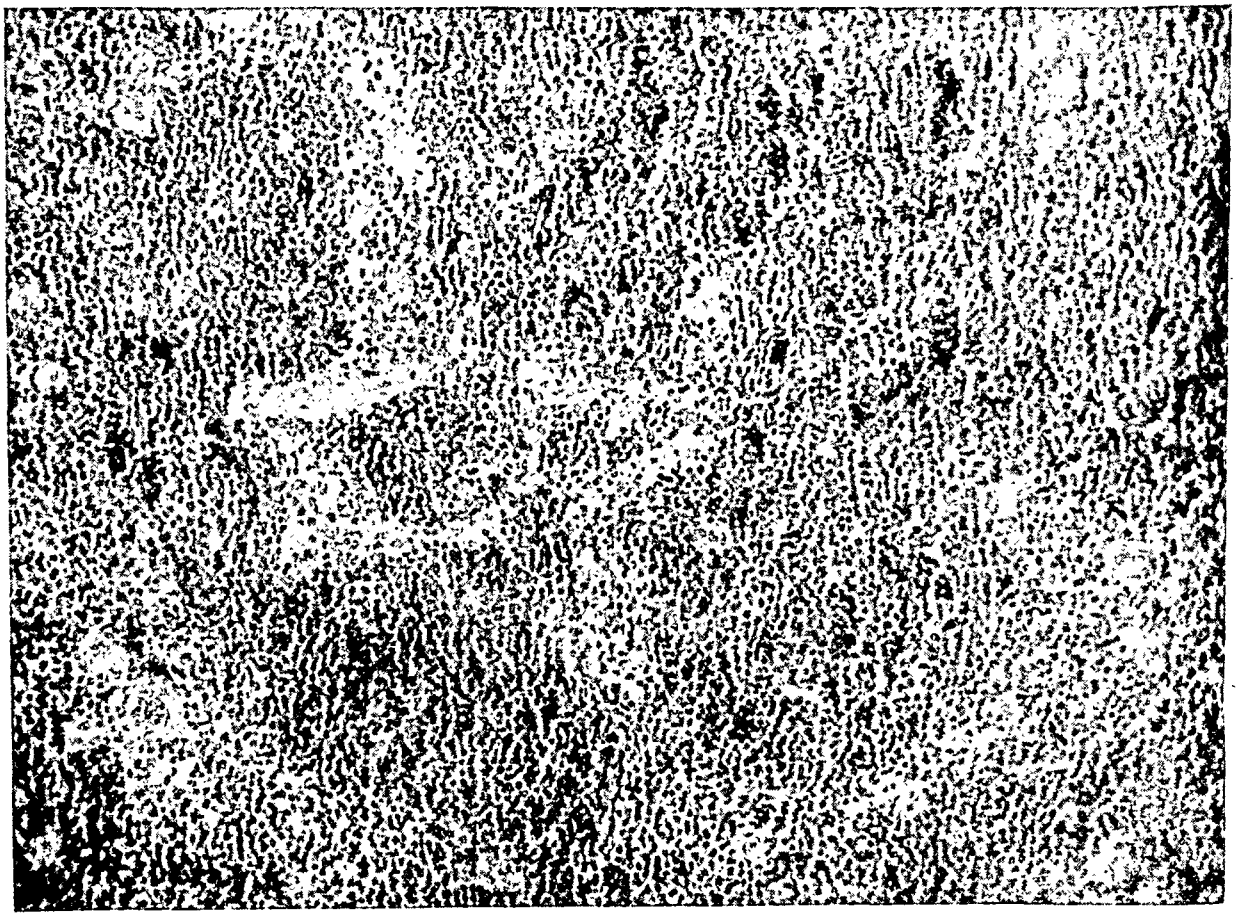

Fig. 1 (Van Wien). Photomicrograph of the biopsy.

Diagnosis. Tumor of left orbit: Lymphocytoma.

Treatment and Course. The patient received 20 drops of saturated potassium iodide for six weeks without any apparent result. She was referred to Dr. H. E. Davis, Chicago, for irradiation, and received 300R on January 7, 9, 11, 13, and 15, 1947—a total of 1,500R. The globe was protected by a lead

contact lens. A decided improvement was noticeable immediately after the first exposure, and the tumor had completely disappeared after completion of the series. There was a slight pigmentation of the episcleral tissue at the site of the small subconjunctival tumor that had not been removed for biopsy.

The patient was seen the last time on June 26, 1947. No recurrence of the tumor was in evidence (see fig. 2).

Fig. 2 (Van Wien). (A) Before treatment. (B) After treatment.

Comment

Hochheim[1] classified lymphomatous tumors of the lids and the orbit according to etiology. He distinguished simple lymphomas, leukemic, pseudoleukemic tumors, and doubtful cases.

Birch-Hirschfeld[2] doubted the correctness of Hochheim's classification, since no complete data of the blood examinations were furnished by this author. He was of the opinion that these tumors could exist with or without other constitutional manifestations. The former occurred in leukemic and aleukemic leukemia as well as in Mikulicz's disease. He admitted the occurrence of a malignant lymphosarcoma in the orbit, but did not believe that differentiation was possible on the basis of the histologic examination only. According to him, neoplasms of this nature may originate from smallest lymph nodes in the orbital tissues, from the lymphocytes of the connective tissue, or from the cells of the vessels. Meller[3] stressed the fact that lymphatic tumors of the orbit might spring from the tear gland.

It is a common experience that lymphomas of the orbit are very sensitive to actinic treatment, a fact that was stressed by Gifford.[4] Not all cases permit biopsy as easily as the one reported. But, if possible, it will help to prevent unnecessary surgery with its unpredictable complications. One such case was reported by Merigot de Treigny.[5] Surgical removal of the tumor was attempted first. This procedure was only a partial success and, to make matters worse, during this attempt the external rectus was severed, resulting in a permanent paralytic strabismus. Histologic examination revealed a lymphocytoma, and subsequent irradiation resulted in complete disappearance of the neoplasm.

Even if the protection of the globe with a lead prothesis should prove unsuccessful, and a cataract should develop subsequently, this may be a more desirable complication than an unsuccessful surgical approach, particularly if functionally important structures are infiltrated by the expanding tumor.

Conclusion

A case of lymphocytoma of the orbit is presented for record.

The diagnosis was established by means of a biopsy, and satisfactory response to roentgen therapy was obtained.

NOTES, CASES, INSTRUMENTS

REFRACTION CLINIC*

DISCUSSION BY

ALBERT E. SLOANE, M.D.†
Boston, Massachusetts

A-17-year-old boy had had poor vision as far back as he can remember. His vision had not become worse. He claimed that he could see well at a distance, but was unable to read. The examination revealed a pigmentary disturbance to both macula areas. His vision was: R.E., 15/200; L.E., fingers at five feet. This vision was not improved with lenses and was reduced with the use of a pinhole disc.

Refraction was attempted with the idea of prescribing a reading aid. Retinoscopy disclosed a negligible refractive error. The right eye was chosen for further testing because it had the lesser amount of involvement. It was found that he could read No.-7 type on the Wells card without glasses and by holding the print close so as to obtain a large retinal image. When a +5.D. sph. was worn, he could read Wells No.-4 type by holding the print at the proper short distance. When a telescopic reading aid (Aloe reading telescope) was placed before the +5D. sph., he could read Wells No. 1. It was suggested that he obtain the following prescription: a +5D. sph. for the right eye, to be worn for reading larger newspaper print, and the telescopic addition to be used when he wished to read very fine material.

DISCUSSION

In these cases, children have no difficulty in meeting ordinary visual needs. Their peripheral field of vision seems to compensate for their central vision loss; thus, this boy did not complain of poor distance vision, although by ordinary standards the visual acuity was substandard. For near, he was very definitely handicapped and could only read by holding the print close to his eyes, utilizing large retinal images, even if the details were not clear. Theoretically, any device which would further enlarge the retinal image size would enable him to read.

For this reason, a strong plus sphere, even though it makes for an awkward short range, can be of great help through enlarging the retinal image, and this can be further magnified by the aid of a telescope. A simple telescope, which is inexpensive, is the reading unit manufactured by Aloe Company. The success with such a device is directly proportional to the willingness of the patient to reëducate himself to its use.

The person must learn to utilize and recognize letters by a sort of piece-meal assembly, which is at first very difficult and later becomes quite easy. Parts of long words must be pieced together, a skill which is easily learned.

Further, a patient must learn to keep the print at a very definite distance which does not allow modification, and the print must be moved rather than moving the eyes. A newspaper, for instance, cannot be read if the pages are wide open and held unsupported. Rather, it must be kept flat on the table, and the light must be peculiarly adjusted to the needs of that individual. The successful patient will usually read at the same table and under the same lamp all the time. When successfully learned, the telescope allows the patient the use of both his hands.

Some other aids in such cases are these. First, and most generally used, is the ordinary hand magnifying glass. The hand magnifying glass has the advantage of allowing the patient a larger distance between his eyes and the glass, which allows a further increase in the effective magnification of the printed material. However, it ties up one hand.

* From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.
† Director of Department of Refraction.

Another reading aid is a magnifying glass mounted on legs, and cut in the shape of a rectangle. The length of the legs corresponds to the distance required for proper magnification, and it may be slid along the material read. Such a device, which contains within it an illumination system, is also manufactured. Another device is the utilization of magnifying loupes, such as are worn by the ophthalmologists in removing foreign bodies. A satisfactory loupe for this application is the Berger. This has the advantage of being enclosed in a metal casing, thus eliminating glare from the sides. It is moderately priced.

In general it is best to avoid correcting both eyes, and simply to correct the better of the two. Occasionally it is possible to correct both eyes, in which case one has to depend upon strong plus spheres, with or without prisms, but no telescope. The telescope should be reserved for monocular use.

QUESTIONS

House Officer: Have you ever used a device with a linear aperture so that only one line of letters can be seen at a time, thus eliminating confusion in losing one's place?

Dr. Sloane: I have never used such a device, but it would seem to have practical value in certain places. Such devices, I know, are incorporated in many of the methods used to help children who have reading difficulties.

House Officer: Why do you not usually correct both eyes?

Dr. Sloane: The answer to that is: (1) It would seem advisable to utilize both eyes, but we may be introducing difficult problems in binocularity due to the power of the lenses we have to use. (2) The pathologic conditions in such cases may not be perfectly symmetrical and thus again produce incongruous factors. (3) The visual field is limited by such devices, particularly the telescope, and it requires very precise adjustment to keep the field of each eye in proper position.

House Officer: Are telescopic lenses suitable for distance wear?

Dr. Sloane: As a rule telescopic aids have limited uses for distance wear. This is primarily due to the narrowing of the visual field, which is a necessary part of the corrected picture. Incidentally, a very effective type of telescopic lens may be procured for distance wear, in this manner. First, give the patient the best distance correction possible with ordinary lenses, and then, secondly, have him purchase a "Sportoscope,"* which is in reality a pair of opera glasses made with temples which fit over one's ordinary glasses. The cost is not excessive and this device can be used effectively for sport events and at the theatre, but of course not in walking.

LEIOMYOMA OF THE IRIS

E. C. MOULTON, M.D., AND
E. C. MOULTON, JR., M.D.
Fort Smith, Arkansas

A search of the literature reveals that seven proved cases of leiomyoma of the iris have been reported. In 1923, Verhoeff[1] reported a case, and at the same time reviewed the literature and established certain criteria as necessary for the diagnosis of this tumor. According to these criteria, he accepted only two previously reported cases as being authentic, Thompson's[2] case, in 1899, and van Duysen's[3] case, in 1911. Frost,[4] in 1937, and Ellett,[5] in 1939, each reported a case. In 1943, Kahler, Wallace, Irvine, and Irvine[6] described a case, and, in 1944, Davis, Sheppard, and Romejko[7] reported one. In addition, two cases which were not the subject of separate reports have been mentioned in the literature. These include a separate case of Verhoeff's, mentioned by Li,[8] in 1923, as a "probable epiblastic leiomyoma," and a case of Zentmayer's, previously reported as

*Also known as "All-scope" and obtainable (before the war) from Andrew J. Lloyd Company, Boston, Massachusetts.

a primary leukosarcoma of the iris, but mentioned in Davis's[7] paper as having been proved on reëxamination to be a leiomyoma.

In order for the diagnosis of leiomyoma of the iris to be made, Verhoeff has said that the tumor must be made up of long spindle-shaped cells of uniform size, containing rod-shaped nuclei, and showing a tendency for the cells to occur in bundles with their nuclei arranged in rows. In addition, differential staining should show myofibrils "coursing along the cells and their terminal processes."

Case report

B. H. C., a white man, aged 56 years, was first seen by one of us on April 17, 1946. He gave a history of having noticed a small growth on the right eye 1½ years previously, and that it had gradually grown to the present size. There was no history of discomfort or inflammation in that eye, although he had noticed that the vision had failed considerably.

Eye examination showed vision to be: R.E., 4/200, unimproved; L.E., 20/200, improved to 20/25 with a +2.5D. sph. There was a large, egg-shaped, salmon-colored tumor mass, approximately 5 by 7 mm., filling the angle of the anterior chamber in the lower outer quadrant, and seeming to replace the iris in that area. The mass was beginning to encroach upon the pupillary area. Blood vessels were seen on the surface of the tumor. The pupil reacted normally except in the area of the tumor. There were no cells in the anterior chamber. The lens showed advanced cataractous changes and details of the fundus could not be made out through these opacities. A diagnosis of leukosarcoma was made.

An attempt at local removal was thought impractical because of the large size of the tumor, and removal of the eye was advised. Enucleation was performed on April 25, 1946, and the eye was sent to the pathologic laboratory of the Massachusetts Eye and Ear Infirmary for examination.

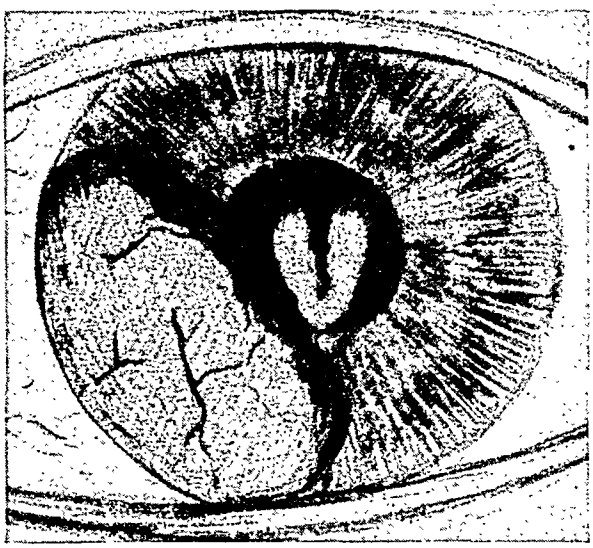

Fig. 1 (Moulton). A drawing made at the time the patient was first seen, showing the size and location of the tumor mass.

Pathologic report

The specimen consisted of an eye of approximately normal dimensions, showing in the gross a mass occupying most of the anterior chamber. Microscopically the angle of the anterior chamber and the iris on one side were essentially normal, except that the pigment epithelium of the iris showed some vacuolization. The pillar of the iris on the other side was largely replaced by a tumor mass extending forward to occupy the entire lateral two thirds of the anterior chamber in apposition with the posterior surface of the cornea.

This tumor was made up of fascicles of spindle-shaped cells showing rod-shaped nuclei with no nucleoli. The cells were arranged in interlacing bundles, with the nuclei occasionally arranged in rows. None of the cells appeared pigmented, although pigment was scattered extracellularly throughout the mass.

The tumor merged gradually into the anterior border of the ciliary body, without any sharply defined border, but did not extend into the ciliary muscle. There was very little vascularization. No necrosis was present and no mitoses were seen. The lens was

cataractous. The rest of the eye was not remarkable.

Further sections were made and stained with Mallory's phosphotungstic acid-hematoxylin stain. These showed a rather dense arrangement of myofibrils coursing along the cells and from their terminal processes. Sections were reviewed by Dr. F. H. Verhoeff who concurred in the diagnosis of leiomyoma of the iris.

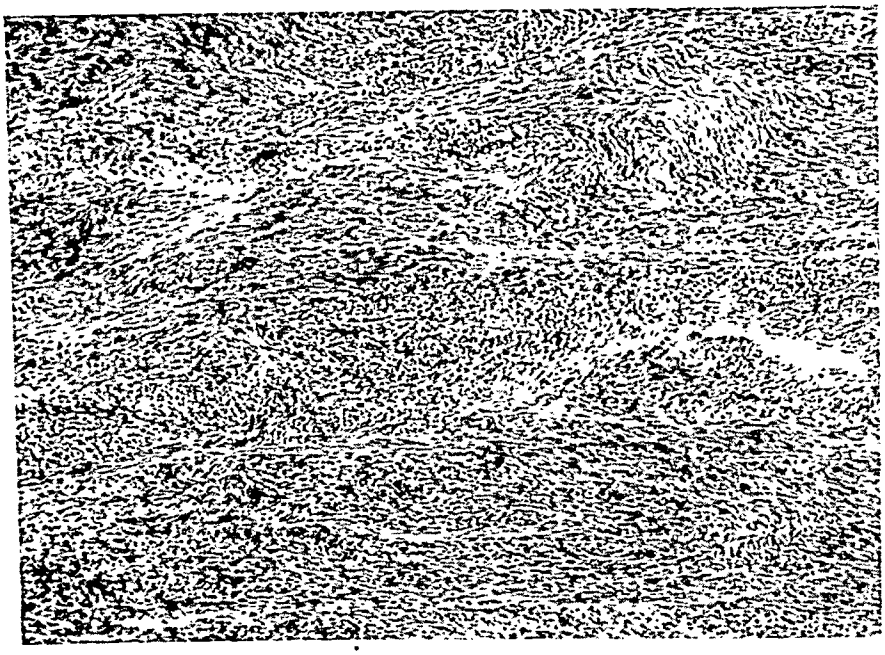

Fig. 2 (Moulton). A photomicrograph (×100) of a section of the tumor tissue, showing the typical architecture of this tumor.

Comment

It was impossible to tell whether this tumor arose from the iris musculature or from the iris stroma, since the tumor mass occupied the whole of the iris pillar, and the individual sphincter and dilator muscle groups were not recognizable in any of the sections showing tumor.

Of the previously reported cases, five were said to be epiblastic and one mesoblastic in origin. The origin of the other three was not stated. Of these cases, six were in males and four in females, ranging in age from 10 to 56 years. The ages in the largest group, five, were between 46 and 56 years of age. All of these growths were described as salmon or flesh colored.

The duration of the growth was from 1 to 2 years in three cases, 20 years in one case, had "always been present" in two cases, and was not stated in the other four cases. Six of these cases were treated by local removal, or iridectomy, and three by enucleation because of suspected malignancy. The other case, reported by Verhoeff, resulted in enucleation after two unsuccessful local procedures.

Of considerable interest was the location of these iris leiomyomas. Of these 10 cases, 8 were found in the lower outer quadrant, 1 in the lower inner quadrant, and the location of the other case was not stated.

Whether there is any connection between this finding and the fact that the lower outer quadrant of the globe is the typical location of the fetal fissure is a matter for conjecture. The fetal fissure is normally closed anteriorly long before the iris proper develops, and these cases do not usually come to a physician's attention before the third decade of life is reached.

There are 93 cases of malignant and nonmalignant melanomas of the iris on file in the pathologic laboratory of the Massachusetts Eye and Ear Infirmary. Of the available

clinical records only 32 mentioned the original location of the tumor. Eight, or 25 percent, arose in the lower outer quadrant; 12 were described as ring sarcomas; and the remaining 12 were evenly distributed among the other three quadrants.

These few cases do not necessarily indicate that leiomyomas of the iris have a predilection for the lower outer quadrant. However, the occurrence in the lower outer quadrant of the iris of a localized, salmon- or flesh-colored tumor mass of slow growing tendencies should suggest leiomyoma, and, if the size of the tumor permits, an attempt at local removal should be considered before the eye is removed.

A CORNEOSCLERAL SCISSORS

William P. McGuire, M.D.
Winchester, Virginia

In an effort to obtain a smoother incision in enlarging the original limbal incision in cataract surgery, a new scissors has been designed. The blades of the scissors are blunt pointed and are angled up 15 degrees at the proximal end of the cutting surfaces. From this angle the blades are curved downward in a gentle curve closely approximating the curve of the anterior surface of the cornea.

In practical application the advantages of this scissors have been found to be:

1. The upward angulation makes for easier manipulation.

2. The downward curve of the blades produces a smoother cut along the limbus than does the ordinary flat-bladed scissors or scissors with the blades curved upward.

3. It is unnecessary to cut the conjunctiva with the scissors as the curve permits the outer blade to be inserted beneath the conjunctiva and the limbal incision to be enlarged beneath a conjunctival bridge.

4. In the event of involuntary upward movement of the eye, the danger of trauma to the corneal endothelium is lessened and the blunt point slides along the angle of the anterior chamber.

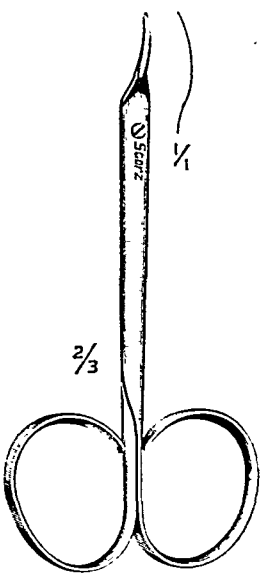

Fig. 1 (McGuire). Corneoscleral scissors of new design.

This instrument is manufactured by the Storz Instrument Company, St. Louis, Missouri.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

February 19, 1947

DR. HOWARD F. HILL, *presiding*

RHEUMATOID IRITIS

DR. LLOYD MILLS presented the preliminary paper of the evening, reviewing the records of 42 patients with iritis that were found in 600 cases of rheumatoid arthritis now being followed by the arthritis service of the Massachusetts General Hospital. In 29 of these 42 cases, no other possible alternative etiology, such as focus of infection and so forth, was found, suggesting a direct association between the arthritis and the iritis. Of these 29 cases, 19 occurred in men, 10 in women. The age of onset varied from 3 to 63 years. In 9 cases the iritis was unilateral; in 20 cases it was bilateral, both eyes being involved at the same time in 15 cases. The visual result in the bilateral cases was approximately the same in both eyes even though the severity of the iritis varied between the two eyes. Usually the iritis was first noticed 1 to 17 years after the onset of arthritis. In one case the onset of the iritis and arthritis coincided, and in three cases an iritis of "unknown etiology" preceded the arthritis with later exacerbations of iritis characteristic of this group. About half the iritis episodes occurred during chronic activity or an acute exacerbation of the arthritis, the others occurring during remissions of months to years or, in three cases, prior to joint symptoms. The severity of the iritis varied widely—three cases had single brief attacks; nine, recurrent mild attacks; four, a mild chronic course; two were classic cases of ophthalmia lenta. There were two fulminating cases, one severe recurrent case, and eight severe chronic cases, all ending in marked visual impairment. The visual end results varied with the course of the disease. In 11 cases, normal vision was retained; seven cases ended with vision of 20/70 to 20/200, and 11 with vision of hand movements or less. Secondary glaucoma resulted in eight of these cases, and enucleations were necessary in two.

Dr. Mills noted that only meager statistics with poor etiologic studies appear in the literature. Evaluation of treatment that has been recommended is difficult because the disease has no known specific treatment and has a fluctuating, if progressive, course. In his series, no case with glaucoma had an iridectomy or filtering procedure early enough to learn the value of early surgery, and he thought such intervention must be strongly considered in obviously progressive cases.

In conclusion, he noted that, statistically, 6,000,000 people in the United States have rheumatic diseases, that iritis of rheumatoid arthritis is an etiologic entity and occurs frequently enough so that adequate medical investigation with thorough case following will decrease the enormous group of cases which at present are diagnosed as "Iritis—cause unknown."

SURGICAL TREATMENT OF STRABISMUS IN CHILDREN

DR. MAYNARD WHEELER of New York gave the principal paper of the evening. He said that preoperative analysis is of the greatest importance in cases of strabismus. The cases can be divided into two groups: (1) those in whom the deviation is discovered soon after birth and (2) those in whom the squint appears gradually after the age of two years. In the first group the deviation is large, frequently with a vertical component; refraction is usually unimportant. Measurement is done by corneal reflexes.

Operation should be done early (one year) for the psychologic effect on both the child and his parents; to avoid muscle changes, amblyopia, and abnormal retinal correspondence; and to give the best chance for binocular vision. In the second and much larger group, refraction is usually of some importance. A more complete analysis is possible with greatest reliance on the cover test. When hyperopia is very high, surgery is usually contraindicated. If glasses are essential for vision but do not straighten the eyes, the portion of the deviation remaining with glasses may be corrected cautiously by surgery. When glasses are not essential to vision, after a trial of several months, they may be discontinued for surgery. In all cases, amblyopia should be treated by occlusion. Operation should be done as soon as other measures fail; surely before the child enters school.

The choice of operation and the technique used were not stressed because of the difficulty of trying to tell anyone how to correct a given deviation. Each surgeon must select the operation that he can do best, and find out what it will accomplish.

In the discussion that followed, Dr. Walter Lancaster suggested the use of the red-green test for measuring the deviation of the eyes in the six cardinal directions. Dr. Wheeler said that he had not found it satisfactory in the usual strabismus cases, possibly because of incorrect use. Dr. Lancaster also commented that he thought that a certain amount of upshoot in extreme adduction is normal, and that he agreed with Dr. Wheeler that the teaching of Bielschowsky and Adler in regard to the overaction of the inferior obliques is the correct one. Dr. Lancaster then brought up the point of orthoptic training to break up the convergence-accommodation relationship and to teach the patient with hyperopia to keep the eyes straight without wearing his correction.

Dr. Frederick Verhoeff discussed the factor of "anticipatory movement" complicating the cover test. He suggested that instead of passing the cover from one eye to the other, it was only necessary to cover the fixing eye, thus decreasing the anticipatory movement. He also said that in a strabismus that is not strictly concomitant it would make a difference as to which eye had the prism in front of it when doing the cover test. He stated that so-called alternating hyperphoria is an incorrect term. A better name is exclusion hyperphoria, the eye turning up because it is excluded from vision. This condition sometimes upsets the cover test. He suggested that, instead of using a complete occluder in the occlusion test, one might use a strong sphere in front of one eye, thus using both eyes right along, one for distance, and the other for near. Dr. Wheeler in reply agreed with Dr. Verhoeff's comments on anticipatory movements. He thought that prisms could be used to measure the exclusion hyperphoria, by measuring each eye separately, passing prisms of varying degrees in front of the eye until motion was stopped.

Dr. Paul Chandler asked after what age it is probably not worth while to occlude to improve amblyopia, and also after what age the vision is maintained when the occlusion has been stopped. Dr. Wheeler said that after the age of 6 or 7 years he did not urge occlusion unless the parents were keen for it, since constant occlusion after that age is psychologically bad and results are not too gratifying. He also thought that at about this same age vision is maintained when occlusion has been stopped.

In closing, Dr. Wheeler answered Dr. Howard Hills's questions in regard to prisms and catgut. He said that glass prisms are far preferable to plastic because the latter are inaccurate, rather thick, scratch, and are spoiled by alchohol. He has found that plain catgut is softer, easier to work with, and absorbs more easily. Since he started to use it, he has had no regrets.

Mahlon T. Easton,
Reporter.

COLORADO OPHTHALMOLOGICAL SOCIETY

February 15, 1947

Dr. George Stine, *presiding*

Boeck's sarcoid

Dr. Morris Kaplan presented a paper, including a case report, on this disease which was published in the Journal, 31:83-85 (Jan.) 1948.

Dr. S. S. Kauvar (by invitation) presented a paper on the medical aspects of Boeck's sarcoid. He stressed its close similarity to tuberculosis, both clinically and pathologically. It is entirely benign except in the eye and in such places as the central nervous system and mediastinum where the tubercles cause difficulty because of mechanical interference. He stressed the spontaneity of recovery, with an occasional relapse. In several cases of sarcoid, the patients, years later, developed pulmonary tuberculosis, all of the fulminating miliary type.

Dr. Fritz Nelson presented three oil sketches of sarcoidosis of the iris, made many years ago, in which the true diagnosis was not made for years after the acute phase of the illness. Dr. George Filmer stated that in the Army he had treated five proved cases of uveitis caused by sarcoid. All were mild and painless and were characterized by blurring of vision, with numerous cells in the aqueous. All were bilateral. Four of these cases occurred in Negroes.

Malignant melanoma

Dr. James C. Strong presented a white woman, aged 32 years, who came on February 12, 1947, for an eye examination. Her chief complaint was blurring of vision in the right eye for the past three months. She stated that objects seen with this eye had a wavy appearance, which was first noticed while reading. Progress was slow but her vision failed more with each passing week. She had occasional headaches which were not severe and for the past two months she had noticed flashes of light especially in the nasal field. She also noticed that vision to the left, with the right eye, was somewhat impaired.

The general physical examination was entirely negative except for the eye findings. Examination of the right eye showed the extraocular muscles to be normal. The right iris was as active as the left. The pupil reacted to light and accommodation, direct and consensual. The cornea was normal. No keratic precipitates were present. There was a faint beam in the anterior chamber; however, no cells were observed in definite clumps. The iris was normal throughout its substance. The lens was clear. No opacities were present. The vitreous was filled with golden particles which were quite large. The vitreous was not liquid. Upon opthalmoscopic examination, there was found a large retinal detachment. The detached retina was quite smooth and rounded and was seen in the temporal portion of the eye. It extended from the 11- to the 6:30-o'clock positions, from the ora serrata to within six disc diameters of the optic nerve. At the 9-o'clock position, there was an area composed of brown pigment and some old hemorrhage with a vessel running into this area. Part of the vessel showed sclerotic changes. This pigment area protruded above the level of the retina, surrounding it. Hemorrhage was observed near the ora serrata and inferiorly, at the 6-o'clock position. This hemorrhage seemed very recent.

Six disc diameters from the optic nerve, the retina lost its healthy normal appearance. It took on a grayish cast and there were numerous traction lines which ran vertically and obliquely. There was an area of chorioretinitis superior and temporal to the macula. The margin of the temporal portion of the nerve was not well defined, there being an area of gray, opaque tissue passing from the nasal portion of the disc inferiorly and temporally. New blood vessels were

growing into this tissue. No retinal tears could be observed; however, this pigmented area over the retinal detachment suggested degeneration of the retinal tissue with possible tumor formation showing beneath. The vessels over the greater part of the detachment did not have their normal appearance. Many of the vessels inferiorly and temporally had white streaks along their walls.

The tension of the right eye was 18 mm. Hg (Gradle-Schiøtz) and of the left eye, 19 mm. Corrected vision was: R.E., 20/40; L.E., 20/15. The right eye did not transilluminate in the temporal portion. The field of vision showed marked constriction in the upper and nasal field on the perimeter and on the Bjerrum screen. The left eye was normal throughout. The patient stated that her right eye had previously been her better eye.

Laboratory findings were negative except for the presence of melanin in the urine. X-ray studies of the skull and chest showed no pathologic condition.

Discussion. Dr. Fritz Nelson said that the condition was most likely a malignant melanoma, with detachment over the solid mass and felt that enucleation should be done as soon as possible. Dr. John C. Long quoted Theobald as saying that these melanomas may well originate in the long nerves which should give corneal anesthesia.

Ten days after this case was presented to the Society, the patient's right eye was enucleated. The laboratory report was as follows:

Macroscopic examination. The specimen is an intact globe measuring A/P 23 mm.; horizontally and vertically, 23 mm. each. The cornea is transparent. The anterior chamber is deep and in it there is a white flaky piece of material, measuring 3 x 1 mm.

On section, the cornea appears normal. The lens has been displaced by sectioning. The anterior lens capsule displays a ring of pigment. The outstanding feature of the section it is a rather large oval-shaped grayish mass, measuring 9 x 5 mm., which appears to arise from the choroid and protrudes into the vitreous cavity. The retina is lying over this mass. Numerous hemorrhages are visible in this portion of the retina. Posterior to the mass, the retina is detached for a distance of approximately 10 mm. A white, gelatinous, semisolid material, together with a small amount of blood, lies beneath the retina in this location.

The vitreous chamber is filled with a clear, jelly-like material.

Microscopic examination: The paraffin section shows a tumor mass arising from the choroid. The tumor is composed of spindle cells with oval nuclei, most of which show a definite nucleolus. The reticulation in the nuclei is rather coarse. Both the inner and outer surfaces of the tumor show extensive pigmental deposits. The retina shows extensive hemorrhagic areas and is separated from the tumor by a serous exudate at one margin.

Diagnosis. Melanoma spindle cell, subtype B.

DR. BENJAMIN FRIEDMAN, *president*

TREATMENT OF LINDAU'S DISEASE

DR. STERLING BOCKOVEN AND DR. PAUL LEVATIN presented a case of Lindau's disease with unusual manifestations. Dr. Levatin stated that cord compression was caused by a histologically verified sclerosing hemangioma arising from the cord; whereas, a solitary coexisting retinal angioma was asymptomatic. The retinal tumor was treated by electrocoagulation without any loss of vision and the success of this treatment furnishes additional support for the view that puncture diathermy is the method of

choice in the treatment of von Hippel's disease. The cord tumor had previously been treated by X ray, but one year later further cord involvement had occurred. Dr. Levatin concluded that funduscopic examination under a mydriatic be done preoperatively in all instances of suspected cord tumors to detect isolated cases of Lindau's disease.

Discussion. Dr. Ludwig von Sallmann said that, in 1935, he had reported a case of Hippel-Lindau's disease which was treated successfully with beta rays. He stated that he did not know which was preferable, the beta ray or the diathermy treatment. Dr. von Sallmann concluded that the good result in Dr. Levatin's case would indicate that there is no contraindication for the diathery-puncture treatment in circumscribed lesions.

Dr. Joseph Igersheimer stated that in his experience these cases always become so much worse that they finally become blind. Therefore, he felt that it is justifiable to try the diathermy procedure. Dr. Igersheimer said that von Hippel first described the retinal changes on the ground of anatomic investigations and called them a "very rare disease of the retina." By further studies he came to the conclusion that the retinal disease was a hemangioma and in this conclusion he was correct. About 20 years later, Lindau found that the central nervous system and other organs show these angiomas and that involvement of the eye was a manifestation of a general disease. Dr. Igersheimer proposed that this disease be called von Hippel-Lindau's disease, especially when there are characteristic changes in the eye.

Dr. Adolph Posner said that from his experience in diathermy treatment of retinal detachments, he felt there is no great danger involved in the treatment of dilated veins of von Hippel's disease by this method. Dr. Posner said that he had frequently seen the vena vorticosa coagulated or even punctured with no untoward consequences.

Dr. Levatin (in closing) replied to Dr. Benjamin Friedman as to the advisability of any treatment in cases of angiomatosis retinae, which are nonsymptomatic. Because blindness due to detachment of the retina and secondary glaucoma is the eventual result in all untreated cases of von Hippel's disease, Dr. Levatin said that Dr. Bockoven and he believed that treatment by electrosurgery or irradiation is indicated. Since this was a very early case, it was possible to distinguish between the feeding artery and vein, for the artery was of a light pink color and was beaded.

In reply to Dr. Adolph Posner, Dr. Levatin said that Dr. Posner's observation that surprisingly little bleeding occurs when electrosurgery is used in operations on the eye is important. He said that he felt that diathermy puncture is a safe procedure in treating von Hippel's disease because the electric current coagulates the blood vessels.

Oxycephaly with optic atrophy

Dr. Jack V. Lisman presented a paper on this subject which will be published in the March, 1948, issue of the Journal.

Neosynephrin in glaucoma simplex

Dr. Adolph Posner suggested the use of neosynephrin hydrochloride (10 percent) before considering surgery, in cases of chronic simple glaucoma, when the usual miotics fail to maintain the tension at a normal level. While neosynephrin, alone, has only a fleeting action, it may benefit the patient by increasing the responsiveness of the tension to the subsequent use of miotics. Dr. Posner said that the exact mechanism by which this is accomplished is not known.

Dr. Posner told of two cases in which this method was used. He said that one

drop of 10-percent neosynephrin is instilled into the eye, preferably 12 or more hours after the last use of miotics. The patient is then instructed to dispense with the miotic for 24 hours if possible, after which the use of pilocarpine is resumed in moderate concentrations.

Dr. Posner said that the tension may be slightly increased by the neosynephrin, but that usually it is lowered. The increase in tension never amounts to more than 5 mm. Hg, thus the drug is safe to use in chronic simple glaucoma. Dr. Posner concluded by saying that it should not be used in a congestive type of glaucoma.

Discussion. Dr. James W. Smith said that it is a well-known fact that miotics used over a long period of time may lose their effectiveness. Clarke, in his report on carcholin (doryl) stated that if the use of pilocarpine and eserine would be discontinued and the patients allowed to use carcholin, better clinical results would be obtained when they resumed instillations of pilocarpine and eserine.

Dr. Posner mentioned the variations in tonometric readings in the hands of competent observers. Dr. Smith said that it is known that many tonometers are not calibrated properly. For this reason the tendency in some clinics of using a tonometric recording to establish a rapid diagnosis of glaucoma is to be deplored. The accuracy of the instrument on repeated trials, the mental attitude of the patient, and conditions under which the pressure is recorded are factors that may raise a normal reading to an apparently increased level.

If the perimetric field and visual acuity are unchanged, Dr. Smith said that he would view with reservations a tonometric recording of 5 to 10 mm. Hg above normal unless verified repeatedly on different days.

Dr. Benjamin Friedman said that successive readings with the tonometer frequently produce variations up to 5 mm. Hg either way, so that small discrepancies are no definite evidence of glaucoma.

Dr. Paul Levatin remarked that he had used 10-percent neosynephrin in a few cases of glaucoma, secondary to cataract extraction or to discission, in which 2-percent pilocarpine was ineffective. In each case it brought the tension down to normal very rapidly, although the effect was not permanent. When it was used on one occasion in a youth with a secondary glaucoma after an iridocyclitis, it produced a rapid painful rise in tension to 50-mm. Hg. The tension could not be brought down to normal by 2-percent pilocarpine every 15 minutes for 3 hours. Since that incident, Dr. Levatin said that he has confined its use to glaucoma, secondary to cataract extraction or discission, in which atropine had been used.

Dr. Joseph Igersheimer said that the fact that neosynephrin causes, in rare instances, an acute attack of glaucoma is very unfortunate, but cannot be generalized. He said that the same experience had occurred with the use of glaucosan. Dr. Igersheimer stressed the importance of seeing that the anterior chamber is not shallow because any dilatation of the pupil when the chamber is shallow may cause an increase of intraocular pressure.

In reply to Dr. Smith, Dr. Posner said that he agreed with Dr. Smith in regard to the use of the tonometer. He felt, however, that because the tonometer is not a perfect instrument, we should not do away with it. He stated that fields should be used as a follow up. Sometimes, however, field changes develop only after a long period of time.

To Dr. Friedman, Dr. Posner said that as for variations in readings, he trys to eliminate these by taking repeated readings on each eye, and then going back to the first eye, and if there is any difference between the first and second readings of the same eye, then he said he would wait

one minute or so and repeat again until consistently lower readings are obtained.

Intraepithelial epithelioma

Dr. Benjamin Esterman, Dr. Joseph Laval, and Dr. Clara Okrainetz presented a paper on Bowen's disease of the cornea and conjunctiva treated by radiation which was published in the Journal, 30:1537-1540 (Dec.) 1947.

Discussion. Dr. Ludwig von Sallmann said that he had had no personal experience with the X-ray treatment of Bowen's tumor. He mentioned a report by Kumer and him, in 1929, on 12 cases of epibulbar epithelioma, which were treated postoperatively with beta rays. Six of the cases, with an average observation time of five years, were considered cured.

Cataracts following maternal rubella

Dr. Leon H. Ehrlich described a girl born November, 1943, with congenital cataracts. The mother had had rubella during the first month of pregnancy. Aside from dense complete cataracts, the examination, ocular and general, was negative, although subsequently it was found that the child was deaf. Esotropia and nystagmus also developed. The lenses gradually became thinner and a red fundus reflex could be visualized. Eventually the lenses absorbed completely leaving only thin membranes, which, however, were sufficiently dense to require discission. The right membrane divided easily with no evidence of the presence of any lens substance; the left membrane tore loose and formed a small ball in the anterior chamber. The visual acuity could not be determined but the parents state that the child obviously has useful vision.

Dr. Ehrlich said that this type of transformation of congenital cataracts was well described as early as 1811 by Saunders, but that modern textbooks give it little or scant attention. Three cases were found in the recent literature on congenital rubella cataracts in which empty capsules, with no lens substance, were found at operation, but in none of them had there been a loss of lens substance while under observation. In two cases there was some presumptive evidence of such loss.

Discussion. Dr. Benjamin Friedman said that in children that are difficult to examine without general anesthesia, the condition is frequently overlooked. He said that, when one sees a membranous cataract, one assumes it represents the anterior portion of the lens. Unless one uses the slitlamp or a similar method of examination, this condition is overlooked.

Epidermoid cysts of the caruncle

Dr. Daniel M. Rolett presented two cases of epidermoid cysts—one located in the caruncle and one of the lacrimal gland. His paper was published in the Journal, 30:1577-1580 (Dec.) 1947.

Keratitis associated with lichen planus

Dr. Jacob Goldsmith reported the only known case of deep keratitis associated with atypical lichen planus. This new dermatologic entity was first observed during World War II. The corneal involvement appeared during the height of the skin malady and closely paralleled the course of the skin affection. The pathologic process commenced in the central portion of the posterior layers of the cornea and progressed anteriorly to involve the epithelium. The disease process on regression receded in the opposite direction. Vascularization was absent throughout the keratitis. The patient eventually regained 20/20 vision.

Dr. Goldsmith said that recent studies show that there is a close relationship between prolonged atabrine ingestion and the development of atypical lichen planus. Dr. Goldsmith expressed the opinion that

both the atabrine medication and the severe destructive skin lesions played an important role in the production of the deep keratitis. Circumcorneal pigmentation following long-continued use of atabrine was demonstrated as a yellowish-green limbal glow by sclerotic scatter.

Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

December 16, 1946

DR. WILLIAM A. MANN, *president*

CLINICAL PROGRAM

(Presented by the staff of the Illinois Eye and Ear Infirmary)

BILATERAL CATARACTS DUE TO LATENT TETANY

DR. HARRY I. WEINER presented a 32-year-old white women who entered the hospital on October 21, 1946, with complaint of impaired vision getting progressively worse following a thyroidectomy five years previously. The patient reported that following surgery and while still in the hospital she experienced several attacks of muscle cramps with carpopedal spasm but that she had no convulsions. During the five years following the thyroidectomy, the patient stated she enjoyed good health except that her teeth became carious and had to be extracted, her hair and nails became brittle and that she noticed progressive failing vision bilaterally until at the time of hospital admission she was unable to get around by herself.

Physical examination revealed a congenital shortening, contracture, and atrophy of the right thigh and leg, brittleness of the hair and nails, and edentulousness.

The neurologic examination disclosed the following: Chvostek's sign, positive bilaterally; von Bornsdorff's phenomenon, positive; and Erb's sign, positive. Laboratory findings were: serum calcium, 6.8 mg. per 100 cc.; serum inorganic phosphorous, 7.4 mg. per 100 cc.

Ophthalmologic examination revealed a visual acuity of finger counting at 18 inches, with good light perception and projection in each eye—noncorrectible. The anterior segments were normal. The pupils were round, equal, concentric and measured 3 mm. each. They reacted to light briskly. The anterior chambers were deep and optically inactive. The lens changes were identical in both eyes and consisted of a ground-glass appearance of the capsule with an occasional punctate opacity. There was a clear zone immediately behind the capsule. The deeper layers of the cortex, particularly at the posterior pole, revealed a number of gray and white opacities, punctate and flaky in configuration. The nucleus in each lens was surrounded by a large homogeneous opacity. The media and fundi were not visualized because of lens density.

The lens of the left eye was extracted intracapsularly on October 22, 1946, with no attendant complications. The anterior chamber did not reform completely until the fifth postoperative day. A small amount of bleeding was noted from the lips of the section, but it was resorbed without treatment. The remainder of the hospital tenure was uneventful. The patient was discharged on the 14th postoperative day. Vision was 20/40, with a +11D. sph. $\frown$ +2D. cyl. ax. 45°.

On readmission to the hospital, the patient's vision was 20/30, with +10.75D. sph. $\frown$ +1.00D. cyl. ax. 180°. The lens of the right eye was as previously noted. The extraction was delayed because of an intercurrent polyarthritis of unknown origin.

This patient was presented as a typical case of hypoparathyroid cataracts following a thyroidectomy after which latent tetany, with attendant dental decay, brittleness of

hair and nails, and carpopedal spasm, was experienced.

Chorioretinitis sclopetaria

Dr. William R. Eubank presented a colored woman, aged 33 years, who was seen for the first time on June 3, 1946. She stated that 11 years previously she had been shot through the head, the bullet emerging below the left eye. Except for eight hours of unconsciousness and difficulty in swallowing for two weeks afterward, there had been no sequelae. She said that her visual acuity had been checked and found to be equally good in each eye. Recently she happened to notice that the sight in the left eye was much worse than that in the right.

Examination showed that, two inches inferoposteriorly to the right mastoid process, there was a quarter-inch circular scar, evidently the bullet's point of entry. Immediately above the left orbital rim, in its inner third, was a stellate-shaped scar, one-fourth inch in diameter, apparently the point of exit. Unaided visual acuity was: R.E., 20/20; L.E., 20/200, uncorrectible. Externally the eyes appeared normal. No abnormalities of the extraocular muscles were found. The right fundus was a normal negroid type The left optic disc was normal in appearance. The retina immediately surrounding the macular area had an increased pigmentation and light reflex. It appeared to have a slight elevation in the center of which was a round, sharply punched-out hole one-half disc diameter in size. On the temporal rim of the crater were several other very small holes. Beginning three disc diameters inferiorly from the disc, the retina appeared to be disorganized and uneven, with large areas of heavy pigmentation and white scar tissue. A few retinal vessels were seen to course over portions of this. The striking retinal lesion extended from the 3- to 7-o'clock positions and to the extreme periphery. The remainder of the fundus was normal.

General physical and neurologic examinations were normal. Blood Wassermann and urinalysis were negative. X-ray findings were as follows: "Films of the skull show an irregular distribution of metallic densities extending from the atlas anteriorly to the inferior orbital plate. The path of these metallic bodies apparently crosses from right to left along the base of the skull. There is a suggestion of a radiolucent area in the posterior-inferior orbital plate on the left side, which could be secondary to a penetrating wound."

A diagnosis of hole in the macula, and chorioretinitis sclopetaria (from new Latin, sclopetum, a gun) was made. No treatment was considered to be indicated.

Adie's syndrome

Dr. William R. Eubank presented a white man, aged 40 years, who was first seen on December 3, 1946, at which time he complained only of blurring of vision and fatigue after close work of one year's duration. This condition was relieved somewhat by the glasses he had worn for three years. The patient stated that his mother had noticed that his right pupil was larger than the left from the time of his birth. Other pertinent history included a left facial paralysis, thought to be caused by infected tonsils. of six months' duration and followed by complete recovery. In 1941, he had had a moderate hypertension for which he had received intermittent treatment ever since.

Examination showed vision to be: R.E., 20/30—2; L.E., 20/40. This was improved to 20/20 in each eye by a low compound-myopic astigmatic correction. Accommodation was +2.25D. in each eye. Except for a moderate convergence insufficiency and the pupillary abnormalities, eye findings were normal. Both pupils were slightly irregular, the right measuring 4 mm. and the left, 2½ mm. The right pupil did not react appreciably to light, directly or consensually. Following binocular occlusion of 45 minutes, it dilated to 5½ mm., then slowly contracted

to 4 mm. again. Convergence caused a slow constriction to 1.5 mm., equalling that of the left pupil. Relaxation of convergence caused the right pupil to dilate slowly to 4 mm., while the left pupil dilated more rapidly to 2.5 mm. The left pupil reacted to light and convergence both directly and consensually. No subjective lag in accommodation was found in either eye. Instillation of 2-percent homatropine hydrobromide dilated both pupils widely and equally. Neither pupil constricted following instillation of three drops of 5-percent mecholyl.

Other pertinent findings were as follows: Blood pressure was 200/100 mm. Hg. Patellar reflexes were present and equal but diminished. Achilles reflexes were not elicited. Romberg's sign negative. Blood Wassermann and urinalysis were negative.

From the above findings a diagnosis of Adie's syndrome was made. This condition differs from the Argyll-Robertson pupil which has the following characteristics: (1) pupils are miotic; (2) bilateral in 90 percent of cases; (3) pupils react promptly and fully to convergence; and (4) they dilate slowly and imperfectly to mydriatics.

Except for correction of the refractive error and of the presbyopia, no treatment was given because Adie's syndrome is of no pathologic significance and is usually symptomless.

Response to D.F.P.

Because of the current interest in di-isopropyl fluorophosphate, Dr. Joseph S. Haas presented three cases which have successfully responded to its administration. In an attempt to evaluate its usefulness 35 patients were treated with D.F.P. in the past five months. Its use has been confined principally to the patients that are refractory or sensitive to the common miotics. A 0.05-percent concentration has been used almost entirely for this concentration seems to be tolerated better and to produce fewer objectionable symptoms. It also seems to have been equally effective. It has also been noted that an increase in dosage beyond three times a day does not cause further decrease in tension.

The first patient was a 70-year-old white man with glaucoma capsulare. Field studies showed: R.E., 10 degrees for 3/300 white; L.E., 10 degrees for 2/1,000 white. Corrected vision was: R.E., 20/250, L.E., 20/90. Gonioscopy showed the characteristic picture of glaucoma capsulare. The patient did not respond to 2-percent pilocarpine, six times a day, or to 0.25-percent eserine, four times a day. On 1-percent carcholin, four times a day, ocular tension averaged 33 mm. Hg (Schiøtz). In July, 1946, the patient was placed on 0.05-percent D.F.P., twice a day, and the average tension reading since then has been 26 mm. Hg, with no record of the tension going above 28 mm. Hg.

The second patient was a 64-year-old white woman who had had bilateral cataract extractions with delayed reformation of the anterior chamber. Gonioscopic examination revealed many peripheral anterior synechias, most pronounced in the right eye. Corrected vision was 20/25 in both eyes, and the central fields were normal to 2/1,000 white. On 2-percent pilocarpine, six times a day, and 0.25-percent eserine, four times daily, tension in the right eye remained poorly controlled reaching 40 mm. Hg on several occasions. The patient was then placed on 0.05-percent D.F.P., twice a day, in the right eye and the tension fell to soft. When the 0.05-percent D.F.P. was cut to once a day, tension rose to a range of 20 to 26 mm. Hg and has remained there since.

The third patient was a 72-year-old white woman with chronic compensated glaucoma and fields at 10 degrees for 2/1,000 white. When she was first seen, tension was 29/45 mm. Hg (Schiøtz). The tension in the left eye did not fall below 35 mm. Hg on 2-percent pilocarpine nitrate, six times daily, 0.25-percent eserine, four times daily, or 1-percent carcholin, four times daily. The patient was then placed on 0.05-percent D.F.P., for the left eye, one time daily, and the tension

fell to 19 mm. Hg, where it has remained since.

In order not to convey a fallacious impression, it is necessary to present some of the disconcerting factors about this new and promising miotic. The above patients have been selected, and it is only right to state that in many cases D.F.P. has caused no reduction in tension. There are also objectionable features. Many patients complain of pain and blurring due, presumably, to the intense ciliary spasm caused by D.F.P. For this reason the aphakic patient seems happiest on the drug. More important than the above symptoms, however, is the fact that in one group of glaucoma patients the drug may actually be harmful. One of our patients, a 72-year-old white woman with chronic incompensated glaucoma, had her left eye fairly well controlled between 21 and 33 mm. Hg on pilocarpine, six times a day. Her gonioscopic picture showed a very shallow angle with the second portion of the trabeculum visible in areas. Corrected vision was 20/19 with a +2.25D. sph. ⊂ +0.75D. cyl. ax. 120°. Her fields were normal. On October 19, 1946, she was placed on D.F.P. once a day, and tension rose to 45 mm. Hg even though the miosis was maximal. The angle details were obscured to gonioscopy, and the patient was blurred with her glasses, but could read 20/19 unaided. The patient was maintained on pilocarpine, and her tension gradually fell to the range of 27 to 31 mm. Hg, but only after seven days did she require her glasses to read 20/19.

In this case it would seem that the D.F.P., either by its intense ciliary spasm or its action on the blood vessels, produced a narrowing of the angle which, coupled with the pre-existing narrow angle, produced a mechanical blockage of the trabeculum. We may conclude, therefore, that although D.F.P. is a useful weapon in the wide-angle group of the glaucomas, it should be used only with extreme caution in the narrow-angle glaucomas, since it may throw an additional burden on an already handicapped angle.

Posterior lenticonus

Dr. Lester Mermell presented a white child, aged 12 years, who came to the Infirmary in November, 1946, with the complaint that she could not see the pictures clearly at the theatre. Her uncorrected vision was: R.E., 20/70; L.E., 20/30. There were no gross findings, and her extraocular muscles apparently functioned normally.

Under atropine cycloplegia her correction was: R.E., 20/70 with a +1.25D. sph. ⊂ +0.75D. cyl. ax. 90°; L.E., 20/20 with a +1.00D. sph. ⊂ +0.50D. cyl. ax. 90°. A pinhole disc in front of the right eye improved the vision to 20/40—2.

At the time of retinoscopy there was a bright shining droplet in the center of the reflex. On slitlamp examination, it was found that the posterior pole of the lens bulged backward into the vitreous in a conical fashion. There was a small opacity at the apex of the cone and another at the center of the posterior Y. This was a case of what Prof. Ida Mann calls a rare lenticular anomaly, posterior lenticonus. This condition is not quite as rare, however, as internal lenticonus or as anterior lenticonus of which, according to Parsons, there have been only two cases reported.

As is the rule with this anomaly, the remainder of the eye is normal, the other eye is unaffected, and there is no familial history.

About 80 percent of recorded cases have a capsular opacity, as seen in this case, and many show a retained hyaloid membrane adherent to the cone. This finding is absent in this case. The exact etiology has not been determined.

Intermittent iris bombé

Dr. S. W. Penn presented a case of a 56-year-old white man, who, 26 years after an injury to his right eye, developed a very rapid failing of vision in his left eye. The sight in his right eye was lost at the time of the injury. The right eye was enucleated,

following which vision in the left eye returned to normal. The histologic diagnosis of the specimen was not obtained. The patient had no ocular difficulties until 28 years later when he developed an attack of acute iritis. In the following year, there were two similar recurrences, all of which responded to treatment. During the last episode the intraocular pressure became slightly elevated and remained so after the eye had become quiet. At this time it was noted that the pupil was 2 mm. in size and was partially occluded by a membrane which bulged slightly into the anterior chamber. There were a few fine keratic precipitates. Gonioscopy revealed marked iris bulging with no angle detail visible except at the 2-o'clock position where the scleral spur could be seen. The lens, vitreous, and fundus could not be seen.

Because of the persistent elevation of tension in a quiet eye, 2-percent pilocarpine was administered. Shortly afterward the eye developed an iris bombé with an acute further rise in tension, edema of the cornea, ciliary injection, and a heavy beam in the anterior chamber. The pupil was still 2 to 3 mm. in diameter. The eye again became quiet after the instillation of atropine, although the tension remained about 40 mm. Hg, with the anterior chamber returning to an average depth. Two similar reactions to miotics were cleared by administration of atropine.

The patient's vision has been 20/90 (Snellen) for the past three months. There is a central field of about 2 to 3 degrees with a small peripheral island temporally. There has been no fall in the tension below 40 mm. Hg except when seen two months ago. The most recent gonioscopic examinations reveal an angle closed by peripheral anterior synechias except at the 2-o'clock position where the scleral spur can be seen.

This case was presented as a secondary glaucoma due to chronic iridocyclitis, possibly a sympathetic ophthalmia, with an intermittent iris bombé following the use of miotics.

Successful cyclodiathermy in seeing eyes

Dr. J. David Stratton presented two cases in which cyclodiathermy had successfully reduced the intraocular pressure below 30 mm. Hg (Schiøtz) in eyes with useful vision.

Cyclodiathermy has been advised for relief of ocular tension in high degrees of rise due to absolute glaucoma and to closure of the central retinal vein. Its use in the seeing eye has not yet been wholly accepted.

The first case was that of B. L., a white woman, aged 58 years, who was first seen in the Clinic in December, 1945, with acute narrow-angle glaucoma of the right eye of five days' duration. An iridencleisis was performed, followed four days later by a posterior fistulizing operation of Lindner. These procedures were only temporarily effective, so that one month later a cyclodialysis was done at the 10-o'clock meridian. This was effective only temporarily, and a regime of pilocarpine miosis was instituted for one month. It, too, was ineffective. Cyclodiathermy was performed on February 25, 1940, two rows of coagulation being made over the entire lower half of the globe, 4 and 6 mm. from the limbus. Corrected vision before this was: R.E., 20/200; L.E., 20/20. Tension was: R.E., 43 mm. Hg; L.E., 20 mm. When the patient was discharged, vision was: R.E., 20/200−1; L.E., 20/20. Tension was: R.E., 31 mm. Hg; L.E., 20 mm. On April 5, 1946, tension was 23 mm. Hg, soft. From that time until October, 1946, the tension ranged around 40 mm. Hg in the right eye, so that a second cyclodiathermy was advised. This was performed on October 7, 1946. Vision at that time was: R.E., 10/400; L.E., 20/40. Tension was: R.E., 39 mm. Hg; L.E., 23 mm. The operation consisted of surface coagulation of seven spots over the lower half of the globe. Vision on November 15, 1946, was: R.E., 10/500; L.E., 20/32. Tension was: R.E., 27 mm. Hg; L.E., 24 mm.

The second case was that of M. B., a

white woman, aged 66 years, who was first seen in the Clinic in April, 1946, at which time she had narrow-angle glaucoma in the right eye with neovascularization of the iris. There was a history of four months' duration of failing vision and pain in the eye. Vision was: R.E., 20/70; L.E., 20/30. Tension was: R.E., 61 mm. Hg; L.E., 20 mm. Miotic therapy failed; so, in view of the neovascularization, cyclodiathermy was performed. On April 8, 1946, two rows of 12 diathermy punctures were laid down over the lower half of the globe. This reduced the tension only temporarily. On May 6, 1946, vision in the right eye was 20/130; tension was 69 mm. Hg. Cyclodiathermy was repeated, five applications being made over the upper globe from the 11- to the 2-o'clock positions. Tension has remained soft in the right eye, and vision is 20/250. Fasting blood sugar and repeated urinalyses have failed to reveal diabetes.

Double perforation of globe with BB shot

Dr. John Thompson presented a man, aged 29 years, who was seen for the first time at the Infirmary on November 5, 1946, and complained that a BB shot had penetrated his left eye accidentally on October 12, 1946. He was seen by a downstate ophthalmologist who hospitalized and treated him with penicillin and sulfonamides for three days. X-ray pictures were taken. No surgery was performed.

When admitted to the Infirmary, examination revealed a small, circular, depressed area, 1½ mm. in diameter, at the 11-o'clock position, approximately 5 mm. from the limbus. The base of this depression was discolored with uveal pigment. There was a one-plus beam in the anterior chamber but no cells were detected. The pupil was irregular due to posterior synechias, and a massive hemorrhage was seen in the posterior segment. The eye was soft to tactile tension. Vision was light perception and faulty projection.

X-ray studies with a Comberg contact lens showed a metallic foreign body in the orbit, posterior to the globe.

Scientific program

Dr. Justin M. Donegan and Dr. William R. Thomas (by invitation) presented a paper on "Capillary Fragility, Retinal and General: Rutin Therapy." Dr. Jack Fields (by invitation) read a paper on "Ocular Complications of Mumps," which was published in the Journal, 30:591 (May) 1947.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE THIRD PAN-AMERICAN CONGRESS OF OPHTHALMOLOGY

The third congress of the Pan-American Association of Ophthalmology was held in Havana, Cuba, from January 4 to 10, 1948. The stage setting for the congress was one of great beauty and charm. The weather was kind, the occasion cheerful, the social activities were exquisite, and the scientific program was of high excellence. The experience is an unforgettable one to all of those who were fortunate to attend. The local committee, serving under the presidency of Dr. Tomas R. Yanes and the director general, Dr. Gilberto Cepero, had labored hard and long and at great expense to make the meeting a success from every viewpoint. In an endeavor of this size and importance, errors and delays are inevitable. It is evidence of the great skill and hard work of the committee that such errors were remarkably few and unimportant.

The total enrollment was 1,371. This included guests and "adherents," many of whom were beautiful, and at least 50 percent of those who attended were from the United

States. In addition to delegates from the Western Hemisphere, representatives of countries from all over the world were present and took active parts in the program.

Forty-eight courses of instruction, similar to those given during the meetings of the American Academy of Ophthalmology and Otolaryngology, were presented. Twenty-nine of these were given in English, the others in Spanish and Portuguese. A total of 144 hours of instruction was given by experienced teachers in their respective fields, and the courses were well attended. Approximately 45 scientific addresses were offered, and there were 35 "free" papers presented in addition. About 50 percent of the total were given in English and the others in French, Spanish, and Portuguese, the official languages of the congress. Many of the contributions were of great significance and value, and it is hoped that the majority of these will become available in the necessary translations to all members of the association.

The last day of the congress was designated as "Prevention of Blindness Day," and appropriate addresses were given during the morning under the able and charming presidencies of Mrs. Eleanor Brown Merrill of New York and Señora Doña Adela Formoso de Obregón Santacilia of Mexico. The medal of the National Society for the Prevention of Blindness in conjunction with the Pan-American Association of Ophthalmology was presented by Dr. Bandilio Courtis of Buenos Aires to Dr. Harry S. Gradle, formerly of Chicago, in recognition of his great service to the cause of prevention of blindness. Dr. Gradle, the president of the Pan-American Association, was regretfully unable to be present because of physical disability, and the medal was accepted in proxy by Dr. Frederick C. Cordes of San Francisco. The round medal, approximately the size of a silver dollar, is made of bronze and attached to a navy blue ribbon. On one side it reveals a figure of hands gracefully holding the sun, designed by Rockwell Kent, surrounded by the words, "National Society for the Prevention of Blindness, U. S. A." On the reverse side is a map of the Western Hemisphere and across it a scroll bearing the name of Harry S. Gradle, M.D., 1948. On the periphery is the wording, "For service in advancing eye health."

There were approximately 20 scientific exhibits displayed, each of excellent quality and a center of interest to crowds of observers. The physical arrangement of the exhibits was most attractive and satisfactory. A splendid scientific motion-picture program of some 35 titles was arranged. It was highly popular with the members and their guests. A commercial exhibit of considerable size was in evidence in front of the registration desk and included books, artificial eyes, drugs, instruments, and pieces of ophthalmic equipment, as well as the ubiquitous Coca-Cola man, whose refreshing wares slaked a thirst stimulated by excessive numbers of Daiquiri cocktails.

In a graceful ceremony on January 8th, Mrs. Helenor Wilder, representing the U. S. Army Medical Museum, presented its fine exhibit on "Unusual Tumors of the Eye" to the Department of Ophthalmology of the School of Medicine of Havana University. Likewise, the New York Eye and Ear Infirmary, through its representative, Dr. Edward Burchell, gave a collection of 100 microscopic slides, illustrative of ophthalmic pathology, to the university.

The above activities took place in the beautiful, modern Escuela de Medicina de la Universidad de La Habana. The facilities were adequate for all purposes and the arrangements were happy and spacious. Language difficulties were, of course, encountered, and many times were insurmountable. This was the only discordant note in the entire session. In justice to the local committee members, who had gone to so much expense and trouble to overcome the handicap of language difficulties, it must be said that arrangements had been made to translate the addresses and discussions onto lantern slides

through microfilm. The necessary projection apparatus did not arrive on time and their efforts and funds were wasted, which is a great pity. Much of the scientific value was thus, temporarily, lost to the members of the association.

On Sunday evening, January 4th, the formal opening of the congress took place in the beautiful National Capitol Building. His Eminence Manuel, Cardinal Arteaga y Betancourt, Archbishop of Havana, gave the invocation. The Honorable President of the Republic of Cuba, Prof. Ramon Grau San Martin, gave the official opening address to the congress. Among other addresses was that of Dr. Gilberto Cepero who introduced the official delegates from all countries to the congress. The ceremony was most colorful and impressive.

On Monday evening, January 5th, the honorary members of the association gave scientific addresses at the University of Havana. Among them were Bailliart of Paris, A. Fuchs and Lindner of Vienna, Arruga of Spain, Thiel of Germany, and Marquez of Mexico. The president of the University of Havana, Dr. Clemente Inclán Costa, opened the session; and Dr. Angel Vieta Barahona, dean of the Faculty of Medicine, closed it.

On Tuesday evening, the mayor of Havana, Dr. Nicolás Castellanos, held a gracious reception for the members and their guests in the lovely old town hall, or Municipal Palace, of Havana.

On Wednesday evening, in the impressive hall of the Academy of Sciences, a formal session was held, presided over by Dr. Jose A. Presno, the president of the Academy of Sciences. Dr. Derrick Vail of Chicago had the honor of giving the Harry S. Gradle Lecture. His assigned subject was "The Teaching of Ophthalmology," peculiarly appropriate for the first Gradle Lecture, named after that great teacher. Dr. Tomas R. Yanes presented the Pan-American Ophthalmological gold medals to Dr. William H. Crisp of Denver, and Dr. M. Uribe Troncoso of New York, for their scientific work and activities that are so important to ophthalmology of the Western Hemisphere.

In a surprise ceremony, Dr. Tomas Yanes was decorated with the flight surgeon's wings of the American Air Force, by Col. Victor A. Byrnes (MC), U. S. A., in recognition of his successful completion of the course in the U. S. School of Aviation, in 1930.

Dr. Gilberto Cepero, in an impassioned address, discussed the life of Carlos Finlay, former president of Cuba, ophthalmologist and discoverer, in 1881, of the cause of the transmission of yellow fever by Stegomyia fasciata. He pointed out in eloquent terms the fact that certain elements in North America have tended to forget Finlay's great contribution in favoring that of Reed, Carroll, Lazear, and Agramonte, who confirmed Finlay's discovery in 1900. It is just and right that this error be brought to our attention, for the name of Carlos Finlay, as a great benefactor to man, must not be forgotten or belittled. For his labor on behalf of Finlay, Dr. Cepero was decorated with the cordon of the order, Vasco Núñez de Balboa, by the government of Panama, in a colorful ceremony preceding his address.

On Thursday evening, January 8th, the National Medical College and the Medical Circle of Cuba gave a splendid buffet reception to the members and guests of the association. There was music and dancing and cheer.

On Saturday afternoon, the members enjoyed a luncheon on the terrace of the Jockey Club at the Oriental Race Track. It was an unusual sight to see so many distinguished ophthalmic surgeons thumbing through their pesos for wagers on their fancies, some of whom, surprisingly enough, won in the "Prevention of Blindness" and "Pan-American Congress of Ophthalmology" handicaps. However, as one member remarked: "It is easier to make money doing ophthalmology, but not nearly as much fun."

The final and most thrilling event that

closed a most outstanding congress was the fiesta held in the square of the cathedral flanked by old palaces of the Dons which retain, in spite of their commercial uses, the beautiful traditions of the past. In the balmy open air was set up a dancing platform and bandstand surrounded by tables. Floodlights illuminated the entire scene in unbelievable background, like a Hollywood motion picture. Many of the guests came in the colorful costumes of their countries. In the romantic atmosphere of the place, the ladies never looked lovelier nor the men more gallant, one's appetite for food and drink was sharpened, and the lavish entertainment of singing, dancing, and pantomime never could be more thoroughly appreciated nor enjoyed.

The next meeting of the association will be held in Mexico City in 1952. Dr. Conrad Berens of New York was elected president of the association. Vice-presidents were chosen from 12 of the participating countries. Dr. Thomas D. Allen (North America) and Dr. Moacyr Alvaro (South America) were elected secretaries. The president of the congress for 1952 will be chosen by his Mexican colleagues.

One's impressions of the Third Pan-American Congress of Ophthalmology are kaleidoscopic. It will take a very long time for them to be sorted out and catalogued, but the overall impression is one of great beauty, much truth, and considerable good will and pleasure.

Derrick Vail.

CORRESPONDENCE

Tracer-substance study of eye: Correction of discussion

In the December, 1947, issue of the Journal (30:1525-1526 (Dec.) 1947), there appears a discussion of the paper, "Studies on the Physiology of the Eye Using Tracer Substances," delivered at the 16th scientific meeting of the Association for Research in Ophthalmology.

Unfortunately this discussion was very poorly recorded by the stenographer, so much so that I shall have to ask for publication of the corrected text.

(Correct text of discussion, 30:1525-1526 (Dec.) 1947, Paragraphs 1 and 2.)

Dr. Vesey (New York): I would like to ask the speakers if they made any efforts to observe the route of outflow of the aqueous tracer substances from the anterior chamber.

It is today generally accepted that the route of outflow of the aqueous is through the system of Schlemm's canal via the trabecular tissue of the angle of the anterior chamber. Many arguments could be brought up against this theory, which cannot be discussed now.

Dr. Troncoso has beautifully shown that the lower animals, on which the experiments are usually carried out, do not have a structure resembling the canal of Schlemm. He showed that the Rodentia, the Ungulata, and the Carnivora do not have the canal of Schlemm, but that they have a ringlike spongy tissue in their ciliary body, which he termed the scleral sinus. He believes that this is the organ that carries the outflow of the aqueous in these animals. But, as I mentioned, many arguments could be brought up against the theory of filtration in the human eye, as it is accepted today. The experiments, however, should be carried out on Primate, whose eyes are built similarly to the human eye. If able research workers, like the ones who presented this paper, will make good efforts to observe the route of outflow, I believe our knowledge of the physiology of this very important subject would be quite a bit enhanced. I would like to hear something about that from the speakers.

Frank A. Vesey,
New York.

Predilection of left eyes for glaucoma

It was with great satisfaction that I read the comprehensive paper by J. C. Holst in the October issue of the Journal. His ap-

parently dry statistics are most stimulating and, due to the large amount of patients observed, really conclusive.

For me, the most interesting facts were those mentioned in the chapter "The first eye to be attacked." Among 1,040 glaucoma patients, Holst found 390 whose disease began in the right eye, while he found that it started in the left eye of 484; among 189 eyes presenting absolute or nearly absolute glaucoma not subjected to any operation, 87 were right eyes and 102 left eyes; among 109 patients with unilateral glaucoma, the left eye was involved in 119 cases, and the right in 77. According to Holst's cautious statement, these figures seem to indicate that the left eye is more prone to glaucoma than the right eye; for these striking differences, a tentative explanation might be suggested.

While the right innominate vein is shorter and straighter, the left one makes a longer and more bending way to reach the vena-cava-superior union. Therefore, we may expect differences in blood pressure and resistance inside the right and left jugular veins, as well as in their tributaries. Most probably, intravascular venous pressure in the left orbital veins may also be higher than in the corresponding vessels of the right side. And that may well be a contributing factor to the predilection for glaucoma in left eyes.

Similar considerations are valid for the explanation of unilateral glaucoma connected with unilateral nevus flammeus of the face, and with arteriovenous aneurysm. These facts fall well in line with an unconfirmed but interesting observation by Colomba (1938) who found increased venous-pressure values in patients suffering from primary glaucoma, and with the experimental intraocular-pressure increase following the provocative neck-compression test.

K. W. Ascher,
Cincinnati, Ohio.

BOOK REVIEWS

PRINCIPLES OF THE CONTACT LENS. By H. Treissman, M.B., B.S., F.R.C.S. (Eng.), D.O.M.S., and E. A. Plaice. St. Louis, C. V. Mosby Co. 1947. Clothbound, 88 pages, 40 illustrations. Price, not listed.

A description of the purpose and mode of action of contact lenses is adequately presented. Various types are discussed. The relative optical merits of spectacles and contact lenses are given. A resume of eye conditions in which contact glasses may possibly be used to advantage is presented optimistically. It is scarcely to be believed that all of the conditions mentioned would be suitable. Many seem rather bizarre; for example, symblepharon, pemphigus, ptosis with a crutch type of excrescence on the glass, neuroparalytic keratitis, and lagophthalmos.

A considerable part of this book is devoted to the method of testing by the ophthalmologist for a contact glass that may be used as a basis for constructing the final product. The method of making molds of such substances as Negocoll as models for contact lenses is dismissed as being inferior to that of using the contact trial case. Since molding is the method generally used in America, most United-States ophthalmologists may not be deeply interested. The now generally used plastic contact glasses, after being evaluated, are dismissed without strong recommendation.

On the whole it is questionable whether the book will be of great importance to American ophthalmologists.

Lawrence T. Post.

A SCIENTIFIC METHOD OF FITTING CONTACT LENSES. By Philip Salvatori. New York, N.Y., Philip Salvatori, 1947. 170 pages, index, and 88 illustrations. Price, not listed.

This book is an elaborate and detailed manual on the technique of the mold method

of fitting contact lenses. It should be a welcome edition to the ophthalmologist's and technician's library. The author is certain of his subject and has brought it completely up to date. The writing is concise and lucid, and the text is well illustrated. The book is not cluttered with descriptions of outmoded methods. Illustrations and descriptions of molding and final adjustment are detailed enough so that, if followed, unsatisfactory fits will be reduced to a minimum.

One criticism can be made. Encouraging technicians to mark loose or tight areas in the hope that the manufacturer can accurately relieve them is certainly misleading.

The subject of contact lenses needs continued investigation. There is further need of public education as to their usefulness. It is stressed that contact lenses will continue to be fitted but the extent to which this will be done is questioned.

Indication for contact lenses at the present time is quite definite, and many misconceptions held by the public stem from ignorance. Poor technical fittings have discouraged potential users. Those patients, who obtained contact lenses as a fad, are also a source of adverse publicity. Few from this group are willing to expend the effort required to develop a tolerance to their lenses or to try numerous solutions in order to find a suitable one.

Francis W. Parker.

CONTACT LENSES. By Theodore E. Obrig. Philadelphia, The Chilton Company, 2nd edition, 1947. 546 pages. 180 figures, bibliography, and index. Price, not listed.

The author is a recognized authority on contact lenses. He has developed many innovations and techniques and, through his teachings, has done much to popularize the use of these devices, particularly the plastic type of contact lens. His work shows evidence of much scholarship, research, and study.

Contact lenses are still in the process of evolution. It is not inconceivable that in the near future these lenses will be developed so that they can be easily fitted and comfortably worn, for as long as the individual may desire, without harm. At the present time this ideal has not been reached, although closely approached. The struggle to obtain a satisfactory solution for the "liquid lens"; that is, the part between the cornea and contact lens, is an example of the difficulties encountered. The author ably writes of these difficulties and gives an interesting history of his efforts to obtain such a liquid.

The problem of whether to use plastic material, glass, or part glass and plastic is another controversial one that is being worked over. The subject is in a healthy state of flux and has not yet settled to the bottom. Although he is the prime advocate of the molded method of manufacturing contact lenses, the author fairly discusses the contributions of other workers and their methods of fitting. This temperate and considered writing is attractive and scientific, and is quite in contrast with other volumes on the subject that have recently appeared.

The indications for contact-lens use are perhaps unduly comprehensive and enthusiastic, in view of the present state of the development. There is, however, little to quarrel about here, provided no injury to the eye will result from wearing the lens. Should the problem be solved and the ideal reached, it will make nearly obsolete, and overnight, the wearing of spectacles. The glitter, gleam, and sparkle of the human eye will be enhanced with unforeseen biologic results; and the entire male population, insofar as its eyes are concerned, will be available to destroy each other with greater efficiency in warfare.

Mr. Obrig has written an entertaining and instructive book.

Derrick Vail.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

3

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Amsler, M. **Liquids of the eye as part of the body lacunary system.** Ann. d'ocul. 180:418-429, July, 1947.

The body space units which form the lacunary system have much in common. The interstitial tissues of the subconjunctiva and the subchoroid as well as the anterior chamber form parts of this system. These spaces contain very little protein, but carry nourishment, especially in mineral salts, to almost all parts of the body. The liquid in these spaces represents about 20 percent of the body weight and in composition is between the blood plasma and the cellular protoplasm. This lacunar fluid is especially important in the nourishment of the avascular ocular tissues, the cornea and the lens. It is an important factors in uveitis, primary glaucoma, hypertensive and diabetic retinopathies and retinal periphlebitis. In perforating wounds, ciliary permeability is tremendously increased. Eczema, bronchial asthma, epidemic hepatitis, gastric ulcer, and rheumatoid polyarthritis are among the bodily diseases in which the permeability of the blood barrier is affected.

The Tyndall phenomenon is present in the normal aqueous which demonstrates that the blood barrier is permeable to some proteins of the blood plasma. Through the intravenous injection of fluorescein, the ciliary body has been found to be the principal source of the lacunar liquid of the eye. Normally impermeable to large protein molecules, the ciliary blood barrier may permit these to pass into the aqueous under certain conditions. When ciliary permeability is altered the change is usually primarily toward augmentation. The normal albumin content of the aqueous (0.3 to 0.5 percent may be increased to 6 percent in inflammations of the anterior uvea. The aqueous closely resembles the cerebrospinal fluid in its normal composition and also in its reactions to inflammation. The cytolytic properties of the aqueous are illustrated by the frequent rapid disappearance of hypopyon. The reactions of Besredka, Bordet-Wassermann, and Chediak have repeatedly been found positive in the aqueous. The aqueous may contain: 1. blood cells, polymorphonuclear leuco-

cytes, lymphocytes, and red blood cells; 2. desquamated tissue cells of the parts surrounding the aqueous, including corneal endothelium and iris epithelium; 3. reticuloendothelial cells; 4. cells of uncertain origin, probably interstitial tissue elements including cellular debris of different sorts. All of these cells are involved in the local defense mechanism of the interior of the eye. In 20 percent of a series of cases of chronic uveitis, large reticulo-endothelial cells were found in the aqueous. Bacterial cultures of the aqueous are rarely positive. With the ultra microscope, affording a magnification of 1300 diameters, colloid particles in suspension were easily seen and an intense Brownian movement and the Tyndall reaction were observed.

Chas. A. Bahn.

Leplat, G. **Ocular reticulo-endothelial tissue.** Ann. d'ocul. 180:385-391, July, 1947.

The reticulo-endothelial system plays an important part in the action of sulphonamids, choline and atropine as well as some infectious diseases such as tuberculosis. Among the rarer diseases which involve the eyes and in which it plays an important part are hemophilia, familial angiomotosis, and some purpuras, lymphogranuloma benign, (Besnier-Boeck-Schumann), Gaucher's disease and the syndromes of Niemann-Pick, and Hand-Schiller-Christian.

The reticulo-endothelial system includes: 1. the histiocytes which ordinarily live in loose connective tissue and include macrophages which are rarely increased in acute inflammations; 2. monocytes of the blood which can live in the vessels and become histiocytes; 3. the lining cells of the endothelial sinuses especially in the spleen and the bone-marrow; 4. reticular cells which with the reticular fibers form the reticular tissue which is found especially in the spleen, bone-marrow, and lymphatic organs; 5. the cells of Kupfer in the liver; 6. fatty histiocytes which become fat cells: 7. adventitial cells of the blood and lymph vessels; 8. other histiocytic cells located in different parts of the body which include the alveolar cells of the lung and the microglia of the nervous system.

The reticulo-endothelial system is also called the histiocytic system and the active mesenchyme. In the eye its cells are most numerous in the bulbar conjunctiva, and uvea, especially the ciliary processes, are rare in the sclerotic, and absent in the cornea, lens, retina and optic nerve. The cells may take the form of endothelial and giant cells. Their power of mobility is less important than their ability to accumulate in their cytoplasm many and varied substances including solutions and fine suspensions among which are senescent red and other cells. Histiocytic cells contain a relatively high lactic fermentative power or glycolysis which gives them an energy capacity greater than most other cells and enables them to survive in abnormal media. They play an important part in the metabolism of iron, lipids, cholesterol and vitamins C and D. Chas. A. Bahn.

Oggioni, Gianfilippo. **Chronaximetric studies in ophthalmology.** Riv. oto-neuro-oftal. 26:333-352, Sept.-Dec., 1946.

The writer reviews the literature on chronaxia and gives an integrated account of its significance in the understanding of ophthalmologic physiology and pathology. Melchiore Lombardo.

Vidal, F., Brodsky, M., and Travi, O. C. **Carbaminoylcholine and ophthalmotonus.** Arch. de oftal. de Buenos Aires 21:328, Oct.-Nov., 1946.

The authors studied the action of carbaminoylcholine on the tension of eyes with retinal angiosclerosis. The instillation of one drop of 0.33-percent solution

of carbaminoylcholine chloride preceded by two drops of desiccated ox bile in 1-percent solution bring about changes in the intraocular pressure characterized mainly by a retardation of the capillary venous drainage and a decrease or absence of the secondary fall in pressure of the veins of distribution. (Charts, bibliography.)

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Boström, C. G., and Kugelberg, I. **The official methods of testing color sense in Sweden.** Ophthalmologica 114:95-99, Aug., 1947.

As the result of actions taken by the Swedish State Department of Health, the methods of testing color sense in Sweden have become farily well standardized. All routine tests are made with two different sets of pseudo-isochromatic plates, namely the internationally known plates designed by Göthlin and Boström and a new set of plates designed by Boström and Kugelberg in 1944. This new series consists of 20 plates. Three of these show no pattern of any kind and are intended for the diagnosis of dissimulation. The other 17 plates show numbers or letters made up of two confusion colors appearing in three different brightnesses. Because of the rare occurrence and the practical insignificance of tritanomaly or tritanopia, the recognition of these conditions is not attempted. The plates are to be viewed in good daylight. Each pattern must be recognized in less than 15 seconds. The plates do not seem to fade. They are available from the Kirugiska Instrument Fabriks Aktiebolaget KIFA Stockholm.

Questionable cases are tested with an apparatus which permits the production of accurate mixtures of spectral colors.

Peter C. Kronfeld.

Carreras Matas, Marcelo. **Subjective optometry.** Arch. Soc. oft. hisp.-amer. 7: 710-718, July, 1947.

An easy, accurate and rapid method for measuring astigmatism is described. The author's device only consists of a bicylindrical lens and a linear object test.

J. Wesley McKinney.

Esteban, Mario. **Semiologic value of the abnormal chromatic sensations.** Arch. Soc. oft. hisp.-amer. 7:687-702, July, 1947.

The normality of the chromatic sense depends upon a perfect relation between the stimulus which comes from outside and the sensation created by it within the brain. Many times this relation is either not exact or erroneous. For a better understanding the author divides this study into three parts. (1) Imperfect chromatic perception. (2) False and erroneous chromatic perception. (3) Imaginary chromatic sensations. Each one of these divisions is illustrated with examples which make the subject more clear.

Sal Lence, J. **Axone communication between the centripetal and centrifugal fibers of the retina and intimate phenomena of vision.** Arch. Soc. oft. hisp.-amer. 7:683-686, July, 1947.

Among the changes produced in the retina by light stimuli are the following: visual purple is blanched, the rods become shorter and narrower and the cells of the pigment epithelium send protoplasmic processes around the rods and cones. According to the author's concept this process is a physiologic allergy. The changed visual purple is looked upon as a sensitizer which acts upon the sensory endorgans of the retina and initiates the nervous impulse which is carried to the brain over the ascending fibers of the optic nerve. In turn impulses are sent back to the retina by way of the centripetal or retinomotor fibers and these impulses produce the secondary changes in the pigment epithelium and visual cells as an allergic response.

DIAGNOSIS AND THERAPY

Bellows, J. G., and Farmer, C. J. **Streptomycin in ocular infections.** J.A.M.A. 135:491-495, Oct. 25, 1947.

The literature on the use of this drug in ocular infections is still very scanty. Though not substantiated by sufficient laboratory data those reporting their results feel that streptomycin should be added to the usual treatment because of the shorter healing time following its use. In experimental animals huge systemic doses are required to make the antibiotic detectable and even then the concentration probably is at a therapeutically inadequate level. Neurotoxic disturbances might occur if such doses were used in man. High concentrations of streptomycin in the conjunctival sac are obtainable instantaneously by instillation. Adequate concentrations in the aqueous follow the use of a wetting agent or iontophoresis in cases of abraded, infected, and even normal corneas.

Bacillus pyocyaneus was rubbed against the abraded cornea of rabbits. Streptomycin, 10,000 micrograms per cc. in isontonic salt solution was instilled three times at two-hour intervals in different rabbits two, four, six, eight, and twenty-four hours after the innoculation. When the antibiotic was used in the first six hours the infection was prevented in all animals in which the control corneas became destroyed. Streptomycin was considered unexcelled as a therapeutic agent in this type of infection.

Rabbits in which streptomycin used systemically after the vitreous had been inoculated with staphylococcus aureus were unaffected. Vitreous abscess did not form when intravitreous injections were given within six to eight hours after inoculation.

In acute and chronic conjunctivitis where known organisms were found before treatment the sacs became sterile after a few days of instillation therapy. A case of acute meningococcus conjunctivitis responded very well.

Organisms disappear rapidly in most cases of acute and chronic infections of the conjunctiva and cornea; healing generally is prompt if complicating factors are absent.

F. M. Crage.

Camera, J. A. de C. **A new ocular fixation forceps.** Arq. brasil. de oftal. 10:64-66, 1947.

The instrument, well illustrated in the author's article, is designed to obtain episcleral or scleral fixation in such a way as to avoid rotation of the eye. It has three blades, a T-shaped central blade with two sharp points, and two lateral pointed blades which are approximated so as to grasp the central blade. All points coöperate in the grasp of the sclera.

W. H. Crisp.

Cibis, P., and Kimmig, J. **Alloplastics in ophthalmology with Supramid.** Klin. Monatsbl. f. Augenh. 112:75-79, May, 1947.

The superpolyamid Supramid is a new thermoplastic synthetic material which has a certain resemblance to the protein molecule in chemical structure but which is resistant to protein splitting ferments. The authors used this material in 74 plastic operations in the ocular and facial region and found that in 71 cases there was healing without complications. In two-thirds of the patients the material was used for making a plastic stump after enucleation of the eye with attachment of the four recti muscles to the stump. Substitution for bony defects around the orbital rim, substitution for the zygomatic bone, support of the lower lid, and a ptosis operation comprise another third of the reported cases.

Max Hirschfelder.

Milletti, M., and Di Luca, G. **Arterial pressure of the retina and compression of common carotid artery.** Riv. oto-neuro-oftal. 22:1-31, Jan.-Feb., 1947.

Experiments were performed by the writers on 42 subjects whose age ranged from 15 to 75 years, in order to establish the diastolic pressure in the retinal artery on compression of the ipsolateral common carotid artery. This behavior is considered a measure of the adequacy of the collateral blood supply of the brain. The writers established the retinal index of cerebral compensation according to a formula in which the normal diastolic pressure and the diastolic retinal pressure after compression for two minutes are factors. This index is applied in the prognosis of ligature of the common carotid or the choice of a method for this surgical procedure. If the index is not above 20 the cerebral compensation is good and ligature by any method is permissible. If the index varies from 20 to 50 cerebral compensation is not as good and preference should be given to those methods of ligature which cause the gradual occlusion of the vessel; if the index is above 50 the ligature may be dangerous. Melchiore Lombardo.

Missiroli, Giuseppe. **Diagnosic and prognostic investigation with allergometry in ocular tuberculosis.** Boll. d'ocul. 26:31-42, Jan., 1947.

Tuberculin tests were given to 309 patients with a preparation called M.D.C. terr. Instituto Carlo Forlanini, similar to our PPD. Intradermal injections were performed, using dilutions between 1:100 and 1:10,000,000. If a papule measuring more than 8 mm. in diameter was found 48 hours after the injection the reaction was considered to be positive. The diagnoses of the patients were: two Parinaud conjunctivitis, three ulcerative conjunctivitis, four deep keratitis, 14 episcleritis and scleritis, 22 choriorentinitis or choroiditis, 264 iridocyclitis and uveitis. Two tables describe the reactions grouped according to diagnosis and dilution of the tuberculin used and the course of the eye disease compared with the degree of intradermal reaction. Most of the positive reactions were found in tests with dilutions between 1:100,000 and 1:2,000,000:

some of the patients with uveitis gave positive reactions with dilutions up to 1:10,000,000. During the protracted observation, clinically improved patients showed diminishing reactivity sixteen times and stationary readings three times; those with clinical deterioration had stationary readings three times and increase of reactivity five times. In stationary cases there was no change in reactivity eight times, increase four times, and decrease of reactivity five times. K. W. Ascher.

Missiroli, Giuseppe. **Therapeutic study of ocular tuberculosis using allergometry.** Boll. d'ocul. 26:43-53, Jan., 1947.

Thirty-two patients suffering from ocular tuberculosis were desensitized with tuberculin injections of increasing strength. The brand used was "M.D.C. terr., Instituto Carlo Forlanini." The diagnosis was uveitis in 23 patients, choroiditis in 4, episcleritis and keratitis in 2, recurrent vitreous hemorrhages in 2, and keratitis in one. The treatment was continued for 6 to 29 months. Three patients with uveitis and one with keratitis were considered to be cured; four with uveitis, one with choroiditis, one with episcleritis and keratitis, and one with vitreous hemorrhages were not; all others showed some improvement. In the favorable cases, the clinical improvement was seen to coincide with the decrease of cutaneous tuberculin reactivity; the unfavorable cases demonstrated lack of desensitization to tuberculin. (Table). K. W. Ascher.

Muhlman, V., and Lachman, R. **The methyl antigen in ophthalmology.** Arch. de oftal. de Buenos Aires 21:334, Oct.-Nov., 1946.

After briefly describing the method of preparation of the methyl antigen, the authors discuss the frequency of ocular tuberculosis and the specific action of the antigen. It is an innocuous form of medication which produces no untoward general, local, or focal reactions and whose beneficial effects are apparent after a few injections. The treatment, however, must be carried out over a long period of time because of the transient effect of the antigen. (Bibliography.)

OCULAR MOTILITY

Argañaraz, Raúl. **Convergent and divergent strabismus. Esotropia and exotropia. Medical and surgical consideration.** Arch. de oftal. de Buenos Aires 21:67, April-June, 1946.

The author discusses the different types of strabismus. Functional divergent strabismus usually begins in infancy and is accompanied by myopia in most of the cases. The anatomical factors involved make the surgical correction rather difficult. The mechanism of divergent strabismus that results from amblyopia is briefly discussed. Divergent postoperative strabismus generally appears some time after a tenotomy of the internal rectus and results from the retraction of the cut muscle. This type of strabismus is difficult to correct. Spasmodic divergent strabismus is due to spasm of the inferior oblique, and tenotomy of this muscle is the only operative procedure for correcting it. Paralytic strabismus is frequently the result of obstetrical trauma in instrumental delivery. All convergent strabismus that appears at birth is paralytic

and the external rectus is the muscle most commonly affected. In the surgical treatment the different operative procedures and their indications and contra-indications are discussed. The medical and surgical treatment of functional convergent strabismus in infancy, including the pharmacologic, optical, orthoptic and operative treatment is summarized. (Illustrations.) Plinio Montalván.

Braun-Vallon, S. **The non-operative treatment of concomitant strabismus.** Ann. d'ocul. 180:391-403, July, 1947.

An evaluation of British and American methods are presented, based on observations by the author in both countries. Non-operative treatment is indicated in deviations of less than 25 degrees in intelligent young persons. If the amount is greater, surgical treatment may be performed either before or after nonoperative treatment which becomes an important adjunct. Generally speaking, orthoptic treatment does not justify itself if binocular vision cannot be reasonably developed in two months. Ametropia should be fully and accurately corrected. In hypermetropia with exotropia, refractive correction has but little effect on the muscular imbalance. If the accommodative factor is predominant, bifocals may be of value to the very young with alternating esotropia. Occlusion of the better seeing eye with a cover or bandage often is of value if vision is subnormal after refraction. Its value is limited especially in the very young with central scotomas which are frequently not easy to detect. Visual acuity should be observed approximately every ten days if a monocular cover is used continuously, because of functional or structural amblyopia in the covered eye. Abnormal retinal correspondence is detected preferably with the after-image test of Bielschowsky though the amblyoscope may be used. The amblyoscope's big brother is the synoptophore. Favorable cases of abnormal retinal correspondence may be greatly improved after approximately 12 treatments which require about a month. Binocular visual education includes the exercises to develop simultaneous macular perception, prolonged simultaneous macular projection, and stereoscopic fixation.

Chas. A. Bahn.

Cross, A. G. **Neuromuscular aspects in ocular sequelae of head injuries.** Tr. Ophth. Soc. U. Kingdom 65:20-33, 1945.

The most important sign in head injury is the pupil which, having been normal immediately after the injury is found to become dilated and fixed within a short period. This is probably due to pressure on the third nerve center in the midbrain or to traction on the nerve trunk occurring on the same side of the injury at first and later on the opposite side. The Argyll-Robertson pupillary reaction may be associated with injuries which involve the base of the brain. Defects of convergence and accommodation were found frequently and were considered to be due to a lesion in the brain stem or third nerve but frequently no organic cause was present. Recovery was hastened by orthoptic treatments after the stage of fatigability was over. Abnormality of the extraocular muscles was the commonest of the sequelae. The lesion was a paralysis or paresis of one or more of the oculomotor muscles and resulted in double vision. Vertically acting muscles were found to be more commonly affected than the lateral rectus. The superior rectus was involved in 24 percent, the superior oblique in 21 percent and the lateral rectus in 11 percent of the patients with isolated muscle defects. A surgical procedure is indicated if diplopia persists for more than four months and proves a disability to the patient. (33 figures.)

Beulah Cushman.

McGuire, W. P.: **The surgical correction of paresis of the superior oblique.** Tr. Am. Ophth. Soc. 44:527-549, 1946.

The author discusses thoroughly the anatomy, physiology, pathologic physiology, and the etiology of paresis of the superior oblique muscle. He describes an operation that is essentially a modification of Wheeler's advancement operation for paresis of the superior oblique muscle in which he resects the desired amount of the tendon, and then reattaches the cut end of the tendon to the original insertion. With adequate exposure by means of a traction suture pulling the eye down and in, the difficulties of access to the tendon are minimized. Instead of applying surgical maneuvers to opposing muscles, one should logically attack the paretic muscle itself. C. D. F. Jensen.

de Vega y Fernandez-Crespo, R. **Ocular paralysis following spinal anesthesia.** Bol. Inst. path. med. 11:140-143, July, 1947.

A case of this unfortunate association is presented which occurred in a 24-year-old man. About a year previously a painful area developed and later a mass appeared which was diagnosed as a cyst of the internal lateral ligament of the right knee. It was readily removed under spinal anesthesia. The convalescence was without incident. Fifteen days later a sudden convergence of the left eye developed, due to a paralysis of the externus. Intensive vitamin medication, especially of the B complex was given and after two weeks recovery was complete.

Although several hundred similar cases have been reported, this complication is comparatively infrequent in the widespread use of spinal anesthesia. Novacain was employed, and its toxic action seems to have been exerted upon both the substance and central nucleus of the abducens nerve. Vitamin treatment is suggested because of its action in other types of neuritis. The dosage should be high and preferably by injection, even when no other evidences of vitamin deficiency can be discovered.

A. G. Wilde.

Weil, H. **Krecke and Donders on prisms in orthoptics.** Optician 114:247-253, Oct. 10, 1947.

Krecke is credited with being the first to suggest prisms in orthoptic treatment. The paper, published in 1847, has never been published in English. It is in two parts—Krecke's original suggestion and a postscript by Donders.

W. Krecke. A new prismatic lens for squinters.

Squinting occurs because the eye is unable to see for lack of exercise. If the eye could be stimulated and became accustomed after adequate training to refract light rays onto corresponding points of the retina so that the visual axes approach their natural position; if one could proceed in a step by step procedure until the axes revert to their natural position; and if by use of a prism this means could be used for the adjustment of the visual axis in strabismus, then it may be expected that in time the axis will move permanently and will retain a natural position.

The squinting eye should be trained to see by covering the other eye. When sufficiently trained, the angle of squint may be measured by having the patient look at a disc placed midway between the eyes and at the greatest distance in which the patient is able to see. Prisms are then placed before the squinting eye. The lens can be mounted in a spectacle frame and worn with a plano lens for the other eye. The power of the prism is gradually reduced, until a plano lens is used and the patient is cured. The prismatic correction may be devided between both eyes to reduce chromatic aberration.

Donders, F. C. The application of

prismatic lenses to the cure of squinting physiologically tested.

When prisms are used to refract images on to nearly corresponding points on both retinas, the squinting eye will change the direction of the visual axes and merge the double images into one. There must be no paralysis, severe amblyopia or rapid fatigue of the retina. There must be good ocular motility. If one places small prisms before the eyes, the double images will merge. The prism is a means of increasing muscle activity in the opposite direction to that of the squint, for ocular gymnastics after myotomy and as an aid in proper muscle development.

CONJUNCTIVA, CORNEA, SCLERA

Cuntz-Schuessler, E. **Two families with an unusual hereditary corneal dystrophy.** Klin. Monatsbl. f. Augenh. 112:70-75, May, 1947.

The author discusses the German literature on the subject of corneal dystrophy. She then discusses two patients belonging to different families who exhibited a corneal dystrophy with pathologic changes in all layers of the cornea. Other members of these two families who had a lesser degree of dystrophy had only mild changes of the endothelium, whereas the young patients described had also opacities in the interstitial parts and epithelial defects. The cases are related to the juvenile epithelial dystrophy of Kraupa and the bullous endothelial dystrophy of Schlichting.

Max Hirschfelder.

Doggart, J. H. **Modern views on and treatment of phlyctenular conjunctivitis.** Medical Press 218:275-276, Sept. 24, 1947.

Regardless of what relationship this disease has with tuberculosis, and there is much disagreement on this subject, the incidence of this form of keratitis has declined rapidly and progressively. The disease and its clinical diagnosis are described in detail. About 65 percent of the patients are girls. Relapses are the rule in neglected cases. The discussion of the etiology is concerned chiefly with tuberculosis. There is doubt in crediting the decline in the prevalence of the disease to higher nutritional standards. The ocular disease is probably an allergic manifestation of tuberculosis. Local treatment is limited to atropine, dark glasses and mercury oxycyanide. Penicillin, because of its sensitizing effect, is contraindicated. The importance of the character of food and surroundings is stressed.

Francis M. Crage.

Esterman, B., Laval, J., and Okrainetz, C. **Intraepithelial epithelioma of the cornea and conjunctiva. (Bowen's disease).** Am. J. Ophth. 30:1537-1540, Dec., 1947. (4 figures, 6 references.)

Hogan, M. J. **Conjunctivitis with membrane formation.** Am. J. Ophth. 30:1495-1510, Dec., 1947. (12 figures, 1 table, 58 references, discussion.)

Mata, Pedro. **Penicillin in the treatment of serpiginous corneal ulcer.** Arch. Soc. oft. hisp.-amer. 7:641-660, July, 1947.

The author reports in detail 30 cases of serpiginous corneal ulcer successfully treated by means of penicillin. Pure penicillin was used in instillations containing 1,000 to 10,000 units per cc. The drops were put in every half hour until the ulcer was healed and many times they were continued for three or more days afterwards. In severe cases, for instance those which were complicated with hypopyon, penicillin was given by means of iontophoresis and subconjunctival injection in doses of 2,500 to 6,000 units per cc. The iontophoresis took two to four minutes

and was repeated when necessary. At the same time large doses of vitamin C were given because of its beneficial effect upon the infection and especially the hypopyon.

J. Wesley McKinney.

Pasca, Giacomo. **Further contribution to knowledge about the so called epidemic keratoconjunctivitis, concerning a thousand more cases observed in Sassari in 1943-1944.** Boll. d'ocul. 26:54-64, Jan., 1947.

Pasca reported previously about some cases of epidemic keratoconjunctivitis observed in Sassari, Sardinia. The present paper is a continuation and completion of this report. A much larger material (1000 patients) is used. (A graph shows the distribution of morbidity with a peak that occurred in September, October and November of 1943). Treatment consisted of the application of 2-percent solution of silver nitrate to the conjunctiva and the administration of urotropine (hexamethylentetramine) orally or parenterally. The silver salt was used every other day and in the intervals 5-percent solutions of silver protein were instilled three times a day. Conjunctival discharge disappeared within three to six days. Corneal lesions seemed to be inhibited. Where lesions showed fluorescein stain, Pasca used an eye dressing which he also recommends when there is marked chemosis but no discharge. Corneal involvement is more common in adults; of 274 patients aged less than 10 years, only 49 had corneal lesions whereas 83 of 182 patients older than 40 years had corneal lesions in 83 cases. Pasca stresses the occasional appearance of phlyctenule-like perilimbal nodules and of subconjunctival hemorrhages. Sometimes the preauricular gland was enlarged.

K. W. Ascher.

Sédan, J. **Fistulas of the cornea.** Ann. d'ocul. 180:404-416, July, 1947.

Secondary glaucoma is the cause and not the result of obstruction to corneal fistula. Quantitative and qualitative changes in the aqueous which follow prolonged fistulization result primarily from a mild hypertensive form of uveitis. The aqueous in passing through the cornea produces a form of corneal edema in which the adjoining corneal tissue is poisoned. This predisposes to secondary glaucoma both by way of the hypertensive form of uveitis and the keratitis surrounding the fistula. The stage is thus set for actual secondary glaucoma of varying severity by any interference with the normal intraocular secretion or exit of the fluid from the eye. The same predisposition frequently results in secondary endogenous or exogenous infectious inflammations. The practical application of this concept is that all corneal tissues diseased in the above sense, must be removed to make normal, if possible, the uveal secretion and its exit from the eyeball. Four illustrative cases are cited in one of which treatment was successful. In this case all the diseased tissue surrounding the fistula was destroyed by cauterization, and the area was covered with a conjunctival flap. The author has had no experience, with keratoplasty, though he believes the same principles would apply. (4 figures.)

Chas. A. Bahn.

Vancea, P. **Role of nasopharyngeal infections in the resistance to treatment of certain cases of conjunctivitis.** Arch. d'opht. 7:277-280, 1947.

Vancea calls attention to the problem of conjunctivitis which is either unaffected or made worse by ordinary therapeutic measures. He notes that this type of conjunctivitis is usually associated with nasopharyngeal infection; in 27 such conjunctivitides he found nasal abnormalities present in all. Appropriate treatment of the nose and nasopharynx, along with conjunctival instillations of 1-percent

resorcin or 2-percent ephedrine, led to healing in from one to four weeks. Vancea speculates on the etiological connection between the conjunctival and nasopharyngeal infections and considers bacterial allergy the probable mechanism.

Phillips Thygeson.

Walsh, F. B., and Howard, J. E. **Conjunctival and corneal lesions in hypercalcemia.** J. Clin. Endocrin. 7:644-652, Sept., 1947.

About one-half the cases of hypercalcemia examined have shown conjunctival and corneal lesions seen only with the aid of the slitlamp. The conjunctival lesions are small glasslike crystal particles seen within the bulbar conjunctiva in the region of the palpebral fissure. Redness and irritation may occur, the latter may even be the patients' most annoying symptom. In one case of hyperparathyroidism the particles were probably calcium phosphate.

The corneal changes are grayish granular epithelial and subepithelial opacities concentric with the limbus on nasal or temporal sides or both. The opacity is densest at the periphery but may faintly involve the whole cornea. Unlike band opacity which it may sometimes resemble, these lesions of hypercalcemia have clear areas within the area of opacity. Some of these cases may have been erroneously reported as "primary" band keratitis. Arcus senilis is deeper and manifests the white limbus girdle described by Vogt.

Conjunctival deposits were seen associated only with hyperparathyroidism and vitamin D poisoning in eight out of twenty patients with hypercalcemia. Associated keratitic lesions were seen in four patients with vitamin D poisoning and renal insufficiency. Combined with the author's report is that of seven similiar findings in cases reported by Cogan and his associates. Except for the hypercalcemia the metabolism was undisturbed. Two patients with sarcoid had corneal lesions. The conjunctival lesions cleared in two cases after the hypercalcemia was corrected. The corneal lesions have been permanent. F. M. Crage.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Focosi, M. **An interesting case of chorioretinitis Jensen associated with interstitial keratitis.** Boll. d'ocul. 26:1-6, Jan., 1947.

Different etiologic factors were assumed in the pathogenesis of juxtapapillary chorioretinitis (Jensen), among them tuberculosis, multiple sclerosis, unknown virus, influenza and syphilis. Focosi reports the case of a 25-year-old male patient who, during the course of a bilateral interstitial keratitis, developed a unilateral juxtapapillary retinochoroiditis. Serologically positive, the patient was considered to be a congenitally luetic individual and this disease was assumed to be the etiological factor for both the keratitis and the fundus lesion.

K. W. Ascher.

Garbino, Carlos. **Uveitis and Nicolas-Favre's disease.** Arch. de oftal. de Buenos Aires 21:88, April-June, 1946.

In four cases of uveitis, in three of which the usual treatments were of no avail, the patients showed a positive Frei test, were treated with tartar emetic intravenously, and improved markedly. The authors, because of the Frei test, consider lymphogranuloma the etiologic agent. (Bibliography.) Plinio Montalván.

Lachman, R., and Pérez Chacón, E. **Penicillin therapy. Endogenous bilateral uveitis.** Arch. de oftal. de Buenos Aires 21:94, April-June, 1946.

A case of bilateral uveitis with hypopion following an attack of grippe was

treated with massive doses of penicillin hypodermically. The ocular picture cleared up in a very short time. (Bibliography.)

Plinio Montalván.

Safar, K. **Iridodialysis after cataract extraction repaired by electrocoagulation.** Ophthalmologica 114:77-80, Aug., 1947.

During a cataract operation performed (apparently in Vienna) in September, 1945, the lights went out right after the incision. As the lens capsule was grasped "in the dark," a severe hemorrhage occurred into the chamber. The surgeon let go of what he had caught with the capsule forceps and completed the extraction by performing a total iridectomy, capsulotomy with the cystotome, and expression of the nucleus. Examination of the eye three weeks later revealed an iridodialysis of 120 degrees. Five months later the iridodialysis was repaired surgically. With a small Graefe knife introduced from below through the limbus and parallel with it, a horizontal slit was made in the secondary membrane whereby a good optical opening and freeing of the dialyzed iris was accomplished. The peripheral edge of the latter was secured with a blunt iris hook, pulled into the incision and fastened there by electrocoagulation, applying the active electrode to the iris hook which at that moment was also touching the sclera. The postoperative course was uneventful. The final result was satisfactory, the corrected vision 6/24 and the dialysis only visible as a narrow, very peripheral slit on one side of the operative iris incarceration. A case of traumatic iridodialysis after contusion was treated by the same method and with the same satisfactory result. The author believes that fastening of the dialyzed iris by electrocoagulation is preferable to B. W. Key's method of fastening the iris by sutures because the former method is faster and less conducive to loss of vitreous.

Peter C. Kronfeld.

9

GLAUCOMA AND OCULAR TENSION

Goldmann, H. **The outflow pressure of the aqueous in man.** Ophthalmologica 114:81-94, Aug., 1947.

The advent of gonioscopy and the discovery of the aqueous vein have provided a valid foundation for the old hypothesis that there is a steady flow of aqueous from the anterior chamber through certain channels of exit into the anterior ciliary veins. Such a flow is dependent upon a pressure gradient between anterior chamber and anterior ciliary veins. For this pressure gradient Goldmann proposes the term outflow pressure and estimates its magnitude by exerting graduated pressure against the center of the cornea (by means of a spring dynamometer similar to the tonometer of Baillart) until an aqueous vein which is being watched under the slitlamp, shows visible dilation. In normal eyes this phenomenon occurs at dynamometer pressures from 5 to 12 grams. On one human eye with tumor but with normal anterior segment the relationship between dynamometer pressure and resulting rise in intraocular pressure was found to be linear, 1 gram of external pressure causing a rise in intraocular pressure of 1.3 mm. Hg (Schiøtz). A dynamometer pressure of 8 grams which in a given eye brings on the first visible dilation of the clear core of an aqueous vein, would then correspond to a rise of intraocular pressure of 10.4 mm. Hg. Goldmann believes that the actual outflow pressure in the normal human eye is one-half to one-fourth of the value obtained with his method and therefore uses the term "apparent" outflow pressure for the latter.

In eyes with chronic simple glaucoma with high or medically normalized tension the apparent outflow pressure is increased. In eyes with acute (narrow-angle) glaucoma in which the tension has

been normalized with miotics, the apparent outflow pressure is within normal limits. Since aqueous veins can be found in 90 percent of all human eyes, determination of the apparent outflow pressure may prove to be a quick and convenient method to diagnose early chronic simple (wide-angle) glaucoma.

Peter C. Kronfeld.

Longhena, Luisa. **Vogt's cyclodiathermy for glaucoma.** Boll.d'ocul. 26:7-30, Jan., 1947.

Cyclodiathermypunctures were performed on 30 glaucomatous patients; on 26 on one eye each, and four on both eyes. First operations were performed in 7 cases of secondary glaucoma, 7 of absolute glaucoma, 7 of chronic simple glaucomas, 4 of chronic congestive glaucomas, 2 of hemorrhagic glaucomas, 1 of aphacic glaucoma, and 1 of glaucoma associated with nevus flammeus. As second operation, cyclodiathermy, was used on 1 eye with absolute glaucoma, 3 with chronic simple and 1 with chronic congestive glaucoma. Procedure and complications are described. Among 7 eyes suffering from secondary glaucoma, 1 showed normalization of intraocular pressure, 2 eyes maintained tolerable pressure readings with the help of miotics, and in 4 eyes surgery was repeated (two iridectomies, two enucleations). Among seven patients with absolute glaucoma normal tension was reestablished with miotics in two, some had a transient improvement of their tension, others none. The chronic simple glaucomas responded better: four eyes had normal tension with the use of miotics postoperatively, two others a lower tension than before the operation. In one eye the tension was normal for one year after operation and remained good after a second cyclodiathermy for one month only. In chronic congestive glaucoma tension became normal in only one eye. Transient ameliorations of short duration occurred in others. In hemorrhagic glaucoma the tension became normal in one eye suffering from thrombosis of the central retinal vein, and another was relieved of pain. An aphacic eye maintained normal tension after the operation. No improvement was obtained in the eye suffering from nevus-flammeus glaucoma. In three eyes previously subjected to the Lagrange operation, intraocular pressure became normal and stayed so; in one of these eyes, the cyclodiathermy had to be repeated. The author characterizes her operative results as favorable and encouraging. K. W. Ascher.

Torres Estrada, Antonio. **Syndrome of ocular hypertension.** An. Soc. mex. de oftal. 5:213-219, July-Sept., 1947.

The author expresses the opinion that myopia, in the course of its development, is accompanied by a more or less marked degree of ocular hypertension. He regards it as desirable to use miotics and has applied to the general ocular condition of such patients the term "ocular hypertensive syndrome." In the course of discussion, Manuel Márquez declared that he had never seen in childhood the ocular hypertensive syndrome as described by Torres Estrada, but on the contrary that hypotension rather than hypertension was practically always present in myopia. (1 diagram.) W. H. Crisp.

Vidal, F., and Daniel, C. S. **Glaucoma and neuroarteriolar test.** Arch. de oftal. de Buenos Aires 21:111, April-June, 1946.

In 31 patients with glaucoma, the neuroarteriolar test was positive in 27 percent, negative in 39 percent and inverted in 34 percent. This shows a manifest functional disturbance of the venous system of distribution in glaucoma. (Bibliography.) Plinio Montalván.

Vidal, F., and Brodsky, M. **Glaucomatous iridoplegia and Argyll-Robertson**

miosis. Arch. de oftal. de Buenos Aires 21: 123, April-June, 1946.

The authors hold that local metabolic disturbances of the smooth muscle cells of the iris give rise to changes in the size of the pupil according to the type of cells affected: miosis in Argyll-Robertson syndrome and mydriasis in acute glaucoma. (Bibliography.) Plinio Montalván.

CRYSTALLINE LENS

Paras, Chavero, Enrique. **Alloxanic diabetes. Experimental production of cataract.** An. Soc. mex. de oftal. 5:225-230, July-Sept., 1947.

The present author summarizes the reports of 26 writers on the experimental production of cataract by means of alloxan, a product of uric acid which, injected into the general circulation of animals, produces a hyperglycemia of short duration followed by a more or less marked hypoglycemia. The experimental animal may also show polyuria, polydypsia, and loss of weight, and may further develop acidosis, with hypercholesterinemia, acetonemia, and reduced content of carbon dioxide. In rats, changes toward the formation of diabetic cataract can be recognized two months after administration of the drug, and complete blindness may develop by the end of four months. (References.) W. H. Crisp.

Sack, S. Senior. **Atopic cataract.** Ann. Allergy 5:353-363, July-Aug., 1947.

The occurrence of cataract in patients afflicted with skin disorders has been known for a long time. The earliest cases were the Rothmund and Werner syndromes. In the first type, skin lesions appeared in the early months of life and cataracts between the fourth and sixth years. The skin disease was called poikiloderma atrophicans. The latter type, a scleroderma, was associated with endocrine disturbances and cataracts.

The skin lesions of these syndromes differ greatly from disseminated neurodermatitis. It is generally agreed that the latter disease belongs with atopy which is characterized by a hereditary influence on the transmission of hypersensitivity. There is often a high degree of polyvalent hypersensitiveness. The author feels that since the skin and lens are both ectodermal tissue it is believable that the lenticular tissue participates in the disease after there has been a prolonged, extensive, and hypersensitive skin inflammation. This type of lens opacity is classified as atopic cataract.

A description of theories of the mechanism of atopic cataract formation, immunology of lens protein, and the lenticular capsule follow.

The case of a girl aged 17 years is presented. She had had an extensive neurodermatitis since she was two years old and bilateral cataracts, one mature. The cataract in the eye operated upon was probably in existence for only about seven months. F. M. Crage.

Sánchez Borroto, Pedro. **Senile cataract and antireticular serum.** Rev. del Col. med. de Cienfuegos. 2: 547-558, July-Aug., 1947.

The author has treated with antireticular serum eleven patients who had senile cataracts. Only seven were examined after the treatment. The author found no changes in the total opacifications and in the incipient cases there was some improvement. He did not arrive at any conclusions on account of the short time of observation after the treatment.

José Sáenz Canales.

Sédan, J., and Sédan-Bauby, S. **Micropuncture of hypermature cataracts not seizable with forceps.** Ophthalmologica 114:65-67, Aug., 1947.

To make possible the grasping with for-

ceps of the capsule of swollen cataracts, the authors recommend punctures of the lens with a fine sewing needle introduced through the peripheral iridectomy. One such micropuncture relieves the pressure within the lens sufficiently to permit grasping of the capsule. With this method the authors have performed intracapsular, complete extractions in 58 percent of all their swollen intumescent or hypermature cataracts. Peter C. Kronfeld.

11

RETINA AND VITREOUS

Culler, A. M. **The etiology of hemorrhage in the ocular fundus.** J. Iowa M. Soc. 37:486-492, Nov., 1947.

The majority of retinal hemorrhages are arteriosclerotic in origin. Arterial hemorrhages ocur in atheromatous changes and septicemia. Venous hemorrhages occur in mechanical or inflammatory obstruction. Capillary hemorrhages occur in toxic states, venous obstruction, and anemias. Irwin E. Gaynon.

Doucet, M. **Surgical repair of a retinal detachment resulting from a macular hole.** Arch. d'opht. 7:284-293, 1947.

The author describes the case of a 63-year-old woman with incipient cataract, a mopia of eleven diopters, and a flat detachment of the macula with macular hole. After the external rectus had been detached the sclera was exposed at the posterior pole and a single diathermy puncture at 15 milliamperes made over the area of the hole. Reattachment of the retina was obtained.

Doucet discusses the diagnosis of central detachment and stresses the difficulties involved in closing a macular hole without damaging too extensively the macular elements. Exposure is usually obtainable by detaching one or more muscles. For orientation, Doucet believes that the limbus offers the best guide, and as to technic he cites the various methods which have been used such as the undermining operation of Lindner after scleral trepanation, surface diathermy as described by Sohby Bey, catholysis after Vogt, and penetrating diathermy. He concludes that no one method is eminently superior. Phillips Thygeson.

Fleischer, Felix. **When should one fixate the retina prophylactically?** Klin. Monatsbl. f. Augenh. 112:20-29, May, 1947.

Retinal tears can be found in the presence of an attached retina. The visual disturbances may be minimal and may only be those of "mouches volantes" or light flashes. Sometimes one does not find a tear, but can observe a spot which looks as though it might become the site of an eventual tear. This is especially the case in patients with high myopia. After a short review of the literature the author presents 18 cases of his own. In 12 of them a retinal detachment had been present or operated on in the other eye. The second eye which showed tears without detachment was operated in every case with good success. The author states that it is urgently indicated to operate on every patient who had a previous detachment in one or both eyes and who presents the picture of a tear or suspected tear without actual detachment. In other patients who have no previous history of detachment and who present a so called "latent" tear he demands close and continued observation. A prophylactic operation is indicated when subjective complaints increase the threat of an imminent detachment. These cases can be operated on with surface cautery without paracentesis which entails no risk to the eye.
Max Hirschfelder.

Galíndez Iglesias, F. **A case of Eales' disease.** Bol. Inst. path. med. 11:158-165, Aug., 1947.

A case of recurrent vitreous hemorrhage is reported. This usually occurs in males between the ages of 15 and 30 years, although it has been seen as late as 55. When it occurs late it may be associated with a thyroid disturbance. Hemorrhages of this type occur on an average of 1 in 5,000 ophthalmic patients. While the general health may appear fair, or even excellent, detailed examination will usually uncover some form of cardiovascular renal disturbance, or more often a mild type of tuberculosis. This last is shown by glandular enlargements or excessive calcification of the hilus glands. The intradermal tuberculin reaction of Mantoux will show an erythematous papule after 48 hours.

After a hemorrhage, the eye itself shows nothing beyond a diffusely stained hemorrhagic vitreous. In time the blood may be largely or completely absorbed. Then, strands characteristic of retinitis proliferans, which result from the organization of former hemorrhages can often be seen. These, if attached to the retina, can by their contraction bring about partial or even complete retinal separation.

In the case reported absorption was practically at a standstill at the end of five months. Roentgen therapy was applied over the cervical sympathetic and the eye and the exudate then became absorbed with the exception of a few strands, and the vision returned to normal. The various possible causes are discussed; the two that seem most likely are periphlebitis of the retinal vessels, and endocrine disturbances.

A. G. Wilde.

Jaeger, A. **The retinal vessels during low atmospheric pressure.** Klin. Monatsbl. f. Augenh. 112:44-48, May, 1947.

Experimental studies were made in a low pressure chamber simulating altitudes up to 20,000 feet. At 10,000 feet one observes an enlargement of the arteries and veins, mild cyanosis of the arteries and a narrowing of the bright central light reflex on the arterial vessels. In some cases a pulsation of the veins was noted at 10,000 feet. Near the macula a broadening of the branching points of the vessels seemed to exist after reaching an altitude of 10,000 feet. No explanation for this phenomenon can be given. Some persons exhibited a spasm of accommodation under the lack of oxygen in high altitudes.

Max Hirschfelder.

Kruemmel, H. **Clinical and pathologic changes in the fundus in panmyelophthisis, with a contribution to the pathogenesis of retinal detachment.** Klin. Monatsbl. f. Augenh. 112:30-44, May, 1947.

Panmyelophthisis is caused by a deterioration of the bone marrow and is characterized by an aregenerative, anhemolytic, normochrome anemia, necrotizing processes and an increased tendency to bleeding. The case history of a patient with severe fundus changes in the final stages of the disease is presented. The retina showed numerous grayish spots in its deeper layers, some of them slightly elevated. Several small individual hilly detached areas were found in the upper quadrant and necrotic areas were spread over the attached parts of the retina. Numerous hemorrhages were also present. Sections of tissue taken at autopsy showed that the detached areas were produced by a transudate between the pigment epithelium and the rod and cone layer. The large hemorrhages were in the outer and inner parts of the retina and the smaller, spot-like hemorrhages had their location in the Henle fiber layer. The present theories about the origin of retinal detachment by cystoid degeneration and subsequent rupture are critically discussed together with the subject of "detachment without tear." (18 photographs, bibliography.)

Leopold, I. H., Wiley, M., and Dennis, R. **Vitreous infections and streptomycin.** Am. J. Ophth. 30:1345-1352, Nov., 1947. (6 tables, 27 references.)

Levrat, M., and Paufique, L. **The capillary fragility test in diabetic retinitis.** Presse Méd. p. 325, May 17, 1947.

This test is made by compressing the arm of the patient with a bloodpressure cuff inflated to a pressure equal to the systolic pressure minus 20 mm. Hg. The pressure is maintained for five minutes and the number and importance of petechiae present is then expressed in terms of +, ++, or +++. The test was found to be positive in a high percentage of hypertensive patients and in patients with certain other vascular conditions without hypertension. It may appear or disappear during the course of the hypertensive disease and may have a certain prognostic value.

In 14 cases of diabetic retinitis the authors found the test to be positive. In 12 of these cases the reaction was +++. Seven of the 14 were hypertensive but in the remaining seven the systolic pressure was less than 150 mm. The authors discuss the significance of the test in relation to vascular abnormalities and conclude that in diabetic retinitis there are not only profound local vascular disturbances but also systemic vascular lesions. They suggest that the demonstration of a positive test in a diabetic may indicate an impending retinitis. Phillips Thygeson.

Lloyd, R. I. **Pseudotumors of the macula.** Tr. Am. Ophth. Soc. 44:213-218, 1946.

The author describes various lesions he calls "pseudotumors" which characteristically affect the macular area. The initial lesion is a light colored mass of exudate in the macular area that levels out laterally and may not seem elevated unless the binocular ophthalmoscope is used. Cysts may form with clear or opaque contents. At times the initial mass may be filled with blood and resemble an angioma of the choroid. Although pseudotumor is not always the initial stage of Coats's disease, disciform degeneration of the macula or senile and presenile macular degeneration, it is probable that it often is. Hemorrhages beneath the retina are very common at some time or other during the course of the disease. The lesions may be accompanied by retinitis proliferans. High blood pressure does not seem to be a necessary part of the disease. Pseudotumors occur most commonly in older persons with marked temporal sclerosis but may occur in young patients. In the latter tuberculosis is the usual inciting cause. (5 illustrations.) C. D. F. Jensen.

Lowenstein, A. **Cushion cells in retinal pre-capillaries and capillaries.** Nature 160:229, Aug. 16, 1947.

The author has observed large cells of the intimal layer of retinal arterioles, capillaries and venules situated mostly at vessel branches. These cells reduce the lumen to a narrow slit or occlude it completely. The protoplasm of these cells is granular and gives them a different appearance from that of the other intimal cells. These cushion cells are best seen unstained in glycerine-cleared retina with reduced illumination. They have been stained with azo-eosin in bulk. The author was unable to discover them in stained parafin sections. The dehydrating process seems to cause shrinkage which makes the cushion cells indistinguishable from other intimal cells. The author states that it is probable that these cushion cells regulate the retinal blood stream within the fine branches according to need.

Theodore M. Shapira.

Lowenstein, A. **Intramural vessels in the retina (vasa vasorum).** Nature 160: 124, July 26, 1947.

In investigating ocular tissue of man

and animal by a clearing method during the past seven years, the author has found intramural vessels in retinal arteries and veins. They were discovered in uncut specimens and their existence was later proved by reconstruction of serial sections. Intramural vessels in the retinal wall may be parallel to the lumen, may encircle it or may be in spirals around it. They often branch and the twigs frequently reunite. So far they have not been found in the retinal vessels of young healthy human beings. Intramural vessels have been described in atheromatous coronary arteries of the heart. The purpose of these intramural retinal vessels in some cases may be to by pass an obstacle in the bloodstream, but in others the retinal arteries show hyaline sclerosis with preservation of the lumen. It is possible that in the latter case the intramural vessels act as vasa vasorum and improve the insufficient nourishment of the changed vessel wall. They are considered as part of the pattern of repair of the sclerotic process.

Theodore M. Shapira.

Puig Solanes, M. **Retinal angioscopy in essential arterial hypertension.** An. Soc. mex. de oftal. 5:137-213, July-Sept., 1947.

This 76-page article is based upon a study of 300 clinical cases. The work was carried on at the National Institute of Cardiology and the General Hospital of Mexico. A 26-page general discussion is followed by 43 graphs, 51 statistical summaries, 5 pages of references, and conclusions. The author's experiences do not differ essentially from those of previous writers. He calls especial attention to the fact that existence of retinal vascular sclerosis in a hypertensive patient does not imply aortic sclerosis, although statistical comparison indicates that it may suggest sclerosis of the coronary system.

W. H. Crisp.

Renard, G. **Concerning ocular tuberculosis. Retinitis of Jensen.** Presse Méd. p. 376, June 4, 1947.

The author discusses endogenous lesions, particularly tuberculosis, of the retina and choroid and notes that the French school has had the merit of calling attention to the important role of syphilis but has overemphasized the frequency of syphilitic lesions. He notes that almost all cases of ocular tuberculosis occur in persons free from active pulmonary tuberculosis. In some instances the tuberculous nature of the ocular lesion is probably due to the presence of tubercles of the iris but lesions of the posterior segment are notoriously difficult to diagnose etiologically. The tuberculin test should be used with caution because of the possibility of focal reactions. Diagnosis must be made on factors such as a history of exposure to active tuberculosis and on the clinical appearance and course.

The retinitis of Jensen is a clinical entity which the author states is almost always due to tuberculosis. The typical disease is described in detail and illustrated with case reports and colored drawings.

Phillips Thygeson.

Rowen, R. E. **Roentgenographic features of metastases of a retinoblastoma to the long bones. Report of a case.** J. Bone and Joint Surg. 29:805-806, July, 1947.

A six-year-old male Negro whose eye had been enucleated because of retinoblastoma, developed metastases in the humerus of each arm. Roentgenographic characteristics were similar to those of osteogenic sarcoma. Diagnosis was made by biopsy.

Irwin E. Gaynon.

Senà, J. A., and Cerboni, F. C. **Macular changes from observing solar eclipse.** La Semana Méd. 54:419-429, Sept. 11, 1947.

On May 20, 1947, an eclipse of the sun was visible over an extensive zone of Ar-

gentine, and resulted in the usual large number of individuals sustaining more or less ocular injury. The author reports nine clinical cases, and refers to six others. The early fundus changes consisted of an increase in size of the central reflex, with the appearance of a dirty-yellowish-white spot, with sharp edges, standing out upon the dark red of the surrounding fovea. These objective symptoms were accompanied by a fugitive positive scotoma, which then disappeared, leaving a central scotoma which, diagnosed with a test object of 2 mm. diameter on the tangent screen, at 2 meters, had approximately the size of an Argentine centavo coin (2 cm.).

Vitamin A appeared to have some therapeutic effect on these cases. In 30 percent the objective lesions and the subjective symptoms disappeared. In the remainder there had been an evident improvement up to the last examination, although the length of time was too short to draw final conclusions. Two thirds of the cases were bilateral. (8 illustrations, references.) W. H. Crisp.

Shanno, R. L., Griffith, J. Q. Jr., and LaMotte, W. O. Jr. **Capillary fragility and capillary permeability in relation to retinal hemorrhage.** Am. J. Ophth. 30:1556-1563, Dec., 1947. (2 tables, 7 references.)

Spaeth, E. B. **The fundus oculi in diagnosis and in prognosis.** J. Michigan St. Med. Soc. 46:799-804, July, 1947.

The author places the ophthalmoscope second in importance to the microscope in medical diagnosis.

He presents brief descriptions of the fundus findings in syphilis and tuberculosis of the choroid, retina and optic nerve, and in panophthalmitis, toxoplasmosis, endophthalmitis, ocular complications of bacterial endocarditis, and sympathetic ophthalmia. Francis M. Crage.

Vásquez Barrière, A. **Perimetric localization of lesions of the ocular fundus.** Arq. brasil. de oftal. 10:1-15, 1947.

The essay is devoted to localization of detachments of the retina, more particularly before operation, and largely upon the basis of Imre's calculations as modified by Stine. The latter's paper in 1930 devoted itself especially to making the necessary allowances for perspective displacement which would arise from a large protruding detachment. Vásquez Barrière particularly emphasizes the desirability of reducing the size of the retinal bleb before undertaking to localize the tear. Not only is the patient kept for some time in bed in the position which seems best suited to the particular case, but, if the settling due to rest in bed is inadequate, a small perforating diathermic puncture is made at the point corresponding to the greatest prominence of the detachment, after superficial coagulation in the same area. The author has had constructed a modification of the Schweigger hand perimeter, as used by Stine. The modified form is a tiny perimeter of 15 cm. radius, whose arc is formed by a delicate lamina 2 mm. thick by 7 mm. wide. In the center of the arc there is a small circular mirror in which, if the vision is adequate, the patient may maintain fixation by looking at his own eye. Where the vision is inadequate for this purpose, the patient looks at a lamp supplied by a dry cell contained in the handle. The author also uses an arcmeter consisting of a minute "rule" 2 mm. wide by 30 mm. long, curved so that its curvature is adapted to that of the sclerotic. (9 illustrations.) W. H. Crisp.

OPTIC NERVE AND CHIASM

Bartolozzi, Rafael, and Manzano, Toledo. **Anomalies of the sella turcica and**

its ophthalmologic importance. Arch. Soc. oft. hisp.-amer. 7:671-682, July, 1947.

The author is mainly interested in the study of the clinoid process of the sella turcica. The ossification of the ligaments that join the above mentioned process can produce some compression that ends in damage of the chiasm or optic nerve, which would give a fundus picture like that found in glaucoma. There is a defect of the visual field but no increased tension. Two suggestive cases are reported. (9 figures.) J. Wesley McKinney.

Eggert, W. A case of optic atrophy in osteopetrosis (Marmorknochenkrankheit Albers-Schoenberg). Klin. Monatsbl. f. Augenh. 112:66-70, May, 1947.

Osteopetrosis is characterized by extensive osteosclerosis and thickening of the bones which makes a differentiation into cortex and spongy portion impossible. The bones are more fragile, an anemia is present owing to the disturbance of the bone marrow. The condition is hereditary and recessive. Optic nerve atrophy is caused by a narrowing of the optic canal without externally visible deformation of the skull. The case of an almost two-year-old child is presented. The above named findings were present plus a slight protrusion of the bulbi and nystagmus. The prognosis is bad. The disease leads to complete blindness or a fatal anemia or septicimia. Parathyroid hormone has been recommended for treatment. (2 X-ray pictures, bibliography.)

Max Hirschfelder.

NEURO-OPHTHALMOLOGY

Goinard, P., Larmande, A., and Descuns, P. Reëvaluation of unilateral mydriasis as a localizing sign in head injuries. Presse Méd. pp. 281-282, April 26, 1947.

Unilateral mydriasis as a localizing sign has fallen into unjustifiable disrepute because of confusion with mydriasis due to purely local ocular lesions. Moreover, there is common neglect of transitory unilateral mydriasis and of unilateral mydriasis which later becomes bilateral. In a study of 40 cases in which the nature of the lesion was determined by operation or by autopsy the authors found unilateral mydriasis to be an accurate indication of homolateral disturbance of the brain due to a subdural hemorrhage, serous meningitis, or edema. Its occurrence, they conclude, even when only transitory, is an alarming sign although not by itself to be considered an indication for surgery. The article is documented with short case reports. Phillips Thygeson.

Govan, C. D. Jr., and Walsh, F. B. Symptomatology of subdural hematoma in infants and in adults. Arch. Ophth. 37: 701-715, June, 1947.

It is noteworthy that subdural hematoma occurs most frequently before two years of age and again in the third, fourth, fifth, sixth and seventh decades of life. This study is based on the findings in 36 infants and 54 adults. The symptoms of subdural hematoma in adults are quite different from those which occur in infants. Convulsions were present in 28 infants and only 2 adults. Vomiting was present in half of the infants and one third of the adults. Drowsiness and coma were common symptoms in both groups. In infants, when the fontanel was open, bulging almost always occurred and the spinal fluid invariably contained blood or was xanthochromic. In the great majority of adults, the spinal fluid was normal.

The eye findings are discussed in some detail. Papilledema was found in approximately 17 percent of both adults and infants. In infants, but not adults, the papilledema was almost invariably associated with subhyaloid retinal hemorrhages. Dilatation of the pupil on the side of the lesion is an important diagnostic sign.

The hematoma is usually bilateral in infants and results in bilateral pupillary dilatation. Visual field defects were observed in a majority of the patients.

Differences in the anatomic arrangement of the membranes of the brain in the infant and in the adult probably explain the differences in symptomatology and require further study. There is an important difference between the supporting structures of the pial veins of the infant and those of the adult. In sharp contrast to the condition seen in the infant, the dura and the arachnoid membrane of the adult are firmly bound together in the region of the longitudinal sinus.

John C. Long.

Jefferson, Geoffrey. **Isolated oculomotor palsy caused by intracranial aneurysm.** Proc. Roy. Soc. Med. 40:419-432, June, 1947.

Fifty-five of the author's own cases of "circle of Willis" aneurysm associated with isolated third nerve palsy are discussed. Two of them are described in considerable detail. The majority of the aneurysms arose from the internal carotid after the dura was pierced (suprachnoid). Subarachnoid bleeding had occurred in two-thirds of the cases.

The essential early signs and symptoms noted were ptosis, severe frontal and ocular pain, diplopia, and fixed dilatation of the pupil—all on the affected side. The changes in these manifestations during the course of the disease are described in detail. The cases are tabulated as to age, sex, subarachnoid hemorrhage, angiography, surgical treatment and present state.

The author differentiates the condition from palsies resulting from other causes by the fact that there is sudden, complete, uncomplicated third nerve palsy with severe pain involving the first division of the trigeminal nerve. He considers angiography as the best aid to diagnosis of the size, shape, position, and origin of the aneurysm. The most satisfactory, reasonably safe treatment is carotid ligature. Nineteen patients survived ligation; one of these died after seven years.

Francis M. Crage.

Just Tiscornia, Benito. **The neurocapillary test in a doubtful case of disturbance of the cerebral circulation.** Arch. de oftal. de Buenos Aires 21:339, Oct.-Nov., 1946.

The author presents a case of disturbance of the cerebral circulation due either to an intracranial aneurysm or to an angioma of the brain cortex in the area of the internal carotid artery. The neurocapillary test of Vidal and Malbrán revealed a marked metabolic disturbance of the eye which was not shown by other methods of examination and which improved after ligation of the carotid artery of the affected side. (Charts, bibliography.) Plinio Montalván.

Solnitzky, Otmar. **Oculomotor nerve paralysis.** Bull. Georgetown Univ. Med. Center 3:123-128, Oct.-Nov., 1947.

The oculomotor nerve, next to the abducens, is the most frequently involved of the nerves innervating the ocular muscles. Unlike the two other motor ocular nerves, the third supplies both the voluntary somatic muscles and smooth involuntary muscles.

The author gives a detailed description of the anatomy of the third nerve back to its origin in the brain and presents a case of complex third nerve paralysis. He also describes the etiology, signs, and the types of the disease. F. M. Crage.

Symonds, C. P. **Visuo-sensory aspects on the ocular sequelae of head injuries.** Tr. Ophth. Soc. U. Kingdom 65:3-19, 1945.

The author presents visual fields to depict the damage done in closed head injuries and gun shot wounds in anatomi-

cal order. Injuries to the optic nerve were found to have the force applied to the supraorbital region or the neighborhood of the external angular process on the side of the lesion. The force necessary to cause an optic nerve lesion is usually severe but it may be so directed that there is little disturbance of cerebral function. Complete loss of vision was usually reported at first in these cases, and later a partial but satisfactory recovery took place. Bitemporal field defects indicated injury to the optic chiasm in four cases. In each case violent force had been applied to the front of the head. All had had evidence of fracture involving the posterior wall of one frontal sinus and the roof of the orbit. All had anosmia. The visual fields showed bitemporal hemianopia with some macular sparing. The author concludes that the damage in both traumatic and neoplastic injury is to the vessels that supply the chiasm.

Injury to the optic tract was reported in one patient with visual field studies which afforded an example of a transient disturbance of vision which would have been dismissed as hysterical had the fields not been thoroughly examined.

Visual field study after injuries to the visual cortex in the occipital lobe supports the view that representation of macular vision is unilateral.

Visual disorientation was observed and reported in one patient. The patient sustained no loss of vision but he had difficulty in judging distance and ocular convergence was defective.

Beulah Cushman.

EYEBALL, ORBIT, SINUSES

Guyton, J. S., **Exophthalmos associated with endocrine dysfunction.** Texas St. J. Med. 43:280-282, Aug., 1947.

Exophthalmos occurs oftenest in Graves' disease, in about 65 percent of the cases of primary diffuse toxic goiter, and sometimes with "spontaneous" myxedema. It can occur but is rare without thyroid disturbance. It is seldom seen with secondary (nodular) toxic goiter. The primary cause is apparently a dysfunction of the anterior pituitary, probably overproduction of the thyroid-stimulating hormone, which may cause water storage in the orbits. The exophthalmos may be bilateral or unequal to the point of seeming to be unilateral. It persists after death. There is increased water storage, with progressive hypertrophy and degeneration of the extraocular muscles, scattered lymphocytic infiltration, and progressive (permanent) fibrosis of the orbital structures. The acute or progressive stage usually lasts 6 to 24 months and is followed by regression of the edema of the lids and conjunctiva and perhaps by a slight decrease of the exophthalmos. Prophylactic treatment of suspected malignant exophthalmos should be limited to iodine therapy, if possible, as subtotal thyroidectomy and thiouracil often cause an increase in the exophthalmos. If decompression is necessary, the subzygomatic or temporal fossa type, previously described by the author, is the least dangerous and leaves no scar or other cosmetic defect. (References.)

Bennett W. Muir.

Jaensch, P. A. **Pneumatocele of the orbit.** Klin. Monatsbl. f. Augenh. 112:62-65, May, 1947.

A bomb splinter injury produced, aside from a destructive vitreus hemorrhage, the clinical picture of proptosis, lid swelling, limited motion of the eyeball and high fever. This picture developed over a period of four weeks and a subperiosteal abscess was suspected. Incision was followed by escape of air and the exophthalmus disappeared only temporarily. Further investigation showed that a piece of mortar had made a communication be-

tween the frontal sinus and the orbit and had become lodged in the orbit behind the bulbus. The disturbance healed after evacuation of the frontal and ethmoid sinuses with subsequent splitting of the periorbit and removal of the foreign body. (4 Figures). Max Hirschfelder.

Joly, J. P. **Diagnosis and treatment of a varix of the angular vein.** Arch. d'opht. 7:281-283, 1947.

Joly describes the case of a 38-year-old woman whose initial complaint was of a swelling over the right lacrimal region. The swelling was found to increase when the patient inclined her head laterally, or laughed, cried, or indulged in strenuous effort of any kind. It never became red or painful and the swelling was soft and reducible with pressure. It had no connection with the lacrimal sac and was accentuated by pressure over the facial vein or over the jugular vein. There was no bruit such as would be present in arteriovenous aneurysm. The condition was diagnosed as varicosity of the angular vein and treated by ligation of the vein above the tumor. There was complete disappearance of all swelling.

Phillips Thygeson.

O'Brien, C. S., Allen, J. H., and Allen, L. **Evisceration with intrascleral implant.** Tr. Am. Ophth. Soc. 44:296-303, 1946.

Preliminary work on a new method of prosthesis insertion with intrascleral implantation following viscerations is presented. Several methods of utilizing a special lucite implant with a flanged hollow peg projecting from the anterior surface for attachment of a plastic prosthesis with a pin on its posterior surface have been discarded in favor of a new technique that permits retention of all of the corneal tissue except a small central disc which is removed by a trephine for passage of the implant peg. A long meridional incision that extends backward from the limbus in the area between the lateral and superior rectus muscles is made through the conjunctiva and sclera. Through this scleral opening the intraocular structures are expressed and the implant is inserted. The prosthesis fits securely on the implant peg. The authors believe that the operation is in its formative stage. The advantages of this method over the Ruedeman procedure are listed. C. D. F. Jensen.

Offret, G., and Meaux, J. **Pseudosinusitis of the newborn and infant.** Arch. d'opht. 7:250-276, 1947.

The authors describe the acute inflammatory rhinitis accompanied by ocular signs which appears as a sinusitis but is in reality an osteomyelitis of the maxillary bone. Two cases are reported. The first, in a child of 18 months, was characterized by an edema of one side of the face with a fever of 40° C. Later a fistula opened on the lower lid and two alveolar fistulas developed in the mouth. Sulfonamide therapy led to healing of the palpebral fistula but the alveolar fistulas persisted.

In the second case, an infant of six weeks when first seen had an intense edema of both lids on the left side which extended over the cheek. There was an ulcerative lesion of the upper lid and a slight exophthalmos. An alveolar fistula was also present and pus from this yielded streptococci on culture. A small sequestrum was removed from this fistula. On penicillin therapy the ocular signs disappeared but the osteomyelitis of the maxilla failed to heal.

The syndrome of pseudosinusitis is described as having a septicemic phase and a phase of localization. In the phase of localization the ocular signs dominate the clinical picture. The authors review the ocular, nasal, and buccal signs and symptoms in the light of their own two cases and a hundred cases recorded in the litera-

ture. They conclude that the prognosis is grave, death occurring in 70 to 80 percent of the patients. The differential diagnosis and pathogenesis are considered in detail. The embryology and anatomy of the infant's facial bones are considered in relation to this syndrome. The authors conclude that the alveolar surfaces of the maxilla are involved prior to nasal involvement and suggest that the condition is hematogenous in origin. They consider penicillin to be the treatment of choice.

Phyllips Thygeson.

Pentini, Gianfrancesco. **Chronic inflammation of the orbit simulating a neoplasm, pseudotumor of the optic nerve.** Riv. di oftal. 2:37-50, Jan.-Feb., 1947.

Birch-Hirschfeld distinguished two types of these pseudotumors, one without, and one with spontaneous reduction of the masses in the orbit. Tano classified them as uncharacteristic granulomas, lymphomas and plasmocytomas. A retrobulbar lymphocytic pseudotumor 2.5 cm. in diameter and the eyeball were removed from the orbit of a 56-year-old man. Pain was observed 11 months before admission, and diplopia appeared 8 months later. Finally, an unreducible exophthalmos of 9 mm., choked disk, and vision reduced to handmovements were found. (6 illustrations, 2 pages of bibliography.)

K. W. Ascher.

Sanchez Rodriquez, A., and Barthe Postrana, E. **A study of the inflammatory processes in the ethmoid sinuses and their relation to the orbit.** Arch. Soc. oft. hisp.-amer. 7:587-602, June, 1947.

This is an exhaustive review of the anatomy, physiology and pathologic processes of the paranasal sinuses, and of the newer concepts of the role of the sympathetic system in the pathogenesis of retrobulbar neuritis. It is emphasized that acute inflammations of the ethmoid always have orbito-ocular repercussions; that acute exacerbations of chronic ethmoiditis are associated with oculo-orbital symptoms; that chronic ethmoidal cellulitis and such processes as a mucocele are followed by signs of inflammation or compression of the orbit and its contents. The embryology, anatomy, pathology, and surgical experience justify the conclusion that with the exception of a dentigenous maxillary sinusitis the ethmoid sinuses are the primary site of all nasal infection, and the source of all orbital complications. It is hoped that further studies of morbid processes in the nasal mucosa will reveal the relation between latent ethmoiditis and retrobulbar neuritis. It is pointed out that orbital cellulitis and orbital abscess require a different therapeutic pattern. Orbital cellulitis may resolve under medical and physical therapy. Orbital abscess calls for prompt and radical surgical intervention. (9 figures.)

Ray K. Daily.

Simonelli, Mario. **Orbital apex syndrome and generalized neurofibromatosis.** Riv. oto-neuro-oftal. 21:245-257, Sept.-Dec., 1946.

Hysterectomy had been done on a single woman, 54 years of age, because of multiple uterine fibromata about a year before the examination. Ocular symptoms had started a few months later when diplopia developed and was followed by total right ophthalmoplegia, gradual blindness and symptoms of involvement of the ophthalmic branch of the right trigeminal nerve. Exophthalmos was present and excursion of the eyeball abolished. X-ray films showed the right optic foramen to be of normal form and size but there was clouding in the region corresponding to the upper sphenoidal fissure. When subcutaneous fibromatous nodules appeared a diagnosis of Recklinghausen's disease was made. The ocular symptoms

were ascribed to the localization of a nodule at the right orbital apex. The interpretation of the symptoms is discussed at length. (3 figures, bibliography.)

Melchiore Lombardo.

Šuster, Michal. **The treatment of rhinogenous orbital inflammations.** Bratislavské Lekárske Listy 27:674-691, Sept., 1947.

The author describes nine patients who had rhinogenous orbital inflammations. In four of these the process was chiefly subperiosteal and in five the retobulbar tissues were affected. Those of the first group improved after radical surgical operation and chemotherapy with sulfonamids and penicillin. One of them had an extradural abscess, the only intracranial complication in the series. Three of the patients with retobulbar inflammation lost vision, two because of retrobulbar neuritis and one from iridocyclitis.

In eight cases the radical operation was performed (six according to the method of Riedl, two external ethmoidectomy). All patients were given sulfonamids and penicillin and one who had orbital cellulitis recovered without the help of surgery. The results obtained from chemotherapy alone are no doubt remarkable, but early operation is recommended. (9 illustrations, bibliography.) F. H. Haessler.

EYELIDS, LACRIMAL APPARATUS

Beiras García, A. **Conjuctivitis sicca and filamentous keratitis in Sjögren's syndrome.** Arch. Soc. oft. hisp-amer. 7:541-552, June, 1947.

The author reports a case of Sjögren's syndrome, with conjunctivitis sicca and filamentous keratitis of many years duration, in a woman 58 years old, who had dryness of the throat and mouth, difficulty of deglutition, and dryness of the joints. The eye symptoms were completely relieved by closing the lacrimal canaliculi by diathermy-coagulation. The literature on both affections is reviewed, and it is believed that the filamentous keratitis is a direct result of the abolition of lacrimal secretion. Ray K. Daily.

Fox, S. A. **Some methods of lid repair and reconstruction. IV. Total reconstruction of the upper lid.** Am. J. Ophth. 30: 1413-1415, Nov., 1947. (6 figures.)

Gots, J. G., Thygeson, P., and Waisman, M. **Observations on Pityrosporum ovale in seborrheic blepharitis and conjunctivitis.** Am. J. Ophth. 30:1485-1494, Dec., 1947. (4 figures, 7 references.)

Jona, S. **Amyloid degeneration of the upper eyelids.** Rassegna ital. d'ottal. 16: 270-282, July-Aug., 1947.

Fifteen years ago a woman, now 68 years of age, noted slight ptosis, which eventually became almost complete. The skin of the upper eyelids became stiff and discolored. The affected tissue was removed, and areas of hyaloid, amyloid and colloid degeneration were microscopically demonstrable. The author suggests the name paraamyloidosis for the condition. (6 figures.) Eugene M. Blake.

Marín Amat, M. **Surgery of entropion of the upper lid.** Arch. Soc. oft. hisp.-amer. 7:603-610, June, 1947.

The author describes a modification of the Panas operation for entropion of the upper lid. An experience with five thousand operations convinced him of its effectiveness. The modification consists essentially in superimposing the lower lid margin over the upper half of the tarsus, and thus lifting the eyelashes away from

the cornea; in excising the exposed fibers of the orbicularis; and in thinning the upper half of the tarsus. The technique of the operation is well illustrated. In local anesthesia an incision of the skin and orbicularis is made 2 mm. from the palpebral border along the entire length of the lid, the presenting fibers of the orbicularis are resected, and the tarsus is incised 1.5 mm. from the palpebral border, through its entire length. The thickened tarsus is thinned by shaving off layers of it with a thin knife. The ciliary border is superimposed over the superior portion of the tarsus, and fastened in place with fine silk sutures. (7 illustrations.)

Ray K. Daily.

Rolett, D. M. **Epidermoid cysts of lacrimal gland and caruncle.** Am. J. Ophth. 30: 1577-1580, Dec., 1947. (1 table, 3 figures, 8 references.)

Semeraro, Edmundo. **Surgical treatment of entropion.** Rev. brasil. de oftal. 6:37-39, Sept., 1947.

The author illustrates, and briefly describes, the following technique. A fold of skin is grasped with forceps, sufficient to give the appearance of correcting the entropion, and the upper blade of the forceps is applied 6 mm. below the lid margin. Two curvilinear incisions are made in the skin. Their centers coincide with the positions at which the blades of the forceps were applied, and the ends of the two incisions come together so as to include an area of skin that resembles the cross section of a concave convex meniscus. After this area of skin has been removed, the area of skin between the upper incision and the lid margin is dissected free from the underlying tissue, and the lower edge of this marginal flap is sutured to the skin at the lower edge of the previously denuded area. (3 drawings.)

TUMORS

Santoni, A. **Further contribution to the study of the optic nerve tumors.** Riv. otoneuro-oftal. 21:258-277, Sept.-Dec., 1946.

Progressive protrusion of the right eye, straight forward with a slight deviation outward was noted in a girl, 13 years of age. The eye had been always blind, the pupil did not react to light and the disc was atrophic. On the X-ray film the right optic foramen appeared to be almost three times as large as the left one. An inferotemporal orbitotomy revealed a neoplasm, 9 to 12 mm. in diameter, connected with the optic nerve. The tumor was excised and found to be an astrocytoma. In about a year the tumor recurred. The orbit was exposed by a Krönlein operation and all neoplastic masses were removed. No relapse has been noted after two years. (4 figures, bibliography.)

INJURIES

Aranha de Azevedo, Paulo. **Ocular changes and pregnancy.** Arq. brasil. de oftal. 10:47-64, 1947.

The author summarizes the changes recorded and discussed by various writers as having occurred during pregnancy, at labor, and during the puerperium, including changes manifested directly in special ocular tissues, or through the function of vision as dependent upon the general circulation or the central nervous system. (References.)

W. H. Crisp.

Araujo, Helio de. **Ocular lesions from the stings of hymenoptera.** Arq. brazil. de oftal. 9: 140-143, 1946.

Thirteen cases are briefly reported. Except in cases arising from attacks by swarms, the symptoms were exclusively

local, chiefly, in the form of palpebral edema and reactions of the cornea or conjunctiva. Recovery was complete under various forms of treatment, and it may be concluded that the stings of hymenoptera are not malignant.

W. H. Crisp.

Arriaga Cantellera, José. **Craniofacial traumatism with keratitis neuroparalytica.** Arch. Soc. oft. hisp.-amer. 7 :661-670, July, 1947.

The patient suffered a traumatic injury on the left temporomalar region which produced fracture of the left malar and left superior maxillary bones. From the clinical standpoint a diagnosis of fracture of the base of the skull (greater wing of sphenoid) was made in spite of the fact that no X-ray pictures were taken. The right eye was normal; the left had light perception only. There was complete anesthesia of the cornea, the lower one-half of which was occupied by a large ulcer. Paralytic convergent squint and legophthalmos were noted. The injured nerves were found to be the left facial, the left abducens and the first and second branches of the left trigeminus.

J. Wesley McKinney.

Droegemueller, W. H. **The X-ray localization of intraocular foreign bodies.** Tr. Am. Acad. Ophth. 51 :601-603, July-Aug., 1947.

Among the potential causes of error in the Sweet method, Comberg contact lens technique, or sutured markers are differences in relationship between the foreign body and the orientation marking device. These differences may be due to slight head or eye movements as well as difficulties in transposing the charted data to the eyeball proper. The pin point localization of Struble is based on an X-ray plate taken after suturing a small shaving of lead to the eyeball near the site of the foreign body previously indicated in lateral as well as anteroposterior roentgengrams. Accurate localization makes possible minimum trauma during the extraction. Negative X-ray reports should never be taken as proof of the absence of intraocular foreign bodys when other clinical evidence indicates its presence. The Berman and other localizers do not indicate site as accurately as the X-ray. The bone-free method of Vogt, parallax air injection studies, as well as the use of stereoscopic plates are briefly discussed.

Chas. A. Bahn.

Gundersen, Trygve. **Surgery of intraocular foreign bodies.** Tr. Am. Acad. Ophth. 51 :604-613, July-Aug., 1947.

Ocular casualties are ten times more frequent than size of the ocular area leads one to suspect. The eyes expose only 0.2 percent of the body surface, yet ocular casualties constituted almost 3.5 percent of all battle casualties in the sixth General Hospital between March, 1943 and December, 1944. Very small high velocity fragments cause greater ocular damage than would be expected because of their explosive action within the tissues. Multiple foreign body injuries were surprisingly frequent and were observed with a single wound of entrance. Locators that are designed on the same principle as mine detectors frequently accurately indicate the nearest approach to intraocular foreign bodies. Locators give no information which cannot be obtained by precise X-ray examination. The weakest magnetic force possible should always be used in the removal of intraocular foreign bodies. In World War II, the Lancaster hand magnet was most generally used. Routine procedures in ophthalmic military surgery should be avoided because each case presents individual problems. Immediate enucleation should be performed only if it is a part of a general debride-

ment. Differentiation between hemorrhage in the vitreous and in the subchoroidal space is important and can be made by means of visual fields taken with point illumination of low intensity. Secondary foreign bodies such as paint and lashes were frequent and of practical importance. Generally speaking, the toxicity of metallic intraocular foreign bodies is inversely proportionate to their atomic weight. In the removal of intraocular foreign bodies, the trauma involved frequently determines the fate of the eye. Localization must often be of pin point accuracy to avoid calamity. Prompt sulfonamide administration has so reduced the risks of immediate infection that one can take time for accurate diagnosis. The advantages and disadvantages of the anterior and posterior routes are briefly reviewed. The former is less desirable for large foreign bodies which may damage the zonule. To avoid sympathetic ophthalmia necessary enucleations should be performed by the twelfth day.

Chas. A. Bahn.

Nüranen, J. V. **The Navy's plastic ocular restoration.** Military Surg. 100: 402-406, May, 1947.

The paper gives a short history of artificial eyes, the advantages and shortcomings of plastic restorations, the advantages of an individual prosthesis over the conventional stock type, and an explanation as to "why dentistry is the logical profession to undertake this individual prosthesis." Techniques are not described.

In preparing an ocular prosthesis a dental officer is the logical operator to take the impression because of the emphasis placed on the anatomy and physiology of the head and because of his understanding of the physiology, asepsis, and esthetics involved in the problem of dental prosthetics. Francis M. Crage.

Struble, G. C. **Experimental work on intraocular foreign bodies.** Tr. Am. Acad. Ophth. 51:594-600, July-Aug., 1947.

Steel shavings of different sizes, freshly killed pig's eyes and the blunt tip of the giant magnet were used in this experimental work to determine at what distances various sized particles can be drawn through vitreous and uvea and through a scleral incision. The success of the extraction on the first application of the magnet depends on the initial impact of the foreign body on the inner layers of the globe. In these experiments magnetic foreign bodies were in one of four positions: 1. free in the vitreous; 2. imbedded in the retina; 3. between the retina and the choroid; 4. between the choroid and sclera. In position 1 only particles larger than 1 mm. could be consistently brought forward; in position 2, only particles larger than 1 mm. could be disengaged and brought forward and delivered through the ciliary body and anterior chamber; and in position 3, only particles 1.5 mm. or larger could always be delivered. In position 4, 1.5 mm. objects produced choroidal separation and retinal elevation, but in no instance was the retina or choroid prolapsed when the foreign body was delivered. (5 tables.)

Chas. A. Bahn.

Wilder, H. C. **Intraocular foreign bodies in soldiers.** Tr. Am. Acad. Ophth. 51:585-593, July-Aug., 1947.

In military injuries, non-magnetic intraocular foreign bodies predominate by more than 25 percent. In this microscopic study of almost 4,000 enucleated eyes during World War II, more than 18 percent had retained foreign bodies. Among the non-magnetic substances found were copper, brass, lead, nickel, zinc alloys, glass, vegetable matter, eye lashes, shale and clay. Sympathetic uveitis was found in 0.1 percent. Glaucoma was comparatively rare and phthisis bulbi was frequent. The

figures excellently illustrate the basic pathologic process involved. (35 figures.)

SYSTEMIC DISEASE AND PARASITES

Alvarez, W. C. **Psychosomatic medicine that every physician should know.** J.A.M.A. 135:704-708, Nov. 15, 1947.

In an address which the ophthalmologist will read with pleasure and profit, Alvarez points out that every physician must know much about psychosomatic medicine if he is to avoid making many diagnostic mistakes. One should learn to recognize quickly those syndromes which are probably always functional in origin and learn when to suspect that a patient's main trouble is a nervous breakdown or fatigue state. One of the best signs is an inability to work comfortably, if at all. Another good sign is the inability to read. The patient says his eyes quickly tire; he gets tense, his head feels as if gripped in a tight band; he reads a paragraph over and over again and gets little out of it. Usually he cannot sleep, and he is irritable and overemotional.

F. H. Haessler.

Appelbaum, Alfred. **Human toxoplasmosis.** West. Med. and Surg. 1:323-331, Oct., 1947.

The author reviews the literature on toxoplasmosis and presents the record of an adult in whom the diagnosis of the disease was confirmed by a positive neutralizing antibody test. A classification of all types of toxoplasmosis is listed. Ocular defects have been observed in more than half the cases and the finding of bilateral central chorioretinitis suggested the proper diagnosis. The general pathological findings are presented and the laboratory procedures for diagnosis have been found to be quite accurate.

The symptoms in infants may include cranial anomalies, convulsions, cerebral calcification and mental retardation. Adults with acute febrile debilitating conditions with erruptions or atypical pneumonia may be found to have toxoplasmosis.

O. H. Ellis.

Carreras Durán, B. **Ocular manifestations in congenital porphyrinuria.** Arch. Soc. oft. hisp-amer. 7:459-468, May, 1947.

A case of congenital porphyrinuria is reported in which the ocular lesions were localized in the cornea, conjunctiva, sclera and episclera in a man, 49 years old. Since the age of 8 years he had had skin ulcerations especially in the ears, and on the hands and face where scars are still visible. He had bilateral conjunctivitis and conjunctival scars from an old ulceration, bilateral holes in the sclera about 2 mm. in diameter which are covered by the bulbar conjunctiva and a dense leukoma in the left cornea. There is a history of the same disease in two members of his family. Van der Hoeve called this disease scleromalacia perforans and reported nine cases. (2 illustrations.)

J. Wesley McKinney.

Cohen, Martin. **Ophthalmoscopic changes associated with hypertensive vascular disease as a guide to sympathectomy.** Arch. Ophth. 37:491-496, April, 1947.

In 82 patients with benign essential hypertension no progression of the retinal lesion was observed after sympathectomy. Of 60 patients with associated hypertension with mild or moderate retinal lesions, regression of the retinal hemorrhages, exudates and edema were observed in 22 after sympathectomy; but the basic underlying retinal arteriolar sclerosis remained unchanged in 48. Retinal angiospasm was relieved in 12 patients.

Patients with benign essential hypertension and eyegrounds that are normal or have moderate lesions are suitable for

sympathectomy if continued medical treatment is of no avail in alleviating the severe and persisting subjective symptoms. The advisability of sympathectomy is determined primarily by the internist, whose decision is based on the consideration of all clinical data in essential hypertension. John C. Long.

Cordes, F. C., and Aiken, S. D. **Ocular changes in acute disseminated lupus erythematosus. Report of a case with microscopic findings.** Am. J. Ophth. 30:1541-1555, Dec., 1947. (11 figures, 29 references.)

Edson Pinho. **Hysteric amaurosis.** Arq. brasil. de oftal. 10:16-19, 1947.

The patient was a white woman, aged 19 years, who had been married for ten months and had a healthy girl aged one month. The eyes were apparently normal, but no form of mental or physical treatment restored her vision until her husband returned from prison.

W. H. Crisp.

Givner, Isadore. **The eye in diabetes.** Am. J. Digest. Dis. 14:258-260, Aug., 1947.

The author discusses the views of many ophthalmologists on the hemorrhagic and exudative changes in the retina of the diabetic. Cataract is more prevalent in the diabetic patient but a true diabetic cataract exists only in the juvenile type and is manifested by subcapsular opacification. Capillary fragility has been seen to become worse after the administration of vitamin P, and hemorrhages continue despite the use of rutin. The author encourages a more thorough study of the conjunctival vessels since he found phlebosclerosis in an aqueous vein of a patient with retinal phlebosclerosis. The diabetes had existed for 17 years. Not infrequently the vessels of the plica are dilated when the remainder of the conjunctiva is normal.

A new classification for hemorrhages and one for exudates is suggested, also a record chart for diabetics. The author feels that newer instruments and newer interpretations of physiopathology in diabetes should help to harmonize the findings with the more modern concepts of the disease. F. M. Crage.

Grammatico, A. D. **Concerning a case of neurocirculatory asthenia of the eye.** Arch. de oft. de Buenos Aires 21:97, April-June, 1946.

Many cases of asthenopia, not improved by the correction of refractive errors or the removal of the foci of infection, are due to neurocirculatory asthenia of the eye, characterized by an altered arteriovenous relation, contraction of the visual field, low intraocular pressure, bradicoria, intolerance to parasympathomimetic drugs and somatic and hemotologic changes. A definite improvement is obtained by the instillation of L-alphaphenyl-betamethyl-aminopropanol sulphate in 5-percent solution, a diet rich in acid ash and thyroid therapy. The treatment is controlled by frequent examination of the visual fields, which show marked improvement. The intraocular pressure remains unchanged. (Bibliography.)

Hallum, A. V. **Changes in retinal arterioles associated with the hypertensions of pregnancy.** Arch. Ophth. 37:472-490, April, 1947. (See Section 11.)

Holden, F. A. **Migraine as seen by the ophthalmologist.** South. Med. J. 40:757-760, Sept., 1947.

Although the cause of migraine is unknown, the author favors an allergic (food) basis. In a series of over 50 patients who had ophthalmologic symptoms,

all had a protein sensitivity especially to meat and milk. When these were removed from the diet and green vegetables were substituted the patients improved. The main characteristic is periodic paroxysmal headache, preceded by visual disturbance. The headache is usually intense and relieved by sleep. The ophthalmic type can cause permanent eye defects, particularly scotomas. In treatment, all infections are eradicated. All the author's patients showed intoxication from the gastro-intestinal tract, and were constipated. Nicotinic acid and dihydro-ergotamine also have been recommended. (References.) Bennett W. Muir.

Leroy, J. **Ocular reactions during shock treatments in neuro-psychiatry especially electro-shock.** Ann. d'ocul. 180:342-359, June, 1947.

Five stages in the development of shock are recognized: (1) electro-spasm for several seconds; (2) a pre-convulsive phase of 10 seconds; (3) a convulsive phase of one minute; (4) a stertorous phase; (5) and a revival phase. The lid reactions include an intense contracture of the orbicularis, exophthalmos, relaxation, and lastly, lid closure without contraction. In more than 50 percent of the cases observed during the crisis, conjugate deviations of all types were observed, the corneal reflex was abolished and lacrimation increased. The pupillary diameter varied from 2 to 7 mm. and slight mydriasis existed in approximately 70 percent of the patients. Ocular tension was increased above 35 mm. Hg in 14 percent. The intravascular pressure of the retinal arteries was frequently increased temporarily by the treatment, as was the cerebrospinal pressure. Somewhat similar results were obtained with insulin and with cardiazol. Excitation of the neurovegetative centers in the hypothalamus is considered the basic process. (37 references.) Chas. A. Bahn.

Lorofi, H. **Treatment by intravenous novocaine of visual disturbances caused by tryparsamide.** Presse Méd. p. 435, (June 28) 1947.

Eleven observations are reported in which visual accidents that occurred in the course of tryparsamide therapy were treated with injections of novocaine. There were two failures, seven successes, and two improvements. In the seven cases in which the amaurosis was complete the treatment was successful in three and there was improvement in two. The injection of from six to ten cc. of 1-percent novocaine solution was reported from five to fifteen times. The first four or five injections were given daily and the remainder spaced irregularly according to the response of the patient. Positive results, when obtained, were almost immediately apparent.

Phillips Thygeson.

Pittman, H. W., Holt, L. B., and Harrell, G. T. **Effect of irradiation, immunity and other factors on vaccinial infection; a review illustrated by the report of a secondary ocular infection treated with roentgen rays.** Arch. Inter. Med. 80:61-67, July, 1947.

A case of vaccinial infection of the lid appeared five days after vaccination against smallpox. Roentgen treatment (220r) given in four days along with other treatment helped complete recovery.

Experiments on rabbits with primary and secondary vaccinial infection showed that Roentgen therapy diminished the residual corneal opacities, hastened regression of the acute lesions, and diminished the rate of spread of the virus through tissue. The partial immunity that develops as a result of the skin vaccination helps diminish the severity of the secondary lid and corneal infection. The use of immune serum and other methods of therapy are discussed. It is believed that the former inactivates the virus,

alters its virulence, increases the resistance of the host cell, or inhibits the spread of virus through tissue.

H. C. Weinberg.

Potter, L. C. **Industrial eye surgery and treatment; mechanical approach.** Indust. Med. 16:350-352, July, 1947.

A well organized safety department to instruct "lead men" in industrial and emergency work is paramount. The most improved fine mesh goggles with proper filter lenses are necessary. Close coöperation and coördination with the medical services and safety department to minimize injuries and accidents, and immediate treatments of the emergencies, pay big dividends in service to the employer and employee alike.

A total of 10,901 eye cases, treated according to these principles in one year was recorded by the safety department. A score of 99 percent success with no eventual loss of sight, annoying scar tissue, or chronic diseases, gives a measure of the value of the combined services. One point stands out clearer than others, namely: prompt and immediate attention to patients with accidents of the eyes and a careful and complete medical and surgical service, are a necessity.

Theodore M. Shapira.

Schnitker, M. T., and Schnitker M. A. **A clinical test for migraine.** J.A.M.A. 135:89, Sept. 13, 1947.

The authors have developed a technic for the differentiation of two types of headaches which are very similar clinically. It has been found specific in the precipitation of a migraine attack in those who are subject to that disorder. Migraine must be differentiated from the histamin cephalalgia which follows an injection of histamin base. In migraine the pain seems to arise from stretching the cranial arteries, especially the external carotid and its branches. Histamin cephalalgia and those headaches associated with fever are due to the dilatation of the cerebral branches of the internal carotid, especially the vertebral and basilar.

Actual migraine must not be present when the test is begun, and a careful neurologic examination must first exclude intracranial lesions. After the blood pressure and pulse rate in the reclining patient have been recorded, the patient is given two 1/100-grain nitroglycerin tablets. Two to four minutes later the pulse rate will rise, but the blood pressure will drop below the resting level, and the patient will note the first migraine symptoms. The patient is then asked to compare the sensation produced by the tablets with his usual complaint. When migraine is habitually localized in one area, that area will be the first to manifest the typical pain following the nitroglycerin. A more generalized headache will follow in a few minutes.

Relief can usually be given by firm compression of the homolateral carotid artery for one to two minutes, breathing oxygen for five minutes, or injecting a solution of 0.5 to 1 mg. ergotamine tartrate intravenously. Usually the pain disappears spontaneously.

If typical migraine is not produced by the nitroglycerin, the patient rests fifteen minutes, and is then given the subcutaneous histamin test. If this produces his usual symptoms, a diagnosis of histamin cephalalgia is made. He is then given two or three minims of 1:300,000 epinephrin intravenously, and later the usual histamin desensitization procedure is carried out.

This test for migraine has been found uniformly satisfactory in over 250 cases.

A. G. Wilde.

Wagener, H. P. **Progress of medical science: Ophthalmology: ocular lesions in brucellosis.** Am. J. M. Sc. 214:215-219, Aug., 1947.

Most cases of brucellosis reported occur in the acute stage of the disease. It may occur in the form of choked disc, optic neuritis, extraocular muscle paralysis, uveitis, retinitis, keratoiritis, and keratoconjunctivitis. History of recurrence in the chronic forms is important. A positive skin test and an agglutination in a dilution over 1:80 is important.

Irwin E. Gaynon.

Wilhelm, G. **The participation of the eye in typhus.** Klin. Monatsbl. f. Augenh. 112:48-60, May, 1947.

The basic pathological-histological finding in typhus is connected with a vascular cell infiltration in the skin and the organs, particularily the central nervous system. The author discusses the various theories and descriptions, as found in the literature. He then presents the eye findings consisting of a conjunctivitis due to a roseola of the palpebral and bulbar conjunctiva, of a uveitis and of a papillitis. Slides are presented illustrating the histologic findings of these conditions. The optic nerve shows a diffuse increase in cells in the endoneural septi and the optic nerve sheaths. Infiltrates are found in the choroid, especially in the form of nodules of the vesel wall in the layer of the larger arteries. Nodules may also be found in the iris. Sometimes (in one third of the author's material) these nodules can be seen with the ophthalmoscope as grayish white infiltrates close to the papilla near an artery. The retina shows secondary changes through edema or circumscribed detachment, but can also be involved by primary nodules in the wall of the retinal arteries. These retinal infiltrates near an artery are also ophthalmoscopically visible. Due to venous stasis from the papillitis or from venous thrombosis small hemorrhages may occur in the nerve fiber layer of the retina. (16 photographs.)

Max Hirschfelder.

Young, R. H., and McEwen, E. G. **Bacillary dysentery as the cause of Reiter's syndrome.** J.A.M.A. 134:1456-1459, Aug. 23, 1947.

Since 1916 the triad of symptoms that consists of arthritis, conjunctivitis and urethritis has been known as Reiter's disease. The study of 176 cases of bacillary dysentery observed in Algeria revealed 14 cases of post-dysenteric arthritis. In several of them there was also conjunctivitis and urethritis and these cases fulfil the clinical requirement both of Reiter and of Fiessuege and Leroy who independently described this syndrome. In four of the six cases in which the blood was tested significantly positive agglutination titers for Shigella organisms were obtained. The authors believe that Reiter's disease is a particular combination of three of the recognized complications of bacillary dysentery.

A. G. Wilde.

CONGENITAL DEFORMITIES, HEREDITY

Beauvieux, M. **Apparent blindness in the newborn. Gray pseudo-atrophy of the optic nerve.** Arch. d'opht. 7:241-249, 1947.

The author reports a syndrome of apparent blindness in the prematurely newborn characterized by incoordination, absence of photomotor reflex, dilated pupils, nystagmoid movements, and depigmented fundi with mottled gray nerve heads. Although the child appears blind he later is found to have vision commensurate with his refractive error. The clinical symptoms may be of short duration and return to normal may occur within a few months.

Beauvieux considers that there are two varieties of this syndrome. In the first the return of vision is rapid (from four to six months) and is complete. In the second the clinical evolution is less satisfactory and there are numerous sequelae

such as pigmentary changes in the retina, posterior polar cataract, strabismus, nystagmus, high myopia, Little's disease, and various cerebral changes. A certain return of visual acuity is always obtained, however. As to cause, Beauvieux considers that prematurity and abnormal gestation, leading to retarded myelinization of the optic nerve and cortical fibers, are important factors.

In a follow-up study of seven cases over periods of ten years or longer, three patients were found to have normal vision and four to have reduced vision varying from 3/10 to 5/10.

Phillips Thygeson.

Cavalcanti, L. R. **Ocular changes in heredo-degenerative diseases of the nervous system.** Rev. brasil. de oftal. 6:5-14, Sept., 1947.

This is a rather broadly generalized consideration of various diseases of the nervous system which may be represented in the eyes, with numerous brief references to the literature, but without any very precise classification or description.

W. H. Crisp.

Crespí, G. **Coloboma of the cornea.** Arch. Soc. oft. hisp.-amer. 7:577-586, June, 1947.

A man, 26 years old, with a negative family history had bilateral, symmetrical coloboma of the cornea and iris in the lower nasal segment. It appeared as though a cone of sclera invaded the cornea for 3 to 4 mm. The pupil was oval with its axis down and in. A portion of the pectinate ligament appeared to have entered the anterior chamber in this region. The pathogenesis of these disturbances is reviewed, with special reference to a differential diagnosis of malformations originating from interference in the development of the fissure of the optic cup, and those stemming from disturbances in the facial fissure. The author attributes the malformation in his case to a developmental disturbance at the end of the cleft in the optic cup, and it is pointed out that disturbances of either fissure may cause malformations in the anterior ocular segment. (7 illustrations.) Ray K. Daily.

Sala, Guido. **The so called "Hypertelorism" of Greig.** Riv. oto-neuro-oftal. 22:32-50, Jan.-Feb., 1947.

The writer reports two cases of Greig's hypertelorism characterized by an abnormal distance between the two eyes. This condition is frequently associated with other cranial malformations but in the Greig syndrome it is only a manifestation of an anomaly in the development of the sphenoid bone which consists in a disproportion in the growth of the great and small wings of the bone. The writer discusses briefly the probable factors in the development of the anomaly and suggests that the name be changed from hypertelorism to telophthalmus because the latter describes the clinical picture more accurately. (Bibliography.)

Melchiore Lombardo.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Apin, K. **The practice of trachoma control in Latvia.** Klin. Monatsbl. f. Augenh. 112:60-62, May, 1947.

This report summarizes statistically the effect of a recent Latvian edict forcing trachoma patients to undergo treatment. Admissions of trachoma patients to eye clinics increased over 100 percent. The early stages showed a more rapid healing and less reduction in visual acuity. The patients who lived close to oculists benefited in a much higher percentage. Close cooperation between oculists and public health doctors revealed the necessity of intensive special treatment like grattage in 18 percent, surgery in 9 percent and hospital admission for a serious stage in 5

percent of the patients during field surveys. Ten percent of all trachoma patients sooner or later had a pathologic condition of the lacrimal duct, but in only five percent of the patients this was present at the first examination. Max Hirschfelder.

Hallermann, W. **The geographic distribution of ocular tuberculosis.** Klin. Monatsbl. f. Augenh. 112:13-20, May, 1947.

In the Sanatorium Hoechenschwand 3,300 patients with clinically certain ocular tuberculosis were surveyed to determine if certain regions in Germany show a prevalence of ocular tuberculosis. It was found that the number of patients from various districts paralleled the general density of the population. Laborers and civil service workers predominated but this finding is not significant because the medical insurance plan embraces these occupations and does not cover the rural population to an equal extent. A prevalence of ocular tuberculosis in certain regions was not established.

Max Hirschfelder.

Hessberg, R. J. **Review of contributions and experiences of World War II to ophthalmology. 1. Injuries of the eyes and head.** Ophth. ibero amer. 8:1-44 and 2:119-175, 1946. (English and Portuguese).

This lengthy review is based on ophthalmic literature from 1939 to 1945 so far as available at the time of writing. The author reminds us that most observations were made in forward lines and in rear hospitals where the casualties could only remain for a limited time, so that the physician was rarely or never able to follow the development of the cases to the end or until complete clinical healing took place. The scope of the review may be gathered from the following section headings: statistics and first treatment, protection and prevention, special reports, perforating wounds, foreign bodies, the skeleton-free X ray, magnet tests, methods of localization, double perforation, magnets, methods of extraction and their results, contact lenses, enucleation and evisceration, stump formation, contracted socket, sympathetic ophthalmia, injuries by blasting, concussion and contusion, retinal angiopathy, orbit and sinus, pulsating exophthalmos, maxillo-facial injuries, head injuries, psychic disturbances, burns, and plastic surgery.

Most perforating injuries were due to explosions. It is generally concluded that all eye injuries should be sent to special eye departments as soon as possible, only cleaning and dressing being done at the first-aid station. Direct suture of corneal wounds is preferable. Widely gaping perforations need conjunctival flaps. Early enucleation of blind eyes is preferable to evisceration except in the presence of true panophthalmitis. The main objective in burns of the face, lids, and eyes is to prevent or limit infection as completely as possible, and grafting of the burned area is advisable at the earliest opportunity. Plastic surgery should be limited to ophthalmologists having special training for this work. (7-page bibliography.) W. H. Crisp.

Moron-Salas, José. **What can be expected from "radar" for the blind?** Arch. Soc. oft. hisp.-amer. 7:703-709, July, 1947.

With the hope that blind people can be taught how to recognize surrounding objects even to read text books the author briefly describes his experimental work with radar. He utilizes the photoelectric cell as a fundamental base of an apparatus, which would give sounds of different characteristics according to the shape of the objects placed before it.

J. Wesley McKinney.

De Roetth, Andrew. **Blackboard cornea for teaching.** Am. J. Ophth. 30:1299, Oct., 1947. (2 figures.)

Schepens, C. L. **Reflections on a stay in the U. S.** Ann. d'ocul. 180:292-307, May, 1947.

The author was a guest speaker at the 1946 Academy meeting. He spoke on several occasions and presented a binocular ophthalmoscope which has been reviewed in this journal. After a brief description of the Academy meeting, Dr. Schepens described in some detail the medical and surgical advances which he observed there and while on a tour of several American ophthalmological centers. These observations included the types of vertical muscle advancements and resections, tendon transplantations of paralytic muscles, the techniques of enucleation and evisceration as well as the different substances used as implants. The author preferred the implant technique of Cutler to that of Ruedeman. Among the newer drugs described are tyrothrycin, streptomycin, streptothrycin, and the anti-glaucomatous drugs, doryl and D.F.P. The author discusses in some detail the organization of the ophthalmological department of the Mayo Clinic, and the procedures of superficial keratectomy, the radio-therapeutic treatment of vascular corneal opacities before transplantation, and round and square corneal grafts which he observed in New York.

Chas. A. Bahn.

Velter, Edmond. **Ophthalmology in France from 1939 to 1945.** Arch. de oftal. de Buenos Aires. 21:63, April-June, 1946.

The author reviews French ophthalmology throughout the war years, emphasizing the considerable difficulties and hardships created by the dispersal of personnel and scarcity of instruments, chemicals and animals for experimental work. The restrictions on gas and electricity rendered impossible the use of apparatus and equipment. The resourcefulness, spirit of sacrifice and devotion to science of the French ophthalmologists made it possible for them to carry on to a remarkable degree clinical and experimental work under the adverse circumstances of this period. The author lists the most important papers and communications made during war years.

Plinio Montalván.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Milton Julius Ballin, New York, New York, died September 12, 1947, aged 73 years.

Dr. Oscar Dodd, Evanston, Illinois, died October 15, 1947, aged 83 years.

Dr. Frank B. Kistner, Portland, Oregon, died September 25, 1947, aged 73 years.

Dr. Lawrence Cornelius Meredith, Elyria, Ohio, died September 29, 1947, aged 55 years.

Dr. Clarence Henry Smith, New York, New York, died October 6, 1947, aged 72 years.

ANNOUNCEMENTS

UNITED KINGDOM TRANSACTIONS AVAILABLE

The Ophthalmological Society of the United Kingdom holds a considerable stock of certain volumes of the *Transactions* since their first publication. The following years, however, are not available:

1897; 1898; 1899; 1900; 1901; 1902; 1905; 1906; 1907; 1908; 1909; 1911; 1917; 1918; 1919; 1920; 1921; 1922; 1923; 1924; 1926; 1927; 1928; 1929; 1930; 1931; 1932; 1933; 1934; 1935; 1937 (Part I).

The council feels that many libraries, both at home and abroad, may wish to complete their sets and will be glad to present to libraries, medical schools, and hospitals such available volumes as they may desire. No charge will be made other than the cost of postage.

Those interested are asked to communicate with the Bowman Librarian, The Royal Society of Medicine, 1, Wimpole Street, London, W.1.

PRIZE FOR RESEARCH WORK

An honorarium of $1,000 to promote research work in ophthalmology is offered through the American members of the staff of the International Association for the Prevention of Blindness. The jury will consist of the executive committee together with the president and the officers of the association.

The award will be made in connection with the XVIth Concilium Ophthalmologicum. Papers may be presented by any responsible research worker. The subject is to be "Simple Noninflammatory Glaucoma" and may include anything definitely related to the question. The matter must be new and of such value, in the judgement of the jury, as to merit this recognition. Papers may be written in English or French; they should be heretofore unpublished or published between this date and October 15, 1949. They should be in the hands of the secretary of the International Association for the Prevention of Blindness, 66 Boulevard St. Michel, Paris, through whom they will reach the members of the judicial committee, not later than October 15, 1949. The decision of the jury will be final.

PRELIMINARY ANNOUNCEMENT OF COURSE

The University of California is announcing a series of postgraduate courses for qualified physicians to be given during 1948. The course in ophthalmology will be given September 6th to 10th. Requests for completed programs and details should be addressed to Dr. Stacy R. Mettier, head of postgraduate instruction, Medical Extension, University of California Medical Center, San Francisco 22.

GILL HOSPITAL SPRING COURSE

From April 5th to 10th, the Gill Memorial Hospital, Roanoke, Virginia, will hold its 21st annual spring graduate course. Among the guests-of-honor who will appear on the program are: Rear Admiral Clifford A. Swanson, surgeon general of the United States Navy; Dr. H. J. Moersch, professor of medicine, Mayo Clinic; Dr. Bayard T. Horton, Mayo Clinic; Prof. Adalbert Fuchs, formerly of Vienna; and Dr. Conrad Berens, New York.

The first three days, Monday, Tuesday, and Wednesday, will be devoted primarily to instruction in otolaryngology. There will, however, be two clinics of interest to ophthalmologists. The first, at 10:45 on Tuesday morning, will be conducted by Dr. Conrad Berens on the subject, "The Relationship of Uveitis to Chronic Sinus Infection"; and the second, conducted by Dr. Bayard T. Horton, will be held at 2:30 Tuesday afternoon on the subject, "Diseases of the Eye, Including Retrobulbar Neuritis: Treatment with Histamine."

On Thursday, Friday, and Saturday, intensive instruction in ophthalmology will be offered. The complete program follows.

Thursday, April 8th

8:00 to 9:00 a.m. Clinic conducted by Dr. John M. McLean, professor of ophthalmology, Cornell University Medical School, New York.
Subject: "Intracapsular Cataract Surgery."

9:00 to 10:00 a.m. Clinic conducted by Dr. A. D. Ruedemann, professor of ophthalmology, Wayne University Medical School, Detroit, Michigan.
Subject: "Enucleation and Substitutes for the Removed Eye."

10:00 to 11:00 a.m. Clinic conducted by Dr. Edwin B. Dunphy, chief of ophthalmology, Massa-

chusetts Eye and Ear Infirmary, Boston, Massachusetts.
Subject: "An Evaluation of Miotics."

11:00 to 12:00 a.m. Clinic conducted by Dr. Trygve Gundersen, assistant professor of ophthalmology, Harvard Medical School, Boston, Massachusetts.
Subject: "Experiences with Ocular Complications of Herpes Zoster."

12:00 to 1:00 p.m. Clinic conducted by Professor Adalbert Fuchs, UNRRA-WHY, Nanking, Shanghai, China.
Subject: "Injuries of the Anterior Part of the Eye."

1:00 to 1:30 p.m. Luncheon at Hotel Patrick Henry.

1:30 to 2:30 p.m. Clinic conducted by Dr. John M. McLean.
Subject: "Detached Retina."

2:30 to 3:30 p.m. Clinic conducted by Dr. A. D. Ruedemann.
Subject: "The Place of Orthoptics in Ophthalmology and the Use of the Orthoptic Technician."

3:30 to 4:30 p.m. Clinic conducted by Dr. Edwin B. Dunphy.
Subject: "Evaluation of Chemotherapy in Ophthalmology."

4:30 to 5:30 p.m. Clinic conducted by Dr. Trygve Gundersen.
Subject: "The Diagnosis and Treatment of Common Diseases of the Cornea."

7:30 to 8:30 p.m. Clinic conducted by Professor Adalbert Fuchs.
Subject: "Endophthalmitis and Panophthalmitis."

Friday, April 9th

8:00 to 8:30 a.m. Surgical Clinic conducted by the Members of the Staff of the Hospital.

8:30 to 9:15 a.m. Clinic conducted by Dr. Donald J. Lyle, professor of ophthalmology, University of Cincinnati Medical School, Cincinnati, Ohio.
Subject: "The Effect of General Vascular Disorders upon the Brain and Eye."

9:15 to 10:00 a.m. Clinic conducted by Professor Adalbert Fuchs.
Subject: "Eye Operations."

10:00 to 11:00 a.m. Clinic conducted by Dr. A. D. Ruedemann.
Subject: "Early Diagnosis and Treatment of Cataract."

11:00 to 12:00 a.m. Clinic conducted by Dr. Alston Callahan, professor of ophthalmology, University of Alabama Medical School, Birmingham, Alabama.
Subject: "Repair of Ectropion."

12:00 to 1:00 p.m. Clinic conducted by Dr. Rudolph Aebli, professor of ophthalmology, New York Post Graduate Hospital and Medical School, New York.
Subject: "Anatomy and Physiology of the Extraocular Muscles. The Differential Diagnosis of the Heterophorias and Heterotropias."

1:00 to 1:30 p.m. Luncheon at Hotel Patrick Henry.

1:30 to 2:30 p.m. Presentation of Patients with Unusual Clinical Interest by the Staff of the Hospital.

2:30 to 3:15 p.m. Clinic conducted by Dr. Donald J. Lyle.
Subject: "The Effect of Increased Intracranial Pressure as it Concerns Ophthalmology."

3:15 to 4:00 p.m. Clinic conducted by Dr. A. D. Ruedemann.
Subject "The Use of the Beta Radiation Therapy in Ophthalmology."

4:00 to 4:45 p.m. Clinic conducted by Dr. Alston Callahan.
Subject: "Traumatic Blepharoptosis, and Reconstruction of Upper Lid."—Illustrated.

4:45 to 5:30 p.m. Clinic conducted by Professor Adalbert Fuchs.
Subject: "Glioma Retinae and Sarcoma Choroidea."

7:30 to 8:30 p.m. Clinic conducted by Dr. E. G. Gill, Roanoke, Virginia.
Subject: "Ophthalmic Surgery."

8:30 to 9:30 p.m. Clinic conducted by Dr. Rudolph Aebli.
Subject: "The Medical Management of the Phorias."

Saturday, April 10

8:00 to 9:00 a.m. Clinic conducted by Dr. Donald J. Lyle.
Subject: "Hereditary Eye Conditions."

9:00 to 10:00 a.m. Clinic conducted by Dr. Alston Callahan.
Subject: "Fascia Lata Repair of Retrotarsal Atrophy, and Removal of Orbital Tumor by Inferior Route."—Illustrated.

10:00 to 10:45 a.m. Clinic conducted by Professor Adalbert Fuchs.
Subject: "Diagnosis of Glaucoma."

10:45 to 11:15 a.m. Clinic conducted by Dr. Ralph O. Rychener, professor of ophthalmology, University of Tennessee, Memphis, Tennessee.
Subject: "Ocular Allergies."

11:15 to 12:00 a.m. Clinic conducted by Dr. Rudolph Aebli.
Subject: "Principles of Ocular Muscle Surgery."

12:00 to 1:00 p.m. Clinic conducted by Dr. Donald J. Lyle.
Subject: "The Autonomic Nervous System Relative to the Eye."

1:00 to 1:30 p.m. Luncheon at Hotel Patrick Henry.

1:30 to 2:30 p.m. Clinic conducted by Dr. Ralph O. Rychener.
Subject: "Treatment of Dacryocystitis."

2:30 to 3:30 p.m. Clinic conducted by Professor Adalbert Fuchs.
Subject: "Nonperforating Injuries of the Fundus."

3:30 to 4:30 p.m. Clinic conducted by Dr. Rudolph Aebli.
Subject: "Congenital Anomalies."

Miscellaneous

Holmes memorial lecture

Dr. E. V .L. Brown, Rush clinical professor

emeritus of ophthalmology, University of Illinois College of Medicine, delivered the first presentation under the gift of the Rudolph Wieser Holmes and Maria Baxter Holmes Fund in memorial to Edward Lorenzo Holmes at the Palmer House on Friday evening, January 30th, at a joint meeting of the Institute of Medicine of Chicago, the Chicago Ophthalmological Society, and the Society of Medical History of Chicago. His subject was, "Edward L. Holmes: Pioneer Chicago Eye Doctor."

Glaucoma clinic

Montefiore Hospital, New York, has established a glaucoma clinic in its ophthalmological service. Although cases in all stages of glaucoma that are eligible for clinic care will be accepted, the Hospital is especially interested in early cases.

Societies

Egyptian meeting

The annual meeting of the Ophthalmological Society of Egypt will be held at the Memorial Ophthalmic Laboratory, Giza, Egypt, on Friday and Saturday, March 12th and 13th.

AOS meeting announced

The 84th annual meeting of the American Ophthalmological Society will be held at the Homestead, Hot Springs, Virginia, on May 17th, 18th, and 19th. The members are requested to send the titles and brief abstracts of such papers as they desire to present at the meeting, to Dr. Frank B. Walsh, Johns Hopkins Hospital, Baltimore 5, Maryland, as soon as possible. All titles and abstracts must be forwarded to Dr. Walsh before April 1st to be incorporated in the call for the meeting to be sent out about April 15th.

Brooklyn Society program

On the program of the 102nd regular meeting of the Brooklyn Ophthalmological Society, December 18, 1947, were: Dr. Jesse M. Levitt, "Occlusion of the Cilioretinal Artery of the Left Eye"; Dr. Ludwig von Sallmann and Dr. W. C. Stone, "Clinical Experiences with Di-isopropyl Fluorophosphate in the Treatment of Glaucoma"; Dr. John M. McLean, "Soft Glaucoma."

Philadelphia officers

The Section on Ophthalmology, College of Physicians of Philadelphia, announces a change of officers. Dr. Perce DeLong, 37 South 20th Street, Philadelphia, is chairman; and Dr. M. Luther Kauffman, Medical Arts Building, Jenkintown, Pennsylvania, is clerk. Meetings are held the third Thursday of every month from October through April, at 8:15 p.m., in the College of Physicians Building.

Pennsylvania Academy meeting

The next regularly scheduled meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology will be held on April 23rd, 24th, and 25th, at the Hotel Penn-Harris, Harrisburg, Pennsylvania.

Utah society changes name

At a recent meeting of the Utah Ophthalmological Society, a new constitution was adopted. In this constitution, the name of the society was changed to the Inter-Mountain Oto-Ophthalmological Society. This was done to recognize the fact that the society was no longer comprised of local men, but included members from outside the state.

The officers of the new society are: Dr. James A. Cleary, 804 Boston Building, Salt Lake City, president; Dr. Earl H. Phillips, 224 Judge Building, Salt Lake City, vice-president; and Dr. Homer E. Smith, 1005 Medical Arts Building, Salt Lake City, secretary-treasurer.

Reading speaker

Dr. Frederick Willson addressed the 73rd meeting of the Reading Eye, Ear, Nose, and Throat Society. His subject was, "Visual Perception Other than Ocular."

Personals

Awarded Pan-American medal

Dr. Harry S. Gradle, for many years a leading ophthalmologist in Chicago, was awarded the first Pan-American Medal of the National Society for the Prevention of Blindness in the United States, at the recent meeting in Havana. The medal honors Dr. Gradle's contributions toward the prevention of blindness and his service to the establishment of friendly relations with Latin-American countries. Dr. Gradle, now retired, is living in California.

New associate

Dr. Samuel V. Abraham of Los Angeles and Beverly Hills, California, announces that Dr. Philip D. Shanedling is now associated with him in the practice of ophthalmology.

Opens offices

Dr. Barbara Spiro, formerly of the Billings Hospital and The University of Chicago Clinics, announces the opening of offices at the Medical and Dental Arts Building, 7449 Cottage Grove Avenue, Chicago 19.

Receives Snyder grant

Dr. K. W. Ascher, Cincinnati, has received a $2,000 grant from the Snyder Ophthalmologic Foundation to further his research on the aqueous veins.

EARLY DEVELOPMENT OF THE FILTRATION OPERATIONS FOR GLAUCOMA

WILLIAM H. CRISP, M.D.
Denver, Colorado

The problem of glaucoma is far from solved, and this disease is still the most frequent cause of incurable blindness among persons past middle age. But it can at least be said that the prospect of surgical relief from this disorder, or group of disorders, has vastly improved in the last half century.

It is now nine decades since Albrecht Graefe[1] first announced that he had found in surgical iridectomy a cure for many cases of glaucoma, especially acute glaucoma. He himself was prompt to admit that the operation was not always successful even in acute cases, and that its success, or at least its complete success, was rather the exception than the rule in the chronic type of the disease. Conjectures and observations arising out of this fact played a considerable part in the later invention of operations which have proved much more reliable for the chronic cases.

In earlier editions of de Schweinitz's *Diseases of the Eye,* that author[2] remarked that one of the complications following the operation of iridectomy in glaucoma was the formation, at the seat of the incision, of a bulging scar sometimes called a cystoid cicatrix; and that on the other hand, in severe cases, this very cystoid cicatrix, by permitting a filtering of the liquids, had sometimes been described as a favorable condition; but that to this view of a cystoid scar the author could not subscribe.

William Campbell Posey,[3] writing on glaucoma in the *American Encyclopedia of Ophthalmology,* regarded Graefe's discovery of iridectomy for glaucoma as "the greatest contribution which has been made to ophthalmic science." Yet, within relatively few years after Graefe's introduction of this operation, various authors proposed other surgical methods of treatment.

Thus de Wecker,[4] in 1867, put forward the operation which he termed anterior sclerotomy, by which it was hoped to establish at the angle of the anterior chamber a cicatrix through which the intraocular fluids might filter out of the eye. Four years later the same author announced a modification of his original operation, in order to avoid prolapse of the iris. This he sought to accomplish by carrying the cutting edge of the knife slowly through the limbal structures until only a 2-mm. bridge of undivided tissue remained.

Panas[5] made an incision with the Graefe knife below and to the outer side, and plunged the knife through the iris for 8 to 10 mm., cutting both iris and sclera in association with a 2- or 3-mm. wound of exit from the anterior chamber. De Wecker[6] later tried the effect of iridodialysis made by pulling the iris toward the pupil after a keratome incision at the limbus. In England, Bader,[7] more or less upon the basis of de Wecker's method, made the corneal puncture and counterpuncture as near as possible to the insertion of the iris, but tried to leave a large bridge of conjunctiva reaching across the scleral incision, dividing an extent of sclera

equal to nearly a third of the circumference of the cornea.

In Graefe's own brief though brilliant career (he died of tuberculosis at the age of 42 years), his use of iridectomy for acute glaucoma was rather vigorously condemned by eye surgeons of great eminence, men who are given high praise whenever the history of ophthalmology in the second half of the 19th century is under discussion. *The Medical Times and Gazette* of London, England, for many years an outstanding example of medical journalism of the 19th century, contained, in 1858, as many as eight original papers dealing with iridectomy. In the first of these, by Hulke[8] of King's College Hospital, reference is made to a fact which today sounds strange, namely that Graefe at first tried atropine in the treatment of acute glaucoma, for which locally the previous operative treatment had practically been limited to paracentesis of the anterior chamber. Although iridectomy was welcomed enthusiastically by Hulke,[8] Bowman,[9] and Critchett,[9] two other surgical writers, whose names are still familiar to many of us, questioned both Graefe's ability as an ophthalmologist and the efficacy of the operation for glaucoma. These were T. Wharton Jones, professor of ophthalmic medicine and surgery in University College, London, and William Mackenzie, surgeon-oculist to Queen Victoria and lecturer on the eye in the University of Glasgow. Jones and Mackenzie[10] condemned Graefe's practice of iridectomy as "opposed to the plainest principles of surgery and common sense," and they had no doubt that in a short time iridectomy as a means of treating glaucoma would be abandoned in favor of "the practice . . . of more frequently puncturing the cornea and sclerotica in this disease."

In the same medical journal Graefe[11] took up the cudgels in his own defense, remarking that he had doubted "whether the article merited an answer or not, for the esteemed authors confess that they are without any personal experience on the questionable point," but he undertook a reply "as a tribute . . . to their earlier merits." He pointed out that the inadequacy of paracentesis had been clearly demonstrated for years in his own large practice. In conclusion he says "I willingly pardon older, and so highly deserving men, for their want of that elasticity requisite for the immediate reception of new views; . . . but I should indeed have expected more moderation from the Nestor of English ophthalmology."

A fact which seems worth mentioning here, although perhaps of picturesque rather than practical significance, is that in 1874 that famous Scot, D. Argyll Robertson,[12] published a paper under the title "Trephining the sclerotic—a new operation for glaucoma." Argyll Robertson thought that the increase of tension was due in some cases to increased secretion of vitreous humor, in others to serous transudation into the chamber of the vitreous humor. He expressed the opinion that all measures undertaken for the cure of the disease should have for their object the reduction of the intraocular pressure. He had therefore undertaken to drill a circular aperture through the sclerotic at or about the junction of the ciliary processes with the choroid, "so as to avoid as far as possible the more anterior parts of the ciliary processes." The instrument used was the "corneal trephine devised by Mr. Bowman for operating on cases of conical cornea," or subsequently a modification of this instrument which Argyll Robertson himself devised. The operation had been used on only four eyes, in very advanced glaucomatous condition. The results were inconclusive.

The most striking period of development in the surgery of chronic glaucoma appears to have been the first decade of the present century, although of course much preliminary investigation went on before the resulting publications appeared in the literature.

Herbert's subconjunctival fistula

As early as 1903, writing under the title of "Subconjunctival fistula formation in the

treatment of primary chronic glaucoma," Herbert[13] remarked that in a large proportion of the eyes operated upon in his work in India, typical iridectomy failed to relieve tension or even destroyed sight through various complications. In his own work, as well as that of other operators, success was much more generally obtained when the iris had by chance healed in the wound. He had also observed that proplapse of the iris following cataract extraction, when not covered by conjunctiva, was often associated with iritis from the beginning, whereas a similar prolapse, mainly or entirely covered by a conjunctival flap, did not exhibit this tendency, and he added that the evil repute of cystoid cicatrices in rendering eyes permanently liable to infection had been earned mainly, at any rate in the cases following cataract extraction, by prolapses and incarcerations which were left partly or completely uncovered by conjunctiva. It was this line of observation and reasoning which had caused him to leave prolapsed iris—in nearly all cases purposely—in 130 operations for primary glaucoma. The relief of tension provided by a fistulous cicatrix appeared, he said, to be certain and permanent. Herbert concluded that the perspective in our views upon the operative treatment of chronic glaucoma needed correction, and that too much had been made of the fear of late infection, and too little of the fact that fistulous scars provided the only certain means of permanently relieving some cases of glaucoma.

Holth's iridencleisis

A model of clear thinking and patient observation is contained in the communication read by Holth[14] before the Medical Society of Christiania (now Oslo), on September 26, 1906, and which was also presented in condensed form in the same year to the French Ophthalmological Society and to the meeting of the German Ophthalmological Society in Heidelberg, and was published in full (in French translation) in *Annales d'Oculistique,* May, 1907. It is proper to regard this paper as one of the classics of ophthalmic literature, by virtue of its logical study of scientific facts and the clarity of its argument.

Except as to iridectomy, proposed by Graefe for the relief of glaucoma 50 years earlier, previous operations for glaucoma had aimed to establish a new channel of drainage of aqueous humor by excision of sclera beneath a conjunctival flap. Holth's operation, generally speaking, excised no tissue; and it depended for success upon the formation of a new drainage channel associated with incarceration of the pigmented iris between the lips of the scleral wound.

It is necessary to keep in mind how important a step in the study of the glaucoma problem, for now nearly a half century, has been the successful tonometer of Schiötz, another Christiania leader. Holth tested with the tonometer a series of glaucomatous eyes which had been subjected to iridectomy. Except within the first few weeks after the operation, he found the intraocular pressure generally above normal. Strangely enough, and in spite of the dread of iris prolapse as a dangerous complication following any intraocular operation, Holth discovered that the iridectomized eyes which had been relieved of their hypertension were usually eyes in which the technique of the operation had in the first instance been regarded as defective, because iris tissue had been left in the scleral wound.

Holth therefore made an intentional experiment upon the two equally hypertensive eyes of a single patient, doing an ordinary iridectomy upon the blind eye, and upon the other eye an iridectomy with incarceration of the iris beneath the conjunctival flap. The tension had previously been 54 mm. in each eye. In the former eye the tension fell to 43 mm., and in the latter to 24 mm. Holth further compared other cases in which iridectomy had been complicated by accidental incarceration of the iris with those cases in which the iridectomy had been classically

performed, and this further study supported his conclusion that the subconjunctival incarceration was beneficial instead of harmful. In a number of cases, therefore, Holth proceeded to perform iridectomy with intentional incarceration, and the paper which he read before the Christiania Society in 1906 reported a goodly series of excellent results from such procedure.

It is only natural that the technique of iridencleisis has undergone modifications at the hands of various surgeons. Holth himself preferred a keratome incision, picking up an 8- or 10-mm. conjunctival flap, pushing the keratome along the sclera to within a millimeter of the limbus, and then drawing the iris sphincter into the scleral wound and making a meridional cut to one side of the forceps. Other surgeons have made the incision with the Graefe knife, although Holth himself had tried this method and did not favor it. Other operators have dissected a conjunctival flap from the limbus peripherally, making use, that is, of a Van Lint flap. Some have performed the usual type of iridectomy, but have left iris tissue in each angle of the scleral wound. Others, for example Greenwood,[15] have combined iris incarceration with excision of sclera as recommended by Lagrange.

Borthen,[16] also a Norwegian (practicing at Bergen), after performing a number of operations more or less according to the technique of Holth, raised the question whether it was necessary to cut the iris sphincter. He therefore proceeded to modify Holth's technique by merely seizing the iris sphincter and drawing it out under the conjunctival flap, but without cutting it; and he had excellent results with this modification.

From many sides the proposal to leave iris tissue outside the eyeball was criticized as in conflict with sound surgical principle. From a large mass of statistical material, however, it seems probable that iris tissue remaining between the sclera and a thick conjunctival flap does not endanger the eye. Where the operation is performed according to this principle, postoperative reaction is almost nonexistent in the vast majority of cases. However, an excellent example of this not unnatural prejudice against iridencleisis is the fact that throughout several editions Meller's well-known *Ophthalmic Surgery* refrained from even mentioning Holth's operation.

Herbert's "wedge isolation" and Lagrange's "sclero-iridectomy"

Also in the first decade of this century, Herbert[17] continued and Lagrange[18] began to urge the desirability of creating a filtration scar, and both aimed to accomplish this by excision of a strip of sclera. Herbert and Lagrange both associated the scleral excision with iridectomy. Herbert's procedure was entitled the "wedge-isolation" operation, while Lagrange used the name "sclero-iridectomy." The Lagrange operation was described by the author as consisting of three steps: (1) Puncture and counterpuncture one millimeter from the limbus, the knife emerging at the iridocorneal angle; turning the cutting edge of the knife backward during emergence from the sclera, so as to cut the sclera obliquely in the shape of the mouthpiece of a flute; and continuing the knife beneath the conjunctiva so as to cut a large conjunctival flap, such as had been made by Graefe in his linear extraction. (2) Lifting the conjunctival flap with fine mouse-tooth forceps and with sharp scissors resecting a fairly large fragment of the anterior lip of the scleral incision, without damage to the conjunctival flap. (3) Iridectomy in the usual manner and replacement of the conjunctival flap.

While it was the general tendency to decry incarceration of the iris in the lips of the wound, as occurred in the procedure which was frankly recommended and advantageously employed by Holth, it is probable that more or less incarceration of the iris occurred in many of the successful results obtained by various methods.

In 1909, writing from the Clinic of Ernst Fuchs in Vienna, Meller[19] was able to discuss the interpretation of 27 cases with regard to the effectivenes of Lagrange's operation. His 51-page review led him to the conclusions that the action of sclerectomy differed from that of iridectomy, and that sclerectomy created a safety valve which protected against an excess of intraocular fluid, but that it was undecided whether the question of the pathology of glaucoma coincided with the question of a filtering scar; and finally that there was distinct evidence that the most dangerous symptom of glaucoma, namely hypertension, could be relieved by this operation without danger for the eye and that the operation should therefore be included among the surgical armamentarium of the ophthalmologist, for use in appropriate cases.

Another essay by Meller,[20] based upon microscopic study of 11 eyes enucleated for various reasons after the Lagrange operation, reported that in cases in which the uveal tissue had remained in its normal position, and had not become caught in the wound, the process of repair of the scleral wound proceeded with great rapidity, and led to the formation of dense and entirely impermeable tissue; but that when the iris prolapsed between the lips of the scleral incision the sclera did not share in the process of repair, which was undertaken in part by the subconjunctival tissue.

Heine's cyclodialysis

The proposal made by Heine[21] for treatment of chronic glaucoma by means of the operation to which he at once attached, and which has continued to be known by, the name of "cyclodialysis," approached the problem from a point of view which had little or nothing to do with Graefe's operation of iridectomy. In his short but well-reasoned contribution, the author, then Privat-Dozent and First Assistant at Uhthoff's Clinic in Breslau, recalled Graefe's early misconception of glaucoma as depending entirely upon hypersecretion of fluid within the eye, and de Wecker's later replacement of this idea with the conception that glaucoma was due not to hypersecretion but to inadequacy of drainage. (This change of outlook had an important bearing upon subsequent discussion as to the general topic of secretion and drainage of the aqueous.) In 1876, Knies and Weber (quoted by Heine) had demonstrated displacement of the chamber angle in many cases of glaucoma, and the idea of liberating the angle assumed dominance. Related to this physiologic concept is the supposed favorable influence of near work upon the glaucomatous eye. In 1900 Fuchs (quoted by Heine) had shown for the first time the frequency with which detachment of the choroid occurred after ordinary cataract extraction, and Axenfeld (quoted by Heine) proceeded to call attention to the same phenomenon occurring after sclerectomy or incision at the chamber angle as well as after iridectomy. The latter author raised the question whether such choroidal detachment had anything to do with the curative effect of iridectomy in glaucoma. Fuchs's interpretation of the process by which choroidal detachment occurred in such cases was that under the influence of traction on the eyeball during passage of the keratome or knife through the ocular tissues the pectinate ligament became torn, so that the aqueous humor was able to flow through the tear into the suprachoroidal space. Demaria (quoted by Heine) gave histologic demonstration of such a tear having occurred after iridectomy for glaucoma.

Heine was therefore induced to try experimentally whether communication established artificially between the anterior chamber and the suprachoroidal space had a definitely decompressive influence. This he did in blind human eyes, after studying the operation on the pig's eye. Heine's original operation consisted of making a small subconjunctival incision through the sclera 4 or 5 mm. from the limbus, and then carrying a lens repositor or similar instrument

beneath and close to the sclera, through the pectinate ligament, and into the anterior chamber, and sweeping this instrument 2 or 3 mm. upward and downward so as to separate the ciliary body from the sclera. In his first description Heine spoke of allowing little or no aqueous humor to flow out through the scleral wound, and he indicated that immediately after the operation the tension was unaltered, and that only two or three days later did reduction of tension occur. At the time of publishing the original article, Heine had performed the operation only on blind or almost blind eyes.

Meller[22] wrote from the Fuchs Clinic with regard to the benefit to be derived from cyclodialysis, which had been employed in 42 cases. He declared that, while cyclodialysis could be successfully employed to reduce the tension in primary glaucoma, the operation was not to be regarded as of nearly equal value with iridectomy, since cyclodialysis was in many cases followed by relapse.

Papers evaluating and criticizing the various operations have naturally been extremely numerous, and few of them can be mentioned here. With regard to cyclodialysis, much valuable discussion was contributed by Elschnig, whose mature judgment with regard to cyclodialysis, after ample experience, was expressed in 1909[23] with an analysis of 20 cases in which the operation had been performed. Admitting that the essential factor in the working of this operation was not clearly understood, he declared that this consideration did not increase or decrease the value of cyclodialysis. He reminded his readers that the iridectomy operation had been performed for glaucoma without any satisfactory explanation of its effect having been established. He regarded cyclodialysis as superior to iridectomy in the treatment of compensated glaucoma, and as especially valuable in its freedom from harmful effect upon the eye.

Many surgeons have attributed to cyclodialysis the distinct advantage that it may be performed in an eye in which iridectomy or one of the filtration methods has already been used unsuccessfully. The same is to some extent true of the filtration operations as regards a previously performed and unsuccessful, or only partially successful, iridectomy. The present writer has several times done an iridencleisis operation, although using incarceration without incision of the iris, in an eye which had had a classical iridectomy long previously. One edge of the iris coloboma was picked up and incarcerated in a small scleral incision. The results were excellent. It must be admitted, however, that these were cases in which the original iridectomy had been performed apparently without a conjunctival flap, so that there was no disturbing amount of subconjunctival scar tissue.

Like other modern glaucoma operations, cyclodialysis has had its critics as well as its enthusiastic advocates. The chief objection to it, by many writers, has been that its action was not sufficiently lasting. Many surgeons now perform the operation so as to separate a much larger part of the ciliary body than was at first proposed by Heine. Torres Estrada[24] (Mexico City), who is strongly opposed to any form of fistulizing operation at the limbus, almost always performs the operation which he calls "hemicyclodialysis," in which approximately one half of the ciliary body is separated from its adhesion to the sclera.

Elliot's trephining operation

In 1909, Elliot,[25] then superintendent of the great Government Ophthalmic Hospital at Madras, India (where he had succeeded to Herbert), put forward his preliminary note on the establishment of a filtering cicatrix by means of a trephine opening at the sclerocorneal junction. Elliot had performed both Herbert's and Lagrange's operation a number of times, and had satisfied himself of the soundness of the contentions of these authors (1) that it was possible to form a permanent filtering cicatrix between the anterior chamber and the subconjunctival

space, and (2) that the permanent establishment of such a condition did reduce elevated intraocular pressure. But he criticized Herbert's operation as too complicated, and regarded Lagrange's operation as presenting excessive risk, in that the scleral section had to be made on an opened eye and often on an inflamed eye, it being difficult in these circumstances to graduate the exact amount of scleral tissue removed or to avoid escape of vitreous.

Elliot insisted on the importance of working beneath a triangular conjunctival flap, curetting thoroughly down beneath all episcleral tissue, and setting the guard of the 2-mm. trephine at such a depth as just to allow penetration of the sclera, cutting the trephined disc out slowly. Iridectomy had been performed in 21 out of 50 cases, usually only a tiny peripheral button of iris being removed. The chief danger to be avoided was that of making the trephine hole so far out as to tap the suprachoroidal space instead of the anterior chamber. It was therefore essential to "hug the limbus."

A later paper by Elliot[26] emphasized certain technical details of the trephining operation, in the light of experience in teaching its technique to 15 surgeons at the Government Ophthalmic Hospital, Madras, in a total of 400 cases. The principal points mentioned were that in a troublesome patient who looked obstinately upward, especially during performance of the operation on the second eye, it was often a great convenience to do the trephining below; that an upward flap rarely required a stitch, whereas a flap made downward more often required a suture; that a large flap had been found a great safeguard against infection of the eye and less likely to produce marked astigmatism, as well as favoring free filtration. Later conjunctival flaps had been made without carrying the incision completely to the limbus at either end, as this permitted filtration to occur into the subconjunctival space outside the limits of the incision.

Controversy as to the relative value and safety of the different filtration operations has given particular attention to the danger of producing sympathetic ophthalmia. Allowing for the influence of slight variations in individual technique in producing such a complication, the literature does not substantially support the belief that this danger exists in greater degree in one filtration operation than in another, and it may be considered that iridencleisis, the Lagrange operation, and Elliot's trephining are approximately of equal safety in this regard, while cyclodialysis may perhaps be slightly freer from such a risk. In the hands of the average surgeon, there appears to have been an appreciably greater frequency of recurrent hypertension after cyclodialysis than after the fistulizing operations. On the other hand, cyclodialysis has some advantage as to the possibility of its being repeated after failure from a first attempt.

As regards the surgical and historical status of the Lagrange as compared with the Elliot operation, Rochon Duvigneaud[27] has rather epigrammatically summed up the matter by saying that Elliot's trephining technique is "the best means of executing the Lagrange operation."

Combination of several surgical procedures has frequently been advocated. Cyclodialysis has at times been modified by inclusion of uveal tissue in the operative wound; and Sallmann[28] performed in a considerable number of cases a modified form of cyclodialysis in which preliminary incision of the sclera with the lance keratome was replaced by scleral trephining.

An interesting example of the variations in opinion which keen and catholic minds are apt to experience in the course of years is the fact that Wilmer[29] of the Johns Hopkins Clinic, speaking some 20 years ago at the Oxford Congress, said that he had shrunk from performing the iridencleisis operation because of the possibility of sympathetic ophthalmia and the danger of detached retina occurring much later; although in after years he became a definite

advocate of the iridencleisis operation. Such experiences suggest that it would be an instructive field of investigation to discover how largely choice of surgical technique depends upon geography, and upon the extent to which the worker has come under the influence of a given surgical leader and his writings.

Subject to the limitations still imposed, although in diminishing degree, by time and space, science knows no national boundaries.* The progress of research concerning surgical procedures against glaucoma is one more example of this agreeable and stimulating truth. Side by side, the medical scientists of many countries have moved forward in the utilization of reason and empiricism toward a common goal, the prevention and relief of blindness.

The enormous problem still presented clinically by glaucoma has been materially advanced by the various filtration operations and by cyclodialysis, and many patients to whom, in spite of the long record established by iridectomy, blindness would have been inevitable a half century ago, are now afforded complete relief from the further progress of this disease.†

227 Sixteenth Street.

* The political implications of modern knowledge concerning atomic structure tend to contradict this age-long principle, and threaten to set bounds to intercommunication between the scientists of different nations, thus actually retarding scientific progress.

† The title of this paper is probably sufficient explanation for the author's failure to mention either Otto Barkan's procedure or the diathermy operation.

RETINAL DETACHMENT*

A SURVEY OF THE ETIOLOGY AND RESULTS OF TREATMENTS ON PHAKICS AND APHAKICS

CECIL H. BAGLEY, M.D.
Baltimore, Maryland

The basis of all modern perforating diathermy treatment of retinal detachment is Gonin's historic cautery puncture in 1916 when he attempted by one procedure to evacuate the subretinal fluid, seal off the hole, and cause adhesive choroiditis to hold the retina in place. This was followed by the Guist-Lindner method of multiple trephines with chemical cauterization of the choroid, claiming two advances: namely, a greater possibility of sealing off the hole, and eliminating the possibility of choroidal hemorrhage. The next major step forward was the insertion of Safar or Walker pins by means of diathermy current, whereby more accurate sealing off of the holes and better control of the degree of reaction was accomplished. Numerous modifications of this technique have followed, largely consisting of new types of pins or needles and variations in the technique of application.

The present study was undertaken (1) to compare the various etiologic factors in the production of retinal detachments in phakic and aphakic eyes; (2) to determine the preoperative clinical findings which influence the operative result so cases may be divided into favorable and unfavorable regarding prognosis; and, (3) to compare the results of various operative techniques.

MATERIAL

The material on which this survey is based consists of 304 consecutive cases of retinal detachments operated upon in the Wilmer Ophthalmological Institute between 1927 and 1944. There were 246 phakic eyes and 58 aphakic eyes.

TABLE 1
AGE INCIDENCE IN RETINAL DETACHMENTS

Age	Phakic		Aphakic	
	Number and Percentage of Cases		Number and Percentage of Cases	
	Number	Percentage	Number	Percentage
Under 10	3	1.2	1	1.7
10 to 19	18	8.2	0	0
20 to 29	31	12.7	7	12.1
30 to 39	33	13.5	6	10.3
40 to 49	55	22.4	6	10.3
50 to 59	54	22.0	16	27.6
60 to 69	45	14.3	17	29.3
70 to 79	6	2.4	5	8.6

The age incidence for retinal detachments shows a small rise to a maximum between the ages of 40 and 60 years (table 1). Only 11 Negroes were operated upon, and a slight

*From the Wilmer Ophthalmological Institute of the Johns Hopkins University and Hospital.

TABLE 1A

RACE AND SEX IN RETINAL DETACHMENTS

	Phakic	Aphakic
	Percentage of Cases	Percentage of Cases
White male	55.7	65.5
White female	39.8	24.2
Colored male	3.9	6.9
Colored female	0.8	3.4

preponderance of males over females was found (table 1A).

This series includes all cases both favorable and unfavorable operated upon between these dates. Sixty-eight patients had detachments of at least three quadrants; 25 had detachments of the entire retina; and in 53 patients the duration of the detachment was over six months before operation. Most of such cases were operated upon with full realization that prognosis was extremely poor but that, nevertheless, the patient was entitled to his "day in court." As will hereafter be pointed out, various operative techniques were employed in these patients, the technique varying as advances were made in our knowledge of the treatment of retinal detachment.

COMPARISON OF THE ETIOLOGIC FACTORS IN PHAKICS AND APHAKICS

The importance of myopia in the etiology of idiopathic detachment of the retina has been well established by many observers, including Phelps,[1] Borley,[2] McKeown,[3] and Holst,[4] who found a slight majority of such cases was myopic. In this series 40 percent of the phakic detachments were myopic, but myopia did not seem to be a significant factor in the aphakic detachments (table 2).

TABLE 2

INCIDENCE OF REFRACTIVE ERROR IN PHAKIC DETACHMENTS

Refraction	Percentage of Cases
Emmetropic	41.7
Myopic 1 to 3 D.	11.5
Myopic 4 to 9 D.	16.6
Myopic 10 D. and over	6.9
"Nearsighted"—unknown refraction	4.6
Total myopics	39.6
Hyperopic	18.8

Degenerative changes in the vitreous with the formation of floating opacities and traction bands have been considered by many to be a potent factor in the etiology of simple retinal detachments of both phakic and aphakic eyes. In the present series vitreous opacities were found to be more prevalent in phakic than aphakic eyes, (45.5 percent vs. 10.3 percent). The etiologic importance of disturbances of vitreous structure during extraction of a cataract has been emphasized by many observers. Johnson[5] declared that it is not the loss of a small amount of vitreous that does the real damage, but changes set up through disturbance of the vitreous structure. Shapland,[6] studying 651 cases of retinal detachment in the United Kingdom from 1930 to 1933, also noted the importance of vitreous disturbance. He expressed the theory that vitreous becomes incarcerated in the section and contracts as healing takes place, drawing the retina upward, thus forming a detachment in the lower half of the fundus. He remarked that 10 percent represents with fair accuracy the proportion of retinal detachments occurring in aphakic subjects. Hughes and Owens,[7] in a paper including many of the cases studied here, found that the degree of vitreous

TABLE 3

RELATION OF VITREOUS LOSS TO THE DEVELOPMENT OF POSTOPERATIVE RETINAL DETACHMENT AFTER CATARACT EXTRACTION*

Loss of Vitreous	Number of Cases	Percentage of Retinal Detachment
None	1,720	0.9
Presentation	154	1.3
Moderate	141	5.7
Severe	46	10.9

* Table from article by Hughes and Owens.[7]

loss at the time of the cataract extraction was directly related to the incidence of postoperative simple detachment of the retina (table 3). No difference was found between the intracapsular and extracapsular extractions in respect to this complication. Associated with increased vitreous loss were persistent vitreous opacities, due partly to vitreous hemorrhage and probably in part to disorganization of the normal vitreous structure.

The onset of simple detachments after cataract extraction was longer than six months postoperatively in 55 percent of the cases and longer than two years in 36 percent. This relatively late onset after the extraction of the cataract suggests that degenerative changes in the vitreous were probably taking place in the intervening period. (table 4).

TABLE 4

TIME OF ONSET OF RETINAL DETACHMENT FOLLOWING CATARACT EXTRACTION

Onset after Cataract Extraction	Number of Cases	Percentage of Cases
Less than 2 weeks	4	6.9
2 weeks to 2 months	6	10.3
3 to 6 months	16	27.6
7 to 12 months	1	1.7
1 to 2 years	10	17.2
2 to 5 years	7	12.1
5 to 10 years	3	5.2
Over 10 years	11	18.9

Trauma is somewhat more common in phakic eyes than in aphakic eyes (table 5).

Retinal perforations in aphakics were observed more infrequently than in phakics (table 6). Jeandelize, Bandot, and Gault[8] showed that, in myopia, the degeneration frequently takes the form of peripheral choroiditis with defective vitreous. Vogt considered that cystic degeneration of the retina was one of the most important single factors in retinal separations. In the present series the incidence of degenerative changes in the eye was somewhat more frequent in phakics than in aphakics (table 6). This evidence lends some support to the views quoted above, that degenerative changes in the retina precede retinal perforations and subsequent detachments—an etiologic factor which appears in this series to be more important in phakic eyes.

Practically no cases with undisputed evidence of uveitis are included in this series of operative cases. The discouraging prognosis of detachments associated with uveitis and glial bands in the vitreous is well known. However, 5 percent of the phakic and 10 percent of the aphakic cases had a positive aqueous ray at the time of operation. The operative prognosis appears to be greatly affected by the presence of a positive aqueous

TABLE 5

INCIDENCE OF TRAUMA IN INDIVIDUALS DEVELOPING RETINAL DETACHMENT

	Number of Cases	No Trauma (Percentage)	Indirect to Body (Percentage)	Indirect to Head (Percentage)	Direct To Eye (Percentage)
Phakics	246	79.5	3.7	6.9	9.8
Aphakics	58	87.9	1.7	5.2	3.4

TABLE 6

INCIDENCE OF RETINAL PERFORATIONS AND DEGENERATION IN DETACHMENTS

	Number of Cases	Retinal Perforations (Percentage)	Cystic Degeneration (Percentage)	Myopic Degeneration (Percentage)
Phakics	246	61.8	11.0	6.9
Aphakics	58	38.4	5.2	0

flare, suggesting that this sign may indicate more serious retinal or vitreous pathology.

Preoperative clinical findings determining favorable and unfavorable prognosis

1. Age. In phakics, a significantly poorer prognosis for obtaining mechanical reattachment of the retina after operation occurred after the age of 60 years (table 7). Of 51 cases in the older age group, only 35 percent obtained reattachment in comparison to 60 percent of 191 cases between the ages of 10 and 60 years. No significant difference was found in the results of operation in various age groups of aphakics.

2. Refraction. Myopia, listed high as a contributory cause of retinal detachment, also rated as a factor against operative recovery (table 8). Excluding those eyes of uncertain refraction, designated as "nearsighted," increasing amounts of myopia were directly related to progressively poorer operative results. Hyperopia of over one diopter also appeared to influence adversely the reattachment of the retina. In line with these findings, Phelps[1] cured only 21 percent of those cases in which the myopia was 15

TABLE 7

Importance of age, race, and sex on the operative prognosis of retinal detachments

Age	Phakic			Aphakic		
	Number of Cases	Number and Percentage Reattached		Number of Cases	Number and Percentage Reattached	
		Number	Percentage		Number	Percentage
Under 10	3	1	33.3	1	0	0
10 to 19	18	13	72.2	0	0	0
20 to 29	31	18	54.8	7	2	28.6
30 to 39	33	15	45.5	6	1	16.7
40 to 49	55	26	47.3	6	1	16.7
50 to 59	54	34	62.9	16	8	50.0
60 to 69	45	17	37.8	17	6	35.3
70 to 79	6	1	16.7	5	2	40.0
Total	245	125	51.0	58	20	34.5
Race and sex	Number of Cases	Percentage Reattached		Number of Cases	Percentage Reattached	
White male	137	51.8		38	31.6	
White female	98	52.0		14	30.0	
Colored male	9	22.2		4	0	
Colored female	2	0		2	50.0	

TABLE 8

Influence of refractive error on postoperative results in phakic detachments

Refraction	Number of Cases	Percentage Successful Reattachment	Average Follow-up (Months)
Emmetropic	91	61.5	25
Myopic 1 to 3 D.	25	56.0	26
Myopic 4 to 9 D.	36	44.4	22
Myopic 10 D. and over	15	26.7	18
"Nearsighted"—unknown refraction	10	70.0	17
All myopic (total)	86	47.7	22
Hyperopic	41	39.0	21

diopters or more. Holst,[4] reporting on a series of myopes and hyperopes with trauma, noted only 9 successes out of 19 operations. Samuels,[9] discussing retinal detachment in connection with iritis and glaucoma, added further that myopic eyes developed more complications, and more frequently had to be enucleated.

3. Aphakia. The literature on aphakic detachments is relatively scanty. Shapland[6] remarked, in 1934, of the scant reference in the literature to the disappointing operative results in aphakic detachments. He reported his results on 16 aphakic detachments as disappointing, with only three permanent successes. Gradle and Meyer,[10] reporting on 29 phakic eyes, announced

TABLE 9

INFLUENCE OF VITREOUS DISTURBANCES ON POSTOPERATIVE RESULTS

Aphakics Only	Number of Cases	Mechanically Successful (Percentage)
Vitreous loss at time of cataract extraction	12	16.7
No vitreous loss	40	37.5
Vitreous opacities	5	20.0
No vitreous opacities	53	35.8

cures for 13, while in discussing five aphakic cases, it was noted the percentage of "cures" was far less. The figures collected here showed 35 percent of 58 detachments in aphakic eyes were mechanically successful after operation, contrasting with 51 percent mechanically successful re-attachments in phakic eyes. The causes for discrepancy between the success to be expected after operation for detachment in phakia and aphakia are uncertain. In addition to the fact that the removal of the lens might weaken the supporting structure of the vitreous and retina, are other possible factors; such as, previous loss of vitreous, low-grade postoperative uveitis, and the fact that fewer retinal perforations were detected preoperatively and properly sealed off.

TABLE 10

INFLUENCE OF A POSITIVE AQUEOUS RAY ON POSTOPERATIVE RESULTS

Phakics	Number of Cases	Mechanically Successful (Percentage)
Positive aqueous ray	12	8.3
Negative aqueous ray	231	52.3
Aphakics (at time of detachment operation)		
Positive aqueous ray	6	33.3
Negative aqueous ray	52	34.6

4. Vitreous Disturbances. In aphakics, vitreous loss at the time of the previous cataract extraction and persistent vitreous opacities have a suggestively detrimental effect against subsequent reattachment by operation (table 9).

5. Positive Aqueous Ray. There is no information in the literature on the influence of a positive aqueous ray on successful reattachment by operation. In phakic eyes with positive aqueous ray, there were 11 failures out of 12 operative attempts, sharply contrasting with 52 percent of successful reattachments in 231 cases with a negative aqueous ray (table 10). Such a relationship does not hold in the smaller number of aphakics.

6. Duration of Detachment Before Operation. The time interval between detachment and operation vitally affects the prognosis. This was strikingly illustrated by Arrizonis[11] in Switzerland who recorded 74 percent success when less than three weeks had intervened between retinal separation and operation, whereas between three weeks and three months the ratio dropped to 53 percent; and after three months, only 6.7 percent of the retinas reattached. In the present series the importance of early operation is manifested most clearly in the aphakics where, after two months, only one reattachment in 11 attempts resulted, and in that patient the vision failed to improve (table 11). This contrasts significantly with 37-percent successful reattachments in 43 cases

operated within two months of the onset of the detachment, and visual improvement of at least two lines in the Snellen chart was exhibited in 28 percent. Delay in operations for detachment in phakics is apparently of less concern except for the danger of more extensive areas being involved.

7. Location of Detachment. A review of the literature shows that the great majority of detachments are in the temporal half, and a smaller preponderance is noted for the upper as against the lower half. It happens that in this series more detachments were observed in the lower than in the upper half, but as in other series they preponderate on the temporal side (table 12). It can be seen, at least in the case of phakics, that it makes little difference in the eventual result

TABLE 11

INFLUENCE OF DURATION OF DETACHMENT ON POSTOPERATIVE RESULTS

Duration of Detachment	Number of Cases	Mechanically Successful		Vision* (Percentage of Cases)		
		Number of Cases	Percentage of Cases	Improved	Same	Worse
Aphakics						
1 to 6 days	9	3	33.3	11.1	77.8	0
7 to 13 days	15	4	26.7	20.0	60.0	6.7
14 to 20 days	6	3	50.0	33.3	66.6	0
21 to 28 days	4	3	75.0	100.0	0	0
1 to 2 months	9	3	33.3	22.2	55.6	22.2
3 to 5 months	4	0	0	0	75.0	25.0
6 to 9 months	3	1	33.3	0	100.0	0
10 to 12 months	1	0	0	0	100.0	0
1 to 2 years	1	0	0	0	0	100.0
Over 2 years	2	0	0	0	100.0	0
Phakics						
1 to 6 days	13	7	53.8	15.4	53.8	15.4
7 to 13 days	35	21	60.0	40.0	45.7	8.6
14 to 20 days	22	13	59.0	36.4	50.0	13.6
21 to 28 days	24	11	45.8	37.5	45.8	12.5
1 to 2 months	74	36	48.7	32.4	54.1	9.5
3 to 5 months	29	14	48.2	27.8	51.7	13.8
6 to 9 months	17	9	52.9	29.4	51.8	17.6
10 to 12 months	9	3	33.3	22.2	44.4	33.3
1 to 2 years	13	7	53.8	30.8	46.2	23.1
Over 2 years	7	1	14.3	14.3	57.1	0

* Visual improvement or visual decrease refers to a difference of at least two lines on the Snellen chart between preoperative and postoperative vision.

TABLE 12

INFLUENCE OF LOCATION AND SIZE OF DETACHMENT ON POSTOPERATIVE RESULTS

Location	Phakics		Aphakics	
	Number of Cases	Mechanically Successful (Percentage)	Number of Cases	Mechanically Successful (Percentage)
Upper quarter or half	48	56.2	19	31.5
Lower quarter or half	88	54.5	24	20.8
Temporal half	40	62.5	6	66.6
Nasal half	7	0	3	66.6
Total detachment	21	23.8	4	25.0
At Least 40° Field Cut				
1 quadrant	24	75.0	5	20.0
2 quadrants	108	51.0	26	42.3
3 quadrants	48	45.8	20	25.0

whether the detachment is in the upper or lower half, but all of the seven cases with a detachment nasally were unsuccessful. However, 23.8-percent operative success was obtained in total detachments, necessarily including the nasal half. In the nine aphakics here noted there was no difference in operative results between temporal and nasal detachments. According to normal anticipation, the proportion of success in phakic eyes drops steadily with greater area of detachment, as detected by cuts in the visual field.

TABLE 13

INFLUENCE OF RETINAL PERFORATIONS ON POSTOPERATIVE RESULTS

Type and Number of Retinal Perforations	Phakics		Aphakics	
	Number of Cases	Mechanically Successful (Percentage)	Number of Cases	Mechanically Successful (Percentage)
None	94	40.4	34	23.5
1 Perforation	101	59.3	17	47.1
2 Perforations	14	57.1	1	0
3 or more perforations	7	42.9		
Disinsertion, less than 1 quadrant	17	47.1	4	75.0
Location of Perforation				
Upper temporal	64	53.1	9	66.6
Lower temporal	46	58.7	7	57.1
Upper nasal	14	71.4	3	66.6
Lower nasal	11	54.5	2	50.0
Macular hole	2	100.0	1	100.0

TABLE 14

IMPORTANCE OF PREOPERATIVE TENSION ON POSTOPERATIVE RESULTS

Tension	Phakics		Aphakics	
	Number of Cases	Mechanically Successful (Percentage)	Number of Cases	Mechanically Successful (Percentage)
Under 8 mm. Hg	4	0	0	0
8 to 13 mm.	7	42.9	3	0
14 to 19 mm.	27	48.1	4	0
Low to fingers	32	40.6	3	66.6
20 to 28 mm.	18	61.1	0	0
Normal to fingers	156	53.2	42	35.7
29 mm. and over	20	50.0	0	0

8. Retinal Perforations. Operative results were significantly poorer when no retinal perforation was found (table 13). This might be explained by the fact that a hole was present but undetected preoperatively, and the subsequent generalized barrage did not properly seal off the hole. Those cases in which the retina was disinserted from its attachment to the ciliary body compared favorably with those having retinal perforations. The location of the perforation had no effect on the operative result. Weve[12] remarked that a typical disinsertion at the ora serrata heals well when operated, and in support of his statement reported total success—100 cures in 100 cases.

9. Preoperative Tension. Increased tension is considered by some to be an important factor against operative success in detachment. So strongly does it militate against cure, said Deutschman quoted by Schauren,[13] that he considered a tear in the retina as actually favorable for healing because it

reduces tension. This conclusion is not corroborated by our findings, there being a 50-percent operative success in patients in whom the preoperative tension was 29 mm. Hg (Schiøtz) or over (table 14).

10. Retinal Elevation at Time of Operation. Although statistical tabulation is lacking in the literature on this point, some authors have tacitly assumed that the greater the retinal elevation at the time of operation the less the chance of recovery. The findings in this series show no difference in this respect (table 15). It may be concluded that a wide gap between retina and choroid is no insuperable barrier to success. In this connection it may be interesting to recall a remarkable cure made by Weve in Utrecht, reported by Zorab,[14] of total detachment of such an extreme nature that most of the retina was actually folded over so that its posterior surface was facing anteriorly. Complete reattachment followed operation.

TABLE 15

EFFECT OF HEIGHT OF RETINAL ELEVATION IMMEDIATELY BEFORE OPERATION ON POSTOPERATIVE RESULTS

Retinal Elevation (Diopters)	Phakics		Aphakics	
	Number of Cases	Mechanically Successful (Percentage)	Number of Cases	Mechanically Successful (Percentage)
0	3	66.7	0	0
1 to 3	8	37.5	3	66.6
4 to 6	35	48.6	6	0
7 to 10	71	54.9	3	33.3
11 to 14	34	47.1	6	66.6

Summary. From the above data which correlates preoperative clinical findings with successful reattachment of the retina after operation, it is possible to enumerate those factors which had the most effect on ultimate prognosis in this series in such a way that potentially unfavorable cases can be defined preoperatively as those which had the following characteristics: (a) Phakics—total detachment of the retina, positive aqueous ray, myopia over 10 diopters, and patients over 70 years of age. (b) Aphakics—over two months' duration of detachment before operation, and total detachment. Accordingly the cases have been classified as favorable and unfavorable in Table 16. Such a classification of cases makes an appreciable difference in the results to be expected from operation.

TABLE 16

RELATIVE RESULTS IN FAVORABLE AND UNFAVORABLE CASES

Type of Case	Number of Cases	Mechanically Successful Reattachments	
		Number	Percentage
Phakia—favorable	200	113	56.5
Phakia—unfavorable	46	11	24.0
Aphakia—favorable	45	18	40.0
Aphakia—unfavorable	13	2	15.4

COMPARISON AND EVALUATION OF THE RESULTS OF VARIOUS OPERATIVE TECHNIQUES

1. Year of Operation. Table 17 shows the steady and gratifying improvement made over the years in operation for retinal detachment. Also worthy of note is the contrast in number of cases operated; 31 in the first 7 years as against 215 for the last 11 years. Expansion of hospital facilities does not account for the increased number, and there is no reason to suppose that retinal detachment is any more prevalent now than it was 15 years ago. The answer is that

increasingly good results obtained have brought with them more hope of success, and as a result, many an operation is advised now that would not have been recommended in the not-so-distant past.

2. Type of Operation. Table 18 affords in itself a brief history of the results of various operative techniques for retinal detachment both in phakics and aphakics. In the early pioneer stage, Gonin's operation is the only one having any prospect of success. With the beginning of penetrating diathermy, success rises sharply for both phakics and aphakics. It will be noted that while unmodified Lacarrere diathermy punctures yielded poor results in 19 cases, a combination of Walker pins and Lacarrere diathermy punctures showed up well, particularly on aphakic eyes.

Five straight thermophore operations showed 60-percent success after first operation and one case was successful after second operation, raising the percentage of success to 80.0. Two cases of Lacarrere-Thermophore combined showed 50.0-percent successful reattachment. This number of cases affords too small a basis for reliable comment.

TABLE 17

COMPARISON OF RESULTS OBTAINED BY OPERATIONS FOR RETINAL DETACHMENT IN VARIOUS YEARS (PHAKICS ONLY)

Year of Treatment	Number of Cases	Successful Reattachment (Percentage)
1927–1929	6	16.7
1930–1933	25	36.0
1934–1936	42	50.0
1937–1944	173	53.8

3. Subretinal Fluid. The amount of subretinal fluid obtained at operation has little effect on the final reattachment (table 19).

4. Use of Perforating Diathermy Before or After Escape of Subretinal Fluid. When diathermy punctures were made both before and after escape of subretinal fluid, the effect was about the same as when the punctures were performed only before the escape (table 20).

5. Area Coagulated (table 21). In detachments of comparable size, equally successful results were obtained when extensive areas

were coagulated and when coagulation was limited to the area around the hole or one quadrant. When three quadrants were detached the best mechanical results were obtained when the area of coagulation was relatively limited. Extensive barrage of all three quadrants was less successful in 13 cases.

6. Position of Retina at End of Operation. The position of the retina following evacuation of subretinal fluid was found to be of utmost importance in determining final reattachment (table 22). When the retina remained greatly elevated at the end of operation, the likelihood of successful reattachment was strikingly reduced. In 166 phakic cases in which the retina was found flat or only slightly elevated at the end of operation, in 60.8-percent successful reattachment occurred. However, in 72 cases where the retina remained greatly elevated at the end of operation, only 29.2 percent were eventually successful. In 37 cases of aphakia where the retina was flat or only slightly elevated at the end of operation, 43.2 percent were successful, whereas in 16 aphakics with greatly elevated retina at end of operation, there was only 6.3-percent success.

7. Intraocular Injections. During the past

few years in those cases when at the end of the diathermy operation the retina was still elevated, attempts have been made to restore the retina to proper position at the close of operation by the intraocular injection of either air or saline. The importance of leaving the retina relatively flat at the end of operation has been emphasized above. In many of those cases in which ophthalmoscopic examination revealed marked elevation of the retina persisting after the evacuation of subretinal fluid, saline has been injected into the anterior chamber or vitreous of aphakic eyes. Intravitreous injections are ordinarily made by first incising the sclera with a Ziegler knife or preferably diathermy current to prevent intraocular hemorrhage and aid in sealing off the retinal hole made by the needle. A small gauge hypodermic needle on a 2-cc. syringe is then inserted into the vitreous under direct observation through a dilated pupil or with an ophthalmoscope. Sufficient saline is injected to make the globe firm or to restore the retina to its proper position. Anterior-chamber injections with a hypodermic needle are facilitated by first making a slanting Ziegler incision in the peripheral cornea.

The results of these intraocular injections are given in Table 23. Of 15 phakics in which the retina failed to fall back properly after the withdrawal of subretinal fluid, injection of saline through the attached portion resulted in seven successes (46.7 percent), an improvement but not significant difference from those cases in which the retina was allowed to remain elevated (table 22). Injection of saline through a quadrant in which the retina was detached gave poor results (only one cure in 11 attempts). The intraocular injection of saline by any route in aphakics resulted in significant improvement over those in which the retina remained greatly elevated at the close of operation (table 22). From this table it is evident that in phakic eyes, the injection of

Total cases, one or more operations	246	50.3	58	32.8

saline was apparently of no value, the incidence of mechanically successful reattachments following this procedure being 30.6 percent, against a 29.2-percent success in those cases when the retina was elevated at the end of operation, and no saline injection was made. In aphakic eyes, however, the procedure appeared of definite value, the incidence of mechanically successful reattachments following such injections being 34.5 percent, while in those aphakic eyes when the retina was still elevated at the end of operation, and no saline injections were made, the incidence of mechanically successful reattachments was only 6.3 percent (table 22).

Injection of air in aphakics proved unsatisfactory, only one success being obtained in nine cases.

No serious complications followed the intraocular injections; for example, infection, cataract, hemorrhage, or persistent vitreous opacities. However, attempts to introduce the needle through the detached portion of the retina tended to push off the retina further, and to produce a larger tear through which the saline could escape. Large tears would frequently permit the saline to escape without pushing back the retina.

8. Subsequent Operations. The literature is scanty on the subject of reattachment after two or more operations, and it is therefore of interest to analyze cases in this series to this end (table 24). The retinas of about 41 percent of phakic detachments were successfully reattached on the first attempt. Of the 145 cases which failed less than half had second operations, with 26.4-percent resulting success. Although the ratio is smaller than that achieved in the first attempt, it shows that one failure is by no means final, and offers strong incentive to reoperate. For phakics, the incentive exists for even as many as five operations. Reoperations have raised the final percentage of success to 50.3 percent, notably higher than the 40.6 percent at which it would have remained had not the undiscouraged surgeons, with

TABLE 25

FINAL VISUAL RESULTS IN MECHANICALLY SUCCESSFUL REATTACHMENTS

the permission of undiscouraged patients, "tried again." Of the 43 aphakics whose retinas failed to reattach on the first try, 22 resubmitted to operations and four were rewarded by recoveries on the second attempt. No successes were noted beyond the second operation in 18 third and fourth attempts. Only one operation after failure is therefore advised.

Final visual results

The final visual results in 122 phakic eyes and 20 aphakic eyes in which a mechanically successful reattachment of the retina was obtained are given in Table 25.

The causes for the poor visual results; that is, below 20/40, are shown in Table 26. The predominating causes were macular degeneration and vitreous opacities, conditions which are probably the concomitants of long standing detachments.

Summary

A survey of 246 cases of retinal detachment in phakic eyes and 58 cases of detachment in aphakic eyes reveals the following findings:

A. Etiologic factors

1. Forty percent of the detachments occurred in phakic eyes with myopia, but myopia was relatively uncommon in aphakia.

2. Evidence of vitreous disturbances was present in many of the cases in this series. Floating vitreous opacities were present in 46 percent of the phakic eyes and 10 percent of the aphakic eyes. In aphakia it has been shown elsewhere[7] that the loss of vitreous is associated with high incidence of later detachments of the retina. Such detachments occur relatively late after the cataract extraction, suggesting that degenerative changes in the vitreous have probably been taking place in the intervening period.

3. Myopic and cystic degeneration of the retina were found in 18 percent of the phakic eyes, a likely forerunner of retinal perforations. It is not clear whether 5 percent of the phakic and 10 percent of the aphakic eyes which had a positive aqueous ray at the time of operation represent a low-grade uveitis or possibly are secondary to degenerative changes.

B. Preoperative clinical findings determining favorable and unfavorable prognosis

1. Phakic eyes. The following clinical features if present indicate a poor prognosis: Total detachment of the retina; a positive aqueous ray: myopia over 10 diopters; and an age over 70 years. Less significant factors include the inability to find a hole in the retina, and an age level over 60 years.

2. Aphakic eyes. Those paitents in which the detachment had been present over two months obtained poor operative results, only one successful reattachment being obtained out of 11 cases. Other suggestive detrimental factors include the loss of vitreous at time of

cataract extraction, and the inability to detect a retinal tear.

C. Comparison and evaluation of the results of various operative techniques

1. A notable improvement in final results has followed the institution of various techniques using penetrating diathermy in spite of the fact that more unfavorable cases have been operated upon. Although the number of cases in each group is too small to permit any definite conclusions as to the best operative technique, the use of Walker pins often accompanied by multiple Lacarrere punctures appears to be the most successful.

2. The amount of subretinal fluid evacuated at operation and the escape of subretinal fluid before the diathermy have no appreciable influence on the operative prognosis.

3. For large detachments involving three quadrants, the best results were obtained when the area surrounding a demonstrated retinal perforation and not more than two quadrants were included in the coagulation.

4. The position at the end of operation is of great importance in the determination of final result. This is especially true in aphakic eyes. In aphakic eyes the injection of saline through the pupil into the vitreous chamber was of significant aid in restoring the retina to its proper position and increasing the incidence of mechanically successful reattachments.

5. In aphakic eyes in which the first operation was unsuccessful, a second operation succeeded in 18 percent of the cases. No successes were obtained after two operations in aphakic eyes, while in phakic eyes one success was obtained even after the fifth operation.

THE VALUE OF INJECTING SALINE INTO THE VITREOUS AS AN ADJUNCT TO DIATHERMY OPERATIONS FOR RETINAL DETACHMENT*

EDWIN G. GRAFTON, JR., M.D., AND JACK S. GUYTON, M.D.
Baltimore, Maryland

In the treatment of retinal detachments, injections into the vitreous cavity were tried long before Gonin pointed out the necessity of closing retinal holes to obtain reattachment. Thus Deutschmann[1] (1895) tried injecting rabbits' vitreous, Rohmer[2] (1912) injected air, and Wood[3] (1920) injected a mixture of saline and subretinal fluid. These early injections, given with the idea of forcing the retina back against the choroid, were usually doomed to failure because the retinal holes were not closed. As early as 1902 Galezowski[4] aspirated subretinal fluid and also cauterized the sclera over retinal tears, but his work unfortunately did not gain acceptance and was overlooked for many years.

In the modern surgical treatment of retinal detachments, it is well recognized that not only must an artificial choroiditis be created at such sites as to close the retinal holes, but that subretinal fluid must be drained through openings in the sclera if a high percentage of reattachments is to be attained. The openings through the sclera are most frequently made by means of diathermy puncture or trephine, and should remain patent a number of days. The physiologic formation of aqueous postoperatively is usually counted upon to fill the vitreous cavity, displacing the subretinal fluid and forcing the retina back in contact with the choroid. However, in eyes with very marked elevation of the retina and slow formation of aqueous, the scleral openings may close before this desired result is obtained or else the areas of artificial choroiditis are no longer active enough to close the retinal holes by the time the retina arrives in contact with the choroid. In such cases it is now common practice with many ocular surgeons either to remove subretinal fluid at the time of operation by means of suction applied through the scleral openings or to inject air into the vitreous cavity in order to force the retina back into place at the time of operation.

During the past seven years patients with retinal detachment operated on by members of the full-time staff or the house staff of the Wilmer Institute frequently had saline injected into the vitreous at the close of the diathermy operation in order to force subretinal fluid out of the eye and if possible reposit the retina against the choroid. These saline injections were usually performed only if the retina was still markedly elevated after diathermy application and the establishment of pathways through the sclera for drainage of subretinal fluid. Conversely, in most (but not all) instances where the retina remained elevated at that stage of operation, saline was injected. The present study represents an evaluation of the possible beneficial effects of these saline injections.

MATERIAL

During the period from February, 1939, through June, 1946, a total of 305 patients had diathermy operations for detached retina in the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital. An analysis of the case histories of these patients revealed that 155 cases of retinal detachment not secondary to uveitis or perforating injury had diathermy operations performed by members of the full-time staff or the house staff, and had final ophthalmoscopic descriptions recorded by a member of the full-time staff or by the resident ophthalmologist. In six of these cases, detachment operations

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

were performed on both eyes. The results of operations on these 161 eyes form the basis for this study.

Results

The criterion for successful reattachment of the retina was taken to be a completely flat retina at the time of the last recorded ophthalmoscopic examination. If there was any retinal separation, even apparently localized and nonprogressive, the operation was classified as a failure from the standpoint of reattachment.

In the cases of 159 eyes, the first operation for retinal detachment was performed in the Wilmer Institute. The results of the first detachment operation, classified as to whether the eye was phakic or aphakic and whether or not saline was injected into the vitreous, are shown in Table 1. The results of the second detachment operation, performed on eyes in which the first operation was a failure, are shown in Table 2.

A casual glance at the results pictured in Tables 1 and 2 shows that the percentages of reattachments were not significantly different in those eyes receiving saline injections and in those eyes not receiving saline injections. The natural conclusion to be drawn from a first glance at these statistics is that saline injection into the vitreous does not enhance the probability of reattachment of the retina. However, these figures can be quite misleading. If those eyes receiving saline injections were those with much the poorer prognosis for reattachment, the finding of equal percentages of reattachment in the groups with and without saline injections

TABLE 1

	Total	11	3	27%
Total		40	13	33%

would indicate that the injections were of real value. In general, saline injections into the vitreous were performed only in those eyes where the retina was still markedly elevated after diathermy had been applied and adequate openings made (either by diathermy puncture, trephine, or knife) between the subretinal space and the outside of the sclera.

It has long been our clinical impression that an eye in which the retina flattens out at the close of diathermy operation has an excellent chance for reattachment of the retina, and conversely that an eye in which the retina remains markedly elevated at the close of operation has a poor chance for reattachment of the retina, in spite of entirely adequate openings through the sclera for postoperative subretinal drainage. In an attempt to confirm or disprove this clinical impression, we selected for study all those case histories in which a definite statement was contained in the operative note as to whether ophthalmoscopic examination at the close of operation showed the retina to be essentially flat or still definitely elevated. In 49 instances the operative notes contained this information. The final results of these 49 operations, classified as to whether the retinas were flat or still elevated at the close of the operation, are shown in Table 3. The tremendous difference in these results (69-percent reattachments contrasted to 29-percent reattachments) amply confirms our impression that an essentially flat retina at the close of operation carries with it a good prognosis, and vice versa.

Inasmuch as saline injections into the vitreous were used as a means of flattening those retinas which did not largely flatten after establishment of subretinal drainage alone—that is, were used in those cases with the poorer prognosis for reattachment—we are justified in concluding that the saline injections were of value. The percentage of reattachments, in those cases where saline was injected, should have been much lower if saline had not been injected or unless the retina was flattened at the close of the operation by some other means such as injection of air into the vitreous or drainage of subretinal fluid by suction.

TABLE 3

RESULTS OF DIATHERMY OPERATIONS FOR RETINAL DETACHMENT CLASSIFIED ACCORDING TO POSITION OF RETINA AT CLOSE OF OPERATION

	No. Cases	% Reattachments
Retina flat at close of operation	26	69%
Retina still elevated at close of operation	23	26%

TECHNIQUE OF SALINE INJECTION

Injection of saline into an aphakic eye is performed by making a tiny slanting opening through the cornea at the limbus with a Ziegler knife, introducing a 27-gauge hypodermic needle with an attached syringe filled with normal saline through the tract made by the knife, and injecting saline into the anterior chamber. The saline goes back through the pupil into the vitreous cavity.

For injection into phakic eyes, a 27-gauge needle with attached syringe filled with saline is inserted through conjunctiva, sclera, and pars plana of the ciliary body in whichever quadrant the retina is least elevated. As the needle is inserted, diathermy current is passed through it. The needle is inserted in such a direction that the point slants backward from the lens, thus avoiding the danger of injuring the lens. Saline is then injected directly into the vitreous cavity.

In either phakic or aphakic eyes the injection is performed only if the retina remains appreciably elevated after the diathermy operation, including establishment of adequate scleral openings for subretinal drainage, is completed. The saline is injected before the conjunctiva is closed. It is injected slowly, forcing subretinal fluid out of the scleral punctures and forcing the retina back into

contact with the choroid. A sufficient amount is injected to flatten the retina as completely as possible. If there is not too large a retinal tear, the retina can usually be flattened completely or almost so; the globe will become quite firm when all the subretinal fluid has been displaced, and the reposition of the retina and the firmness of the globe will persist after the needle is withdrawn. However, if there is an extremely large tear or disinsertion, the saline will often pass through the tear and out the scleral punctures without flattening the retina. If such is the case, the globe will not become firm and any amount of saline (10 cc. or more) can be injected without producing the desired flattening of the retina.

In three phakic eyes an attempt was made to introduce saline into the vitreous by way of the anterior chamber, as is done in aphakic eyes. In one case the saline did pass between the iris and lens and filled the vitreous chamber but in the other two the lens-iris diaphragm was merely displaced backward.

Comment

Saline injected into the vitreous does not produce any inflammation. Injection of anything directly into the vitreous cavity will cause some disruption of the vitreous with minor vitreous opacities if the vitreous is "formed." However, all eyes with marked separation of the retina already have considerable disorganization of the vitreous, and inasmuch as saline injections are reserved for such eyes, the injection is in itself a benign procedure. The use of "vitreous" from another eye for such injections must rest on a misconception of the structure of the vitreous. Once vitreous passes through a needle its structure collapses, so that it becomes merely slightly viscous aqueous containing strands of protein molecules which can only serve as vitreous opacities.[5] Actually, saline is not only as good but is better than "vitreous" for injection into the vitreous cavity, because the injection of saline will not introduce undesirable opacities.

We have preferred injecting saline into the vitreous rather than air because saline does not hinder ophthalmoscopic examination. It is theoretically possible that air would flatten a retina which saline would not, since saline may pass through a retinal tear more easily than air. However, in three cases in this series in which injection of saline failed to flatten the retina, injection of air also failed to flatten the retina. These three cases represent the only instances in which air was tried after saline failed. Also, it is possible for air to enter the subretinal space and increase the detachment. It seems probable that if saline injection does not flatten the retina, it is better to try evacuating the subretinal fluid by suction.

Summary

Reattachment of the retina was obtained in 69 percent of eyes in which the retina looked flat at the close of operation. In contrast, reattachment was obtained in only 26 percent of eyes in which the retina was very appreciably elevated at the close of operation.

Injection of saline into the vitreous at the close of a retinal detachment operation will very often flatten the retina in those cases where the retinal elevation does not largely disappear after merely establishing adequate drainage of the subretinal fluid. In a series of diathermy operations for retinal detachment, including 159 first operations and 40 second operations, saline was injected into the vitreous in most instances where the retina remained quite elevated at the conclusion of diathermy application and scleral punctures. The percentage of reattachment in these eyes was as high as the percentage of reattachment in those eyes where saline injections were not necessary to cause flattening of the retina. We believe saline (or air) should be injected unless the retina flattens almost completely without the necessity of such a procedure.

INTEGRATED IMPLANTS AND ARTIFICIAL EYES FOR USE AFTER ENUCLEATION AND EVISCERATION*

WENDELL L. HUGHES, M.D.
Hempstead, New York

Seven years ago necrosis of the cornea occurred in a case of gold-sphere implantation into the sclera by the method of Burch at the time of an evisceration, leaving an eye with what appeared to be a gold cornea.† The motility of the implant was perfect, exactly like the other eye, since the muscle acted normally on the intact sclera. This case stimulated the thought that, if an artificial eye could be attached to the implant by some means, it would improve the eye since there would be little or no lost motion between the stump and the artificial eye as is present in the conventional artificial eye.

In this case, the gold ball was removed six weeks later because it was felt that, if an ordinary artificial eye were fitted, it would come directly in contact with the gold sphere and that scratches on the eye and implant would result in tissue irritation. The probability of an ascending infection was borne in mind.

Ruedemann's[1] epoch-making work, demonstrating that an eye can be sewed in place and that sufficient sealing off will take place around the implanted eye to prevent an ascending infection, stimulated more intensive development of permanently retained, partially exposed implants and integrated detachable artificial eyes which could be replaced or adjusted for position when desired. This paper is a preliminary report of the results to date.

SEARCH FOR MATERIALS

Search for a proper substance from which to make the implants was begun. The most likely materials seemed to be the various plastics, tantalum, gold, and Vitallium.

Plastics were rejected because it was felt that (1) the design contemplated for the implant would not be sufficiently strong if made in one piece; (2) there might be some wear and scratching over a period of time; (3) occasional allergy to plastics might cause tissue reaction in some cases; (4) aging of the plastics might cause cracks to develop; (5) if metal parts were combined with plastic, there would be cracks and crevices for stagnant secretions to collect and infections would be difficult to eliminate.

Gold was rejected because of its prohibitive price. The cost of the raw metal that would be needed to make only one enucleation implant would be about $65.

Tantalum was rejected because of the re-

* Read at the meeting of the Section of Ophthalmology, New York Academy of Medicine, April 21, 1947.

† Movies were taken of this operation and the case was reported at a meeting of the New York Ophthalmological Society in 1941.

action it produces in tissues adjacent to the metal. While this might be desirable in certain locations such as in skull plates, it could lead to limitation of motility if the delicate fascias and muscles controlling movement of the implants were involved. Tantalum is also difficult to fabricate.

Vitallium* was finally selected because of its moderate cost, its strength, its adaptability to casting in any shape, and its prolonged use in orthopedic surgery and dentistry with minimal tissue reaction.[2] This material, an alloy composed of molybdenum, cobalt, and chromium, has practically no electric potential and, therefore, very little tissue reaction in the body.[2] It has been used for buried eye implants,[3] dental plates, colostomy plugs, bile-duct repairs, bone screws and plates, and replacement of portions of bones, such as the jaw, femur, skull, and so forth.

Description of implants

Preliminary models for the implants were made up in brass and discarded until the present designs were decided upon. Two types were made first—one for enucleation (fig. 1) and one for evisceration (fig. 2). Each type had the same standard anterior surface with an oval depression for the reception of a peg on the back of an artificial eye to integrate the movement of the eye with the implant and to help support the eye.

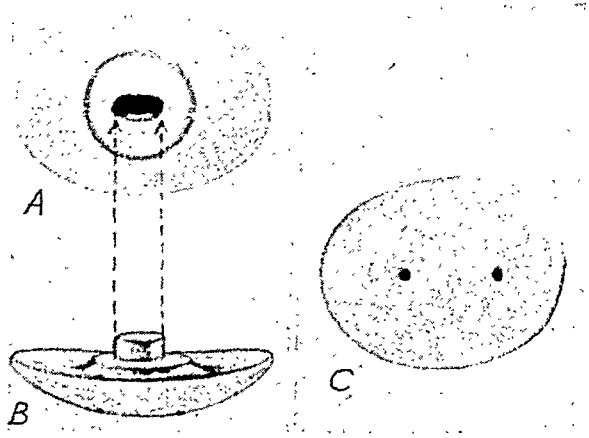

Fig. 2 (Hughes). Original model Vitallium evisceration implant. (A) Front view. (B) Surgical form. (C) Surgical form, front view.

The third type is now ready for use in replacing certain buried implants after enucleation and evisceration.

Enucleation implants

An integrated enucleation implant for immediate use at the time of enucleation is illustrated in Figure 1C. The posterior three fifths of the implant is spherical, approximately 18 mm. in diameter with a highly polished, smooth surface. The anterior portion of the body of the implant is extended to form approximately a truncated cone ending in a flat face, 10 mm. in diameter. On the anterior surface of this flattened portion is a roughly rectangular depression, with all its

* Made by Austenal Laboratories, 224 East 39th Street, New York, New York.

angles and corners rounded extending backward. Its sides slope very slightly for the reception of a slightly tapered peg with similarly rounded corners extending from the rear surface of the artificial eye.

Surrounding this neck is a ring attached to it by eight small attachment bars providing spaces for the ocular muscle tendons in the horizontal and vertical locations and for the reception of the fascia bulbi (Tenon's capsule) in the four diagonal positions. There is sufficient clearance between the bar and the implant to allow for the passage of the tendons of the muscles and the fascia bulbi.

Operative technique. Enucleation. The conjunctiva is ballooned up slightly over the sclera. It is incised around the cornea and dissected back beyond the recti muscle insertions. Parallel incisions are made 4 to 5 mm. apart through the outer two thirds of the sclera toward the limbus parallel to the margins of the tendons for a distance of 3 to 4 mm. in front of the muscle insertions. These strips of sclera in front of the insertion of each rectus tendon are shaved off to the depth of two thirds of its thickness and remain attached to the tendons. These are for the purpose of extending the length of the tendons so that they will be sufficiently long to pass around the attachment bar without tension. One end of a double-armed, 4-0 white-silk (cotton or linen seems to do equally well) suture is passed through one side of each scleral strip and laid aside; 3-0 plain gut sutures may be used equally well.

The enucleation then proceeds in the usual manner. The oblique muscle insertions and posterior small nerves, arteries, and optic nerve are severed. After the oblique muscle tendons are severed, a tonsil snare can be passed over the eye and the structures, posteriorly, including the optic nerve and ophthalmic artery and vein, can be severed. There is less bleeding by this method but it is difficult to get a long section of the nerve if desired. If an intraocular tumor is suspected, the enucleation scissors are used to section the nerve farther back.

When the enucleation is completed, the implant is placed into Tenon's capsule with the long axis of the depression on its front surface placed horizontally. The double-armed white sutures, previously placed in the tendon strips, are threaded through the four horizontal and vertical spaces provided. The muscle tendons with the scleral strips attached are pulled forward and under the bar and sewed back to the muscle itself, forming a complete loop around the bar. An additional suture is placed on the other side of the tendon to spread out its attachment as much as possible (fig. 5). Two sutures are used to attach each of the four strips of fascia bulbi between the muscles (Tenon's capsule) around the bar in a manner similar to the muscle attachments. The fascia is pulled forward between the ring and the body of the implant and is sewed back to itself with two sutures spreading it out as widely as possible. In all, 16 sutures are used, two for each muscle and two for each fascial strip. The conjunctiva is then sewed down around the flat anterior face, anchoring it to the tissues passing over the ring, to assure its healing in the proper position, leaving the face exposed but covering all underlying tissues. A form (fig. 1D) is then placed in the conjunctival sac to retain the fornices, and a moderate pressure dressing is applied. The dressing is changed in 5 to 7 days and, thereafter, every 3 to 5 days for a period of three weeks. For the first two weeks a peep hole of not more than 1.5 cm. is used over the good eye. Hot compresses and mild cleansing drops and ointment are used after the dressing is removed in three weeks.

Integrated implant for replacing buried implants

In cases in which an implant has been buried previously at the time of an enucleation, the implant can be removed and a somewhat similar type with a smaller body (12

mm. diameter) can be implanted in its place. This is feasible if there is good motility of the buried implant and if there is sufficient tissue to form connective-tissue strips attached to the recti. The original implant should also be in approximately normal location and the fornices of normal depth.

Operative technique proposed. The operation of replacing the buried type of implant with the integrated implant can be done either under local or general anesthetic. The conjunctiva is ballooned up so that the fascia in front of the old implant can be separated and dissected into strips, 3-mm. wide, attached to each of the tendons of the recti muscles. These strips are then passed around the attachment bar of the implant and sewed back to themselves in a manner similar to that described in the enucleation implant operation. In the diagonal positions, a sheet of fascia bulbi is dissected and passed forward around the bar in its diagonal positions in a like manner. The conjunctiva is also closed in a similar manner.

In some cases, sufficient tissue may be present on the anterior surface of a large buried implant to permit the use of the larger regular enucleation implant. The strips that pass around the ring to retain the implant should do so without tension. If the larger implant fits easily, it should be used. Procedures for the completion of the operation are similar to those previously described.

Integrated implant for use in evisceration

The original design for this implant was irregularly oval, extending anteriorly to a flat face with an oval indentation similar to the two implants already described. Of the four of these implants used, one was extruded at the end of six months. Two bars were then added,* one above and one below, through which a tongue of sclera could be passed in order to anchor the implant from behind.

Operative technique. The eye is held down by a retention suture at the upper limbus. A transverse conjunctival incision is made over the superior rectus insertion. A suture (double-armed, 3-0 plain catgut) is tied into the muscle tendon which is then detached. An arcuate scleral incision is made. This is a concave posteriorly or V-shaped incision with its apex forward directly behind the insertion of the lateral rectus, and with its use there should be less likelihood of neurotrophic atrophy of the sclera anterior to the incision because there is less severing of blood vessels and nerves than with the straight horizontal incision.

The evisceration is done through the scleral incision, using an iris repositor to detach the root of the iris from the scleral spur and the retina and choroid around the optic nerve. With a large mastoid curette the contents of the eye can usually be removed en masse and, very frequently, the normal anatomic relationships of the iris, lens, ciliary body, choroid, and much of the vitreous body can be preserved for specimen examination, if desired. The interior of the sclera is inspected to see that the scleral cavity is clean. The implant is then placed into the scleral cavity through the upper incision and the cornea is then removed at the limbus. The implant is adjusted to proper position so that the flat surface protrudes through the corneal opening with the long axis of the depression horizontal. The upper scleral incision is sewed up, the scleral edges overlapping, and the superior rectus is replaced. The conjunctiva is sewed up with a continuous mattress suture of 5-0 catgut.

Final step in each of the above procedures. A transparent, concave-convex form is placed over the implant and into the conjunctival fornices to retain them in proper position. In an emergency, if the regular

* One more was extruded after 4½ months necessitating a change in design.

transparent ones are not available, a form can be fashioned for this purpose out of dental wax. A fine dusting of sulfadiazine or tantalum oxide and a moderate pressure dressing are applied. The dressing is changed at intervals of 4 or 5 days for a period of 2½ to 3 weeks. After this, hot applications and mild cleansing drops with some sulfathiazole ointment are used three times daily.

The evisceration cases are usually ready for artificial-eye fittings at the end of 4 weeks, and the enucleation cases at the end of 4 to 6 weeks. As soon as the reaction has subsided, a fitting form is inserted for the purpose of locating the pupillary position so it will match the other eye. The color of the iris is matched in daylight with the iris of the normal eye, the average size of the

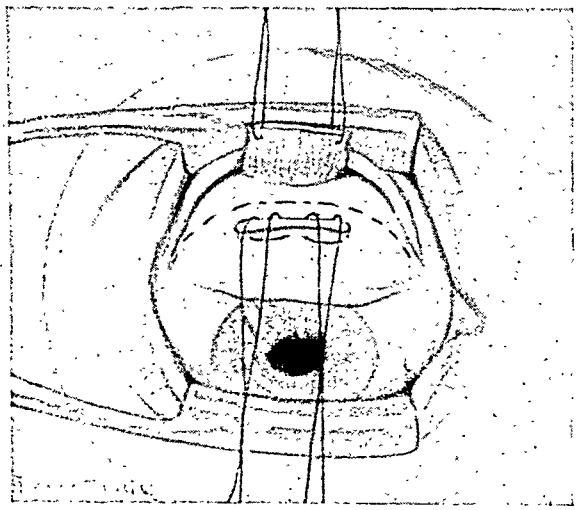

Fig. 3 (Hughes). Evisceration implant operation. Superior rectus detached and incision in sclera planned.

pupil is noted, any enophthalmos or exophthalmos is measured, and the data are sent to the artificial eye maker.* The finished eye is then returned with the iris properly located so it will match the other eye. Any final shaping of the margins can easily be done by a technician skilled in artificial-eye making.

Case reports

Three cases of evisceration and five of enucleation were the first to be done according to the previously described methods.

Evisceration

Case 1. Mr. W. H., aged 28 years, sustained an injury from an intraocular foreign body which resulted in a chronically irritated eye with phthisis bulbi. An evisceration was decided upon and carried out in the above manner on October 23, 1946. Healing was uneventful. Photographs (fig. 5) show the motility and condition of the lids. The motility was measured on a perimeter and found to be temporally 30 degrees; nasally, 20 degrees; up, 25 degrees; and down, 30 degrees. Although this case had excellent appearance and motility, the implant was extruded after six months.

Case 2. Mrs. C., aged 70 years, had absolute glaucoma with uncontrollable pain. An evisceration was done, as herein described, and the final result is excellent motility and position.

Case 3. Mr. A. E. W., aged 56 years, suf-

*The Monoplex Eye Division of the American Optical Company, Southbridge, Massachusetts, is coöperating in the making of this type of eye.

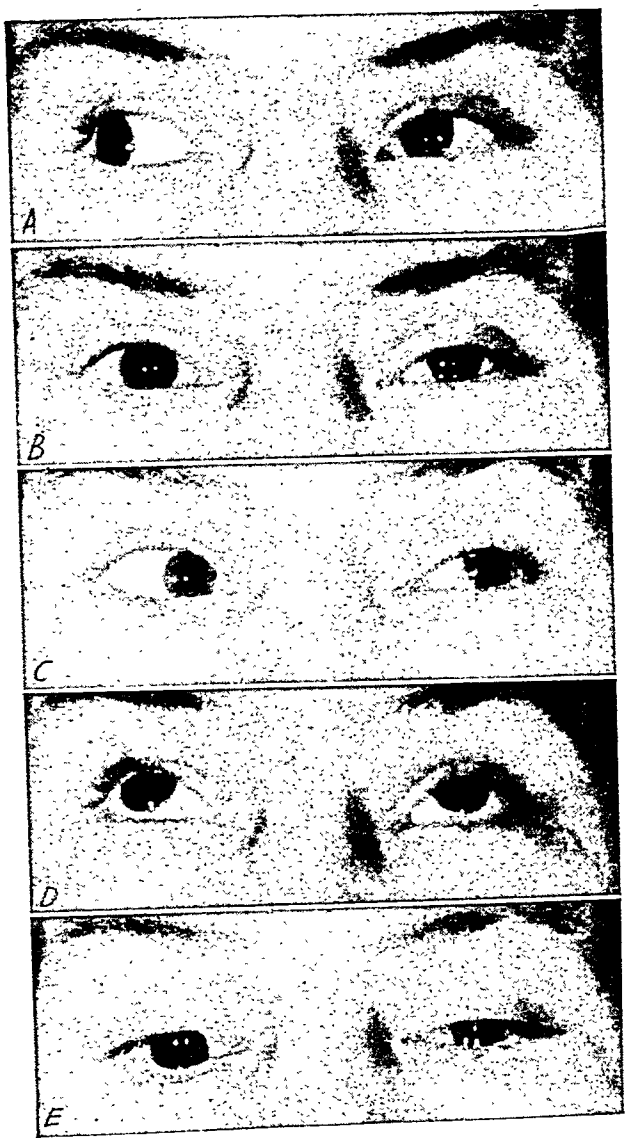

Fig. 5 (Hughes). A study of Case 1, evisceration with integrated prosthesis. (A) Eyes right; (B) eyes straight; (C) eyes left; (D) eyes up; (E) eyes down.

fered a perforating injury of the right eye in December, 1946. He was admitted to the ward service at the New York Eye and Ear Infirmary, and a conjunctival flap was drawn over the corneal laceration. Severe reaction with intraocular hemorrhage necessitated evisceration three weeks later. The afore-described technique was used. There was considerable edema and encroachment of the conjunctiva of the flap over the flat surface of the implant corresponding to the area of the cornea previously covered. This finally subsided but the upper nasal fornix, where the flap had been previously dissected up, was short. This man was reoperated recently and has been fitted with an artificial eye with excellent movement.

Enucleation

*Case 4.** Mr. A. B. had absolute glaucoma with much irritation and pain of the right

Fig. 6 (Hughes). A study of Case 4, enucleation implant with integrated eye. (A) Eyes straight; (B) eyes right; (C) eyes left; (D) eyes up; (E) eyes down.

* Implant was extruded after 4½ months and was replaced with the more recent replacement type of implant.

eye. Enucleation was done by the technique already described. There was moderate conjunctival edema particularly in the lower fornix for about five weeks after the operation. It was two months before an artificial eye was finally obtained for this patient. A plastic eye with a peg on the back was fitted and the motility (fig. 6) was: nasally, 30 degrees; temporally, 35 degrees; upward rotation, 30 degrees; downward rotation, 30 degrees. The fold in the upper lid and its motility provided an excellent match for the other upper lid (fig. 6).

Case 5. Mrs. O'L. had absolute glaucoma, with tearing and chronic irritation of the right eye. Enucleation was performed, and a vitallium enucleation implant of the above type was inserted. Considerable edema of the conjunctiva, particularly in the lower fornix, persisted for about 7 to 8 weeks. This reaction was attributed, at least partially, to the chronic inflammatory reaction in the eye before enucleation. An artificial eye now gives good movement and holds the upper lid in good position with a normal fold and motility.

Case 6. Mrs. M., a colored woman, aged 56 years, had chronic glaucoma in the right eye and absolute glaucoma in the left eye. An enucleation was done by one of the residents and an integrated vitallium enucleation implant was inserted. There was about 20 degrees of divergence with 15 degrees of hypertropia of the face of the implant. A similar eye was finally fitted six weeks after enucleation with good motility of the prosthesis and normal condition of the upper lid.

Case 7. Mr. A. E.* suffered a laceration of the eye by a piece of wire which was followed by long-continued irritation and edema of the conjunctiva. The surgeon who attended the patient at the time of the original accident said that there was no injury to the ciliary body. There was some shrinking of the cornea and the globe. The regular sized implant was placed in the sclera after evisceration through a >-shaped incision under the lateral rectus, and only after the removal of the corneal portion was it possible to close the scleral incision under considerable tension. Fascia bulbi was drawn over the scleral wound and the lateral rectus reattached. The conjunctiva was closed. Because of difficult closure of the scleral wound, it was felt that the implant would probably be extruded, which event took place 10 days later. The sclera healed into a ball, and motility of the stump was quite good. It is planned to put in the replacement type of implant at a later date.

Case 8. Mrs. B had a melanoma of the ciliary body which was first noticed in the anterior-chamber angle four months after a successful anterior sclerectomy with iris inclusion for congestive glaucoma. The tension had remained normal and the inside of the wound area could be well visualized by gonioscopy. An enucleation implant was inserted, using very short scleral lips at the end of the recti tendons. Five weeks later an integrated eye was fitted. The motility was excellent.

Discussion

This is a preliminary report of the progress in the work on this type of implant to date. The final word will not be written for several years.

Advantages

There are some obvious advantages to this type of implant over the buried type of implant.

1. The motility of the implant is transmitted to the artificial eye because of the integration of the eye with the implant. The slippage between the buried type of implant and the eye is eliminated.

2. The position of the eye may be changed by altering the position of the peg on the back of the eye.

* Case operated on by Dr. Kronenberg.

3. A stock plastic eye can frequently be used by placing a peg on the posterior surface to integrate it with the implant.

4. The motility is excellent in all directions as noted by measurements in several of the cases reported. Convergence was noted on many of the cases.

5. The normal fold of the upper lid is retained and the sinking, so common with ordinary artificial eyes with buried implants, is eliminated. This is due to the eye being supported by the implant through the medium of the peg on the back of the eye integrating it with the implant. The eye is held backward so that the peg is held into the depression on the front of the implant by the normal tonicity and muscles of the lids. The lower lid no longer needs to support the entire weight of the eye plus the pressure exerted by the upper lid.

6. The one-piece metallic, hollow construction of metal, 0.002 inch in thickness, is an advantage over any combination of two substances; for example, the combination of plastic and metal.

Disadvantages

The disadvantages of this type of implant at present apparent are:

1. The mere fact that this is a new procedure and a new type of implant renders the final results uncertain.

2. In order to make this artificial eye the technician needs some special training.

3. The cost of the implant and eye is considerably more than that of the spherical implant and ordinary plastic or glass eye.

4. There is more discharge present with the integrated eye than with the ordinary artificial eye with buried implant. This shows a decrease in the more recent cases and new techniques.

Conclusions

Some progress is being made in the matter of a better type of enucleation and prosthesis than has been thought possible in the past. What the final method of choice will be only further experience with various types of implants and eyes can determine.

OXYCEPHALY WITH OPTIC ATROPHY*

Report on results of the King operation

Jack V. Lisman, M.D.
New York

Oxycephaly is a congenital abnormality of the bones of the skull in which there is premature synostosis of the cranial sutures. This disorder is followed by extremely serious sequelae and complications, notably marked deformity of the face and head, increase of intracranial pressure, and loss of vision from optic atrophy.

Classification

Faber classifies the common and most important cranial synostosis as falling into three groups.[1] The cases in the first and most common group are due to closure of the sagittal suture with failure of transverse growth of the skull; there is compensatory lengthening of the skull in the anteroposterior dimension, particularly in the occiput, and often elevation of the frontal region (scaphocephaly).

The second group is composed of those cases in which the coronal sutures are involved; here the normal growth in the anteroposterior dimension is inhibited; growth can now occur transversely, producing a short, broad skull often high in the parietal region (brachycephaly).

Comprising the third group are those cases in which the coronal as well as the sagittal sutures are involved; growth is now inhibited in both the anteroposterior and transverse directions and can expand only vertically. With the suture lines closed tightly, only the anterior fontanelle remains open, as the last part of the suture line to close. The brain continues to exert intracranial pressure in all directions. The point of least resistance at the anterior fontanelle slowly gives way; the bony margins are slowly pushed upward until complete ossification occurs. This results in a distorted skull with the bulging portion at the site of the fontanelle. The deformity of the skull, then, is a resultant of two factors: (1) Limitation of expansion in directions perpendicular to the lines of sutural closure, and (2) overgrowth of those areas where suture lines are still open due to growth pressure of the brain.

Signs and Symptoms

The brain itself is not pathologically small, as in microcephaly, and mental retardation is not as prominent a feature. The development of the brain, however, is restrained because of the small intracranial space. The signs and symptoms are those due to chronic increased intracranial pressure; namely, headaches, vomiting, convulsive seizures, and some mental retardation. The intracranial pressure may rise to levels as high as 500 mm. of water. The inner table of the skull becomes thinned and the convolutional atrophy, as seen by Xray, is extreme. The orbital plates are depressed. Friedenwald[2] found that the vertical diameter of the orbit may be decreased by as much as 10 mm. The great wing of the sphenoid may form the posterior instead of the lateral wall of the orbit, which is shortened, deformed, and its axis changed. These factors contribute to the small volume of the orbits in some of these cases, with resultant exophthalmos and possible lagophthalmos and corneal ulceration. Exotropia is frequently seen and probably is related to a distorted orbital axis.

Vision

Fletcher[3] has reviewed the subject carefully and says of the vision in oxycephaly: "This occasionally is unimpaired, but in the majority of cases sight is very defective." Al-

*Presented before the New York Society for Clinical Ophthalmology, February 3, 1947. From the neurologic service of Dr. Nathan Savitsky, Morrisania City Hospital, New York.

gyogyi[4] estimates the incidence of impaired vision at almost one-half the cases of oxycephaly. Of Mehner's 21 cases, 15, or 71 percent, showed it.[5] Loss of vision occurs early. The choice of operative procedure for prevention or palliation depends upon the underlying pathologic conditions.

Unfortunately, confusion has arisen from a long-standing difference of opinion as to whether the optic atrophy is a result of the increased intracranial pressure or of a narrowed optic foramen. The appearance of choked disc has been observed in many cases. Transition from papilledema to secondary optic atrophy has also been seen. Sometimes, one dise is papilledematous and the other atrophic. Although most reviews of the subject speak of secondary optic atrophy, case reports in the same papers describe the typical appearance of primary atrophy. In 91 percent of Gunther's[11] cases, optic atrophy developed.

It is always a great temptation to diagnose secondary atrophy when the intracranial pressure is known to be very high. This was true in the report by Levine[6] of the case operated by Cushing in 1916; secondary optic atrophy was reported many times until 21 years later when examination revealed typical medullated nerve fibers.

In some cases, it may be that deformities of the body or wings of the sphenoid lead to narrowing of the optic foramen. The hypoplasia of the bones at the base of the skull may result in stenosis of the various foramina-transmitting blood vessels and nerves; venous return may be interfered with, and the optic nerves may be dragged down and injured by being forced against the sharp edges of the sulcus chiasmatis; or they may undergo compression because of an abnormality of the internal carotid artery (Behr).

Faber[7] has studied the case reports that form the basis for the contention that a small optic foramen is the cause of optic atrophy; on critical analysis he finds no basis for this theory. Wilson[8] reports that the foramen opticum itself does not appear to be narrowed as some have maintained. Autopsy reports reveal the optic nerves to be stretched and thinned due to great distortion of the normal anatomical arrangements.

Differential diagnosis

The syndrome of oxycephaly develops during the first five years of life, affecting males more frequently than females, and rarely has a hereditary or familial incidence. The cranial deformity is recognizable at or shortly after birth; the syndrome may develop very slowly; characteristic examples are not likely to be confused with other anomalies of development. Resemblance to craniofacial dysostosis is sometimes rather intimate. Differentiation depends on the local character of the deformity in the dysostosis and the diffuse nature in oxycephaly. The hereditary transmission of craniofacial dysostosis is not seen in oxycephaly. The low sella turcica of oxycephaly is not seen in craniofacial dysostosis.

Differentiation from hypertelorism is made by the presence of marked mental and physical retardation, the great breadth between the eyes and the presence of open suture lines.

Report of a case

I. C., a nine-year-old Negro schoolboy, was first observed on the neurologic service of the Morrisania City Hospital on May 9, 1941. The patient himself had no complaints, but the guardian had noticed abnormal posturing of his head on reading; for the preceding year he had developed the habit of turning his head to the right to allow reading matter to be visualized by the left eye. There was an occasional frontal headache. Adequate familial history, as well as details of his birth and postpartum development, were not obtainable. His mother had died five years previously, cause unknown, and he was under the care of a guardian. Two siblings were living and well. Apparently, his development had been normal. School was begun at the age of seven years and there had been adequate progress. There were no per-

sonality difficulties and no history of craniocerebral trauma or convulsions.

PHYSICAL EXAMINATION

Examination revealed a well-developed, adequately nourished, nine-year-old Negro boy with a peculiarly shaped head (figs. 1 and 2). Measurements revealed the cranium to be smaller than normal with elongation in the anteroposterior and narrowing in the transverse diameters. The boy was alert and coöperative, bright and of average intelligence. There were no focal neurologic signs. General physical examination failed to reveal any abnormalities. Blood, urine, and serologic studies were negative.

OCULAR EXAMINATION

There was no exophthalmos. The motility was not impaired and no strabismus was evident. There was moderate insufficiency of convergence.

Right eye. Vision was light perception with poor projection. The pupil was larger than its fellow and reacted sluggishly to light through a small arc. It responded well consensually. Optic atrophy of the primary type was present. A visual field could not be obtained.

Fig. 1. (Lisman). Lateral view of head taken when the patient was nine years of age. The skull is small in the anteroposterior diameter but does not rise to a point at the site of the fontanelle.

Fig. 2 (Lisman). Frontal view of the head at the age of nine years. The narrowing in the transverse diameter is evident.

Left eye. Vision was 20/20. The pupillary responses were physiologic; the consensual reaction was poor. The nerve head was suspiciously pale in the temporal half only. The visual field was normal in its extent, without contractions or scotomas; the blind spot could not be mapped out.

LABORATORY STUDIES

X-ray studies of the skull (figs. 3 and 4) showed an increase in height of the cranium together with a narrowing in its transverse diameter. There was marked convolutional atrophy of the inner table. The sella turcica was normal in position and configuration. The lambdoidal and coronal sutures were

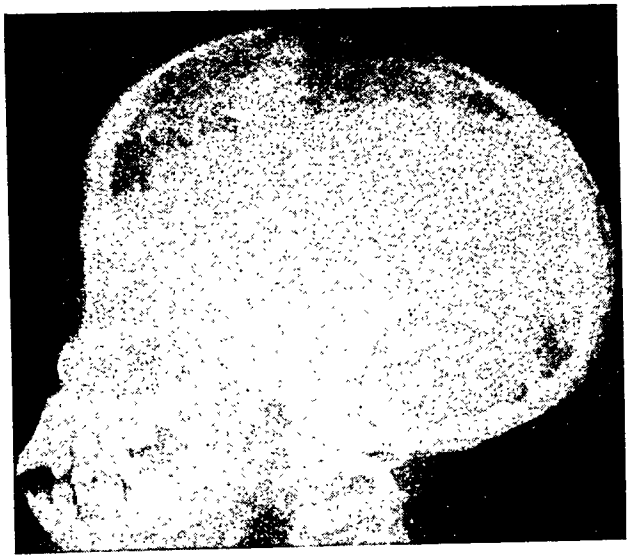

Fig. 3 (Lisman). Lateral X-ray study of the skull showing the convolutional atrophy of the inner table.

open; the optic foramina were of normal size. The sagittal suture was not well visualized.

Spinal tap. Initial pressure was 260 mm. of water. The Ayala index was 4.5. There was no response on pressure over the left jugular but adequate response on the right.

The spinal fluid analysis showed sugar present and no increase in protein or cells.

Diagnosis. A diagnosis of synostosis craniae with optic atrophy was made.

Operation

A King morcellation operation was performed on May 24, 1941, by Dr. Sidney Gross. After reflection of the scalp and periosteum, multiple perforator openings were made on each side of the midline through the bones of the vault down to the dura. These were joined by means of a Gigli saw, leaving only an intact ridge of bone over the longitudinal sinus. As the fragments of bone were cut loose, each became slightly elevated above the surface of the skull indicating high intracranial pressure. After careful attention to hemostasis, the scalp incision was closed (fig. 5).

Postoperative course

Postoperatively, the course was uneventful. The visual acuity improved to finger counting at 12 feet within two weeks.

On September 22, 1942, a tonsillectomy was performed under ether anesthesia without complications. The patient was readmitted to the hospital on November 5, 1944, following minor trauma to his head, sustained the preceding day. A few hours after striking a glancing blow to his head on a door knob, he complained of headache, vomited, and became semistuporus. Examination 24 hours later revealed a semistuporous boy with a stiff neck, a temperature of 101°F., and without any focal neurologic signs. A spinal tap revealed a clear, acellular spinal fluid under a pressure of 150 mm. of water; sugar was present, and there was no elevation of protein. The blood count was W.B.C. 23,440, 77-percent polymorphs, and 23-percent lymphocytes. Within 24 hours, the boy was alert and coöperative and fully re-

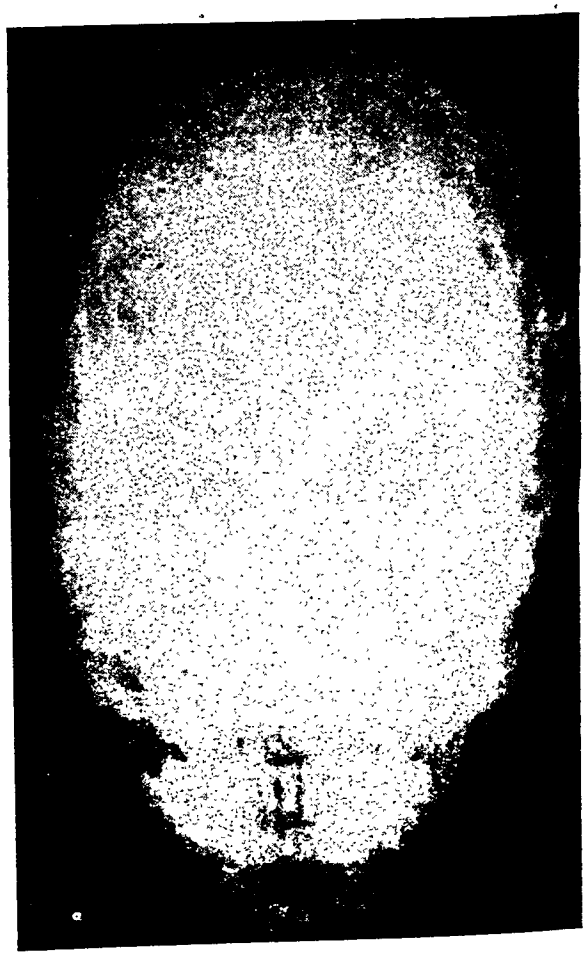

Fig. 4 (Lisman). An anteroposterior X-ray view of the skull showing the convolutional atrophy and the increase in height.

covered; there were no relapses. The etiology of this episode is obscure. Skull X-ray studies at that time revealed only a small part of the operative site that was not completely filled in with new bone.

Reëxamination after five years

A reëxamination on August 28, 1946, revealed an alert, coöperative boy, aged 14 years. The skull had increased in size and its contours were more rounded (figs. 6 and 7). His physical stature was smaller than average. Psychometric studies gave him a composite I.Q. rating of 76 on the Bellevue scale. The classification of "borderline intelligence" was given with the note that this boy was handicapped by having only one eye

Fig. 5 (Lisman). An X-ray picture of the skull taken two weeks postoperatively showing the surgically produced fracture lines of the King operation.

which undoubtedly penalized him in the tests that required perception.

A radiographic examination of the skull (fig. 8) on this date showed: "The skull vault is small and of peculiar form. The bitemporal diameter is narrow. There is an old, healed fracture in the right parietal region; probably the result of a surgical procedure. There is slight increase in the convolutional markings. In a subject of this age, this degree of increase is without clinical significance. No pathologic changes are ap-

parent in the base of the skull, including the sella turcica. The optic foramina are within normal limits of size and form."

Ocular examination. There was primary optic atrophy of the right eye, with no light perception. Vision in the left eye was 20/20. The fundus was normal, as was the field. There was no exophthalmos as measured on the Hertl exophthalmometer.

Spinal tap. The initial pressure was 190 mm. of water. The Ayala index was 5.

Comment

Optic atrophy in oxycephaly is a result of one or all three of these factors: (1) small optic foramina, (2) papilledema, (3) distortion of the optic nerves by traction.

Most frequently mentioned, and yet most infrequently seen, is optic atrophy due to compression by a small optic foramen. Papilledema, while discussed, is reported only infrequently in case reports. It appears that the traction and distortion of the optic nerves subsequent to the marked skull deformity is the most important factor producing optic atrophy in synostosis craniae.

As is the case with maldevelopments of any kind, it is never easy to specify at what point departure from the normal becomes anomalous. Surely many persons with oxycephaly of mild degree grow to be normal adults and require no operative correction. If severe, however, the condition should be recognized in infancy and preventive measures should be taken. Faber and Towne[12] make an impassioned plea for preventive operation before the age of six months.

The palliative operations that have been recommended are: (1) Subtemporal decompression that gives only temporary relief. (2) The operation of linear resection that does not permit satisfactory symmetrical enlargement of the skull. (3) Resection of the optic canals if stenosis has occurred (rare). (4) The preventive operation of "linear craniectomy" of Faber appears to be the most rational; in this operation, channels of bone are cut at the side of the sagittal suture and another paralleling the coronal suture.

The cure of exophthalmos in oxycephaly has never been satisfactorily explained. The exophthalmos recedes immediately after operation, even though the orbital volume has not been increased.[9, 10] Probably, most of the exophthalmos is due to an increase in orbital contents by edema. The hypoplasia of the bones at the base of the skull in craniostenosis results in distortion of veins and interferes with the venous return from the orbit. After any operation that increases cranial volume, the exophthalmos decreases; this is probably due to better venous drainage from the orbit.

Summary

1. A case of craniostenosis is presented.

2. The King morcellation operation was performed and the patient was observed after five years.

3. The temporary improvement in visual acuity in the eye with optic atrophy was not maintained. Vision remained normal in the unaffected eye.

4. The intracranial pressure was partially controlled.

5. The etiology of optic atrophy is discussed.

SOME METHODS OF LID REPAIR AND RECONSTRUCTION*

V. Displacement of the canthi

Sidney A. Fox, M.D.
New York

Cases of displacement of the canthi are not common and have been rarely reported. They are usually complicated cases because the trauma causing them must of necessity be extensive and severe. Thus, in the three cases listed below, not only were all the involved eyes lost but the first patient had an attendant cicatrical lagophthalmos and partial lid loss (fig. 1a) and the other two had a complicating cicatricial epicanthus (figs. 5 and 6).

Wheeler[1] has described a method of handling this type of traumatic deformity but his exposition of the technique is deceptively simple. It was undoubtedly a simple procedure in the hands of this master surgeon. However, as may be inferred from the reports below, the surgery required is usually extensive and occasionally formidable.

Report of cases

Case 1

History. R. J. S. was injured on January 28, 1945, in Germany by mortar-shell fragments. He sustained wounds of the left frontal area of the skull, left eye and face, and right knee. The next day the left frontal sinus was exenterated, the left frontal brain lobe debrided, and the left eye enucleated. After convalescence, he was returned to this country. The defect in the skull was repaired with a huge tantalum plate (fig. 1b). He was then referred for plastic repair of the lids.

Examination disclosed (fig. 1a) an empty left socket and a severe cicatricial lagophthalmos, with the external canthus drawn up to an angle of 45 degrees. The outer half of the left upper lid was absent The lid was bound down to the subjacent tissues by cicatrices and was immobile.

Technique of repair. Anesthesia was ob-

* From the Department of Ophthalmology, New York University College of Medicine.

tained by local infiltration with 1-percent novocaine with adrenalin. A Z-shaped incision was made as illustrated in figure 2a. All three arms of the incision were 3.5-cm. long. The upper two arms included the displaced external canthus between them. The lower

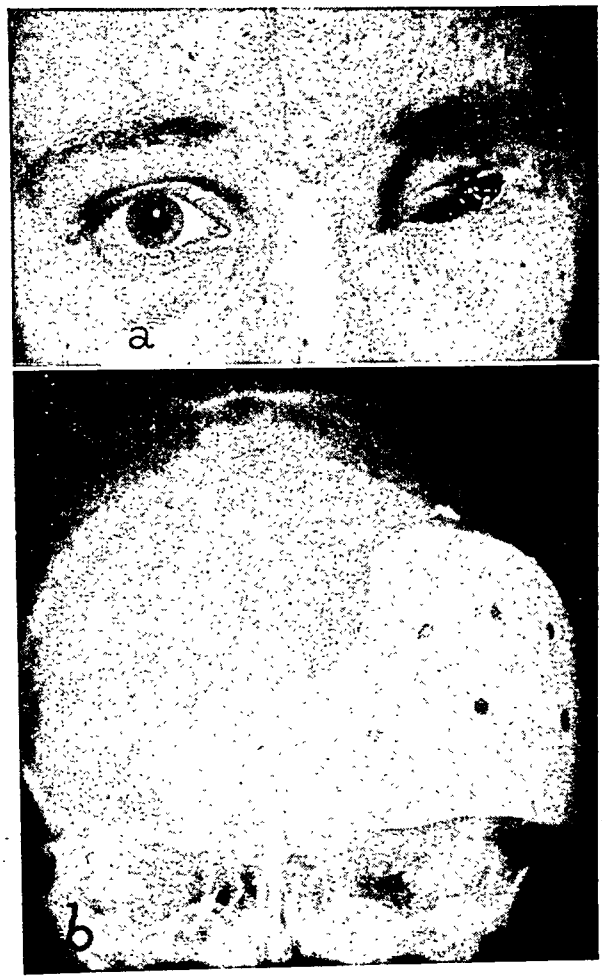

Fig. 1 (Fox). *Case 1.* (a) Left anophthalmos with dislocated outer canthus, cicatricial lagophthalmos, and loss of outer half of upper lid margin. (b) X-ray picture of skull showing extent of injury and tantalum plate.

two arms created a flap of skin from the lower lid. The incisions were carried down to the tarso-orbital fascia. Much scar tissue was encountered and resected. The external canthal ligament was difficult to identify but plenty of equivalent tough fibrous tissue was found to serve. In order to lower the external canthus and conjunctival sac to their normal positions the tarso-orbital fascia had to be incised to attain sufficient mobility (fig. 2b). The flaps were transposed and the ligament was sutured to the zygomatic bone behind the orbital rim at the same height as the external canthal ligament of the fellow eye with 3-0 chromic catgut sutures (fig. 2c). Subcuticular sutures were used to fasten the lower flap to the periosteum of the lower orbital margin and a double-armed stay suture of 3-0 black silk was passed through skin, external canthal ligament, and periosteum of the lower orbital rim, brought out through the skin of the cheek, and tied over oiled silk pegs (fig. 2d). The skin wound was closed with interrupted 4-0 black silk sutures. Figure 3a shows the repair six days

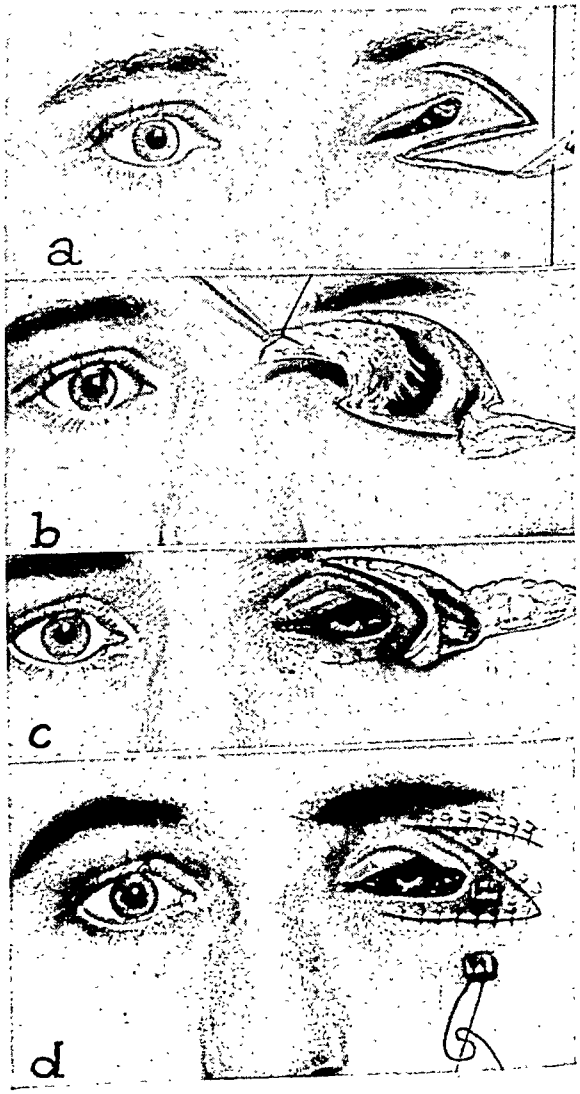

Fig. 2 (Fox). Technique used for repair of dislocated outer canthus in Case 1. For complete description, see text.

later before removal of the skin sutures. The canthal stay suture was removed on the 12th day.

Eight weeks later the outer half of the left upper lid was repaired and lashes grafted. Figure 3b shows the final result eight months after the first operation.

CASE 2

History. L. E. R. was injured by machine-gun fire in February, 1945. His left eye was destroyed, the left frontal, left ethmoid, and right frontal sinuses fractured, and the dura lacerated. The left eye was enucleated, the brain wound debrided, and the dura repaired by a graft of fascia lata. Convalescence was uneventful.

Examination. The patient was returned to this country where examination disclosed a vertical scar running across the forehead down through the medial end of the left brow and through the left inner canthus. The canaliculi were severed. There was a left cicatricial epicanthus with downward displacement of the inner canthus (fig. 5a).

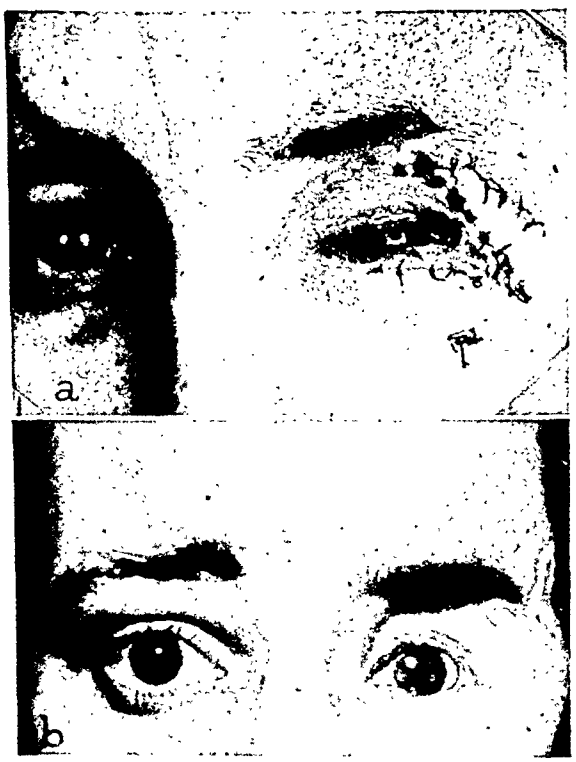

Fig. 3 (Fox). *Case 1.* (a) Appearance six days after repair and before removal of sutures. (b) Appearance after repair of upper lid margin with lash graft and prosthesis in place.

Technique of repair. At operation under local anesthesia a Z-shaped incision was made as shown in Figure 4a with the displaced canthus enclosed by the incision angle BCD. The incision was carried down to periosteum. The two flaps thus created were

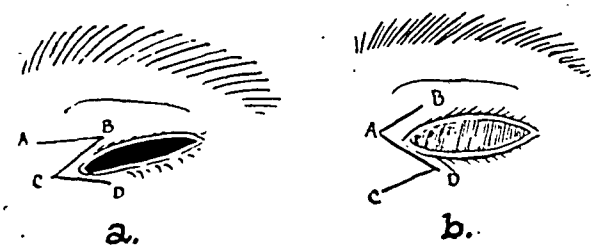

Fig. 4 (Fox). Incision and transposition of flaps used for repair of dislocated internal canthus in Cases 2 and 3. For complete description, see text.

mobilized by free incision of the tarso-orbital fascia and excision of fibrous tissue. The flaps were transposed so that flap ABC occupied position ADC and flap BCD was rotated up into position BAD (fig. 4b). The flap BCD (fig. 4a) included the internal canthal ligament and some surrounding scar tissue which was sutured to the periosteum of the anterior lacrimal crest with a double-armed 3-0 chromic catgut suture. Subcuticular sutures of the same material were used to suture the flaps to the periosteum of the upper nasal orbital rim. The skin incisions were closed with 4-0 black silk interrupted sutures.

Figure 5b shows the repair six days after operation before removal of the skin sutures. Figure 5c shows the patient eleven weeks after operation with a prosthesis in place.

CASE 3

History. E. F. R. was struck by an automobile in November, 1942. He sustained lacerations of the face, rupture of the left eye, and a fracture of the left maxilla. He was in a hospital until February, 1943, during which time his left eye was enucleated and his maxilla repaired by wiring.

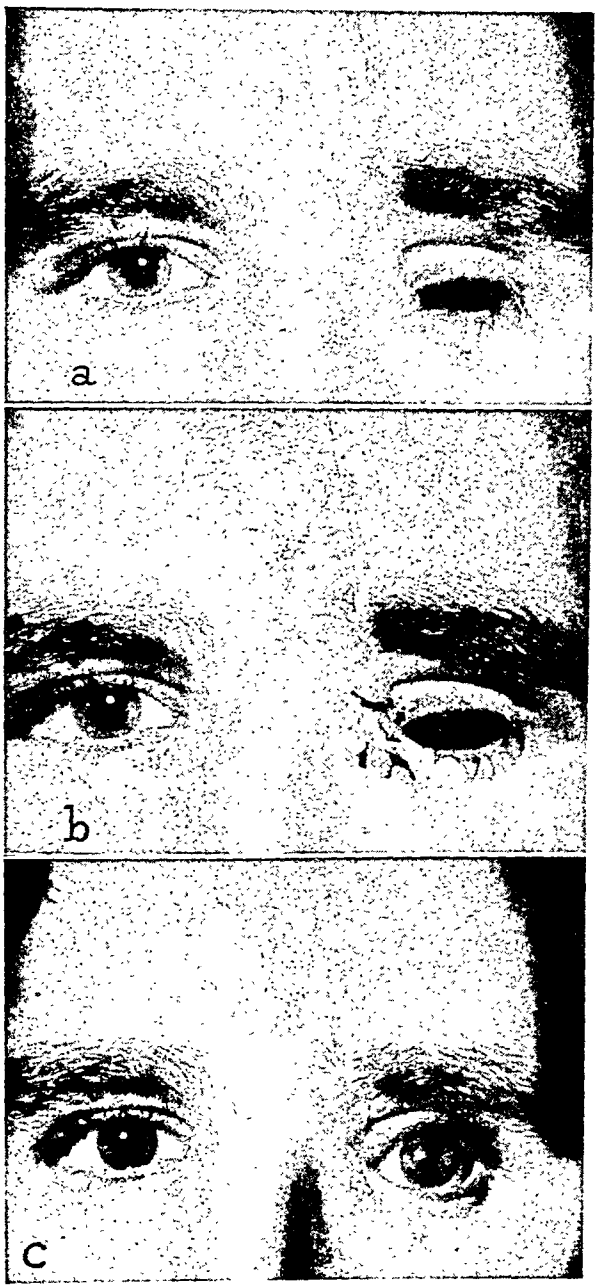

Fig. 5 (Fox). *Case 2.* (a) Left anophthalmos with cicatricial epicanthus and downward displacement of the internal canthus. (b) Six days after repair, with sutures in place. Operative site still shows some postoperative edema. (c) Final repair with prosthesis in place.

Examination. When seen in September, 1944, he had a wide linear scar running from his forehead down the left side of his nose, over the left ala to the vermilion border of the upper lip. The left socket was anophthalmic. There was a left cicatricial epicanthus with the superficial skin knobby and scarred and a large, irregular mass of subcutaneous fibrous tissue involving the caruncle and the internal canthus which was displaced downward about 8 mm. The canaliculi were severed. There was a congenital epicanthus on the right side (fig. 6a).

Technique of repair. A Z-shaped incision was made as described in Case 2 with the two lower arms of the "Z" enclosing the dropped canthal ligament (fig. 4a). The resultant skin flaps were undermined and a mass of subcutaneous fibrous tissue exposed and resected. The dislocated canthal ligament and adjacent fibrous tissue were identified

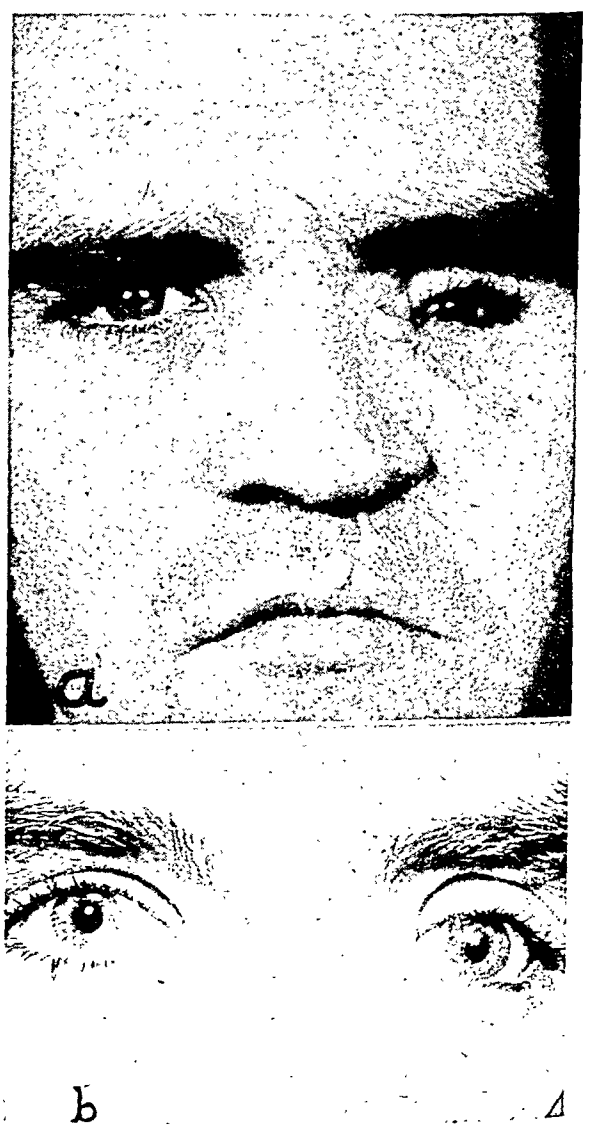

Fig. 6 (Fox). *Case 3.* (a) Left cicatricial epicanthus with downward displacement of the internal canthus. (b) Appearance after repair. Note absence of caruncle and bilateral epicanthus.

and freed. The external canthal ligament was cut, as recommended by Wheeler,[1] and the tarso-orbital fascia of the lower nasal orbital quadrant was incised to attain full mobility. The ligament was then rotated upward and sutured to the periosteum of the anterior lacrimal crest at the same height as the attachment in the right eye. Closure was made as described in Case 2. Recovery was uneventful. After healing it was seen that the canthus was back in normal position but the epicanthus persisted. A double-Z plasty was then performed after the method of Blair[2] to repair this. A secondary orbital implant and excision of the scar of the face were done subsequently to complete the repair.

The final result is shown in Figure 6b. Note that a trace of the epicanthus remains. This, however, just about matches the congenital epicanthus of the right eye and is not noticeable. What is obvious is the absence of the caruncle; this would have improved the result a great deal.

Discussion

One of the few cases in the literature describing this condition was reported by Roy[3] at the International Ophthalmologic Congress in 1922. This was a case of bilateral lagophthalmos with displacement of both external canthi upward. The repair here was also made by a relocation of the external canthal ligament although there was no preliminary "Z" incision. Apparently not so much scar tissue was encountered since this was not a traumatic case and hence less dissection was necessary to free the canthal ligaments. The result was excellent.

It must be emphasized that unless the ligaments or their equivalents are thoroughly mobilized the operation will be a failure. This requires sufficient incision of the tarso-orbital fascia so that the ligaments can be placed in proper position easily and without the slightest tension. When the internal canthal ligament is displaced, it is usually necessary to sever the attachment of the external canthal ligament to assure sufficient mobility.

It is also important to bear in mind the points of attachment of the two ligaments. The lateral palpebral ligament inserts into the orbital tubercle on the zygomatic bone which is behind the lateral palpebral raphe of the orbicularis. Thus it lies deeper than the medial palpebral ligament and does not form a prominence as does the latter. The medial palpebral ligament attaches to the frontal process of the superior maxilla *beyond* the anterior lacrimal crest and forms a prominence which is normally easily palpable. Despite this the attachment is deeper than one would suppose. This is important especially when the caruncle has been preserved. For unless the canthus is replaced back to its original position at the lacrimal crest the caruncle and semilunar folds are hidden and the optimum cosmetic result has not been obtained. This defect is especially noticeable in Case 3 where the caruncle has been lost, and illustrates this point nicely.

All fibrous tissue must be resected to reduce as much as possible the danger of displacement by scar-tissue pull during the healing process. Hence, also, the ligament must be firmly anchored in place.

There are two advantages in using the Z-incision technique in such cases. First, it tends to counteract the danger of healing scar-tissue pull, which may displace the canthus again, by using the skin flaps and skin sutures as well as subcutaneous sutures to counteract this tendency. Secondly, the transposition of skin flaps supplies skin tissue where most needed from adjacent sites; this is always a good rule in plastic surgery. In Case 1, it added tissue to a lagophthalmic lid which would have had to be obtained from somewhere else either by pedicle flap or free graft. The additional advantage here is that next to lid skin itself, skin from below the lower lid is nearest in appearance to actual upper-lid skin. Furthermore it has the advantage (in this case) of being somewhat heavier and less elastic and hence more like-

ly to counteract upward pull by healing scar tissue. In the last two cases this particular technique also happens to be an excellent method for the repair of epicanthus as well.

In general it is probably true that replacement of the external canthus is easier than the internal. This is due to the fact that the structures around the internal canthus are more important cosmetically and their destruction or improper repair will affect the final result much more adversely. Should the lacrimal passages be intact the problem then becomes much more delicate and difficult. Fortunately, or unfortunately, trauma in this area usually severs the continuity of the lacrimal passages and this problem is not often encountered.

Summary

Three cases of traumatic dislocation of the canthi with the methods of repair are reported.

The first was a case of upward displacement of the external canthus with cicatricial lagophthalmos.

The second and third cases showed downward displacement of the internal canthus with cicatricial epicanthus.

EYE INJURIES FROM SO-CALLED NONCASUALTY WAR GASES

Report of cases

George I. Uhde,* M.D.
Louisville, Kentucky

The partial incidence[1] and eye lesions of the clinical[2–4, 9] and experimental[6–8] burns caused by some of the casualty war gases during World War II have been described. On the other hand, little clinical information regarding the so-called noncasualty war gases has been presented, mainly because these gases do not ordinarily cause serious eye damage.

Tear gases

The most important tear gases are chloroacetophenone, chloroacetophenone solutions, and bromobenzylcyanide.

A soldier, aged 20 years, was admitted to the hospital at Edgewood Arsenal, Maryland, for burns of both eyes from a chloroacetophenone solution. This solution was dispersed as a spray from an experimental 3-gallon decontaminating apparatus attached to a jeep. The epithelial surfaces of both corneas were hazy and stained a bright green with a 2-percent alkaline fluorescein solution (6× loupe). The epithelium recovered and/or regenerated within 24 hours after treatment with homatropine and 10-percent albucid (sodium sulamyd, sodium sulphacetamide, or sodium-amino-benzene-sulfonyl-acetylimide).

A droplet of liquid bromobenzylcyanide placed in the eye of a rabbit produces corneal edema and ulceration with fluorescein staining extending even to Descemet's membrane. Usually the eye recovers in about 72 hours. Particles of solid chloroacetophenone entering the eye result in effects similar to those from droplets of bromobenzylcyanide.

In September, 1943, while riding a bicycle across a firing range in the European Theater Operations, a man was struck in both eyes with bromobenzylcyanide dispersed as a spray from a diving plane 50 to 75 feet overhead. Although he saw the spray leave the plane, the attack was unexpected and he was unable to shield himself. He felt drops enter both eyes and had instant severe pain, blepharospasm, lacrimation, and photophobia—to such an extent that he fell off his bicycle. During the next 45 minutes the spasm of the eyelids was so severe that it was practically impossible to irrigate his eyes. Three hours later, however, his subjective symptomatology subsided so that he was able to carry on with his usual duties. His eyes were examined by slitlamp an hour after contamination and the following findings were observed: Swelling of the lids, moderate edema and injection of the conjunctivas, bedewing (edema) of the corneal epithelial cells with superficial punctate staining of the lower two thirds of the corneas (fig. 1).

It is interesting to note that many of the patients during World War I were hospitalized for as long as two weeks, and the soldiers complained of photophobia and lacrimation for three to four weeks. Unless there is secondary infection or reëxposure, facts now indicate that even patients with the severest burns need not be hospitalized longer than 3 or 4 days.

If infection is able to get a foothold, however, the prognosis may be poor. Schmelzer[5] reported the case of a young man whose left eye was injured by a shot from a tear-gas pistol. On the 14th day the cornea became cloudy, the anterior chamber filled with pus, and blindness resulted.

During a demonstration at Edgewood Arsenal a second lieutenant threw a hand grenade filled with chloroacetophenone. The

* Formerly Chief, EENT Service, Station Hospital, Chemical Warfare Center, Edgewood Arsenal, Maryland, and Experimental Officer in Ophthalmology, Chemical Defence Experimental Station, Porton, England.

grenade failed to detonate. After a few moments the officer picked up the grenade and the explosion occurred. Both corneas were damaged to such an extent that permanent blindness resulted. This case is interesting in view of the fact that the degree of damage attributable to the physical force of the

Fig. 1 (Uhde). Photograph taken one hour after contamination with bromobenzylcyanide from an airplane spray shows swelling of the lids and moderate edema and injection of the conjunctiva. Slitlamp examination showed bedewing of the corneal epithelium with superficial punctate staining of the lower two thirds of the cornea.

solution striking the corneas is an unknown quantity. In other words, if water, or any nonirritating solution, was placed in a grenade and exploded a few feet from the eyes, how much damage would there result to the corneas?

Rather severe allergic reaction may ensue from prolonged and/or repeated exposure to the tear gases. A white chemical engineer, aged 28 years, who was working on important tear-gas problems in the Technical Division, Edgwood Arsenal, developed a severe conjunctivitis, blepharitis, and contiguous dermatitis. These signs, and his symptoms, disappeared only after removal from the vicinity of the tear gases. Medicaments were useless. At the patient's request, since his work was important to the war effort, an attempt was made to keep him at his job. However, since the lesions always appeared after a reëxposure and became progressively worse after each succeeding exposure, the effort was finally given up three months after the appearance of the initial lesions.

Although irrigation was recommended in tear-gas splashed eyes, it appeared to have little value in the presence of the severe lid-spasm. The profuse tearing which results from the action of the gas per se is probably as adequate as any irrigation from a canteen. Soldiers should be warned not to rub their eyes because the corneal epithelium is damaged.

In the European Theater Operations, medical officers in forward echelons carried discs of flourescein, homatropine, and atropine for diagnostic and therapeutic care of corneal injuries. Discs were used because of their nonspillable (and perhaps less deterioration) advantage over solutions.

Choking gases

The common choking gases, or pulmonary irritants, are phosgene, chlorine, and chloropicrin.

On November 8, 1942, at Edgewood Arsenal, a Negress, aged about 19 years, was supposedly splashed in her left eye with phosgene, when a new employee became excited and dropped a tube of liquid phosgene on the table in front of the patient. Although the cornea did not stain with alkaline fluorescein (6× loupe), there was severe edema and hyperemia of the lids and conjunctiva with complaints of lacrimation, photophobia, and blepharospasm. The eye recovered in 72 hours without any specific treatment.

It is said that liquid chloropicrin when splashed upon the cornea will cause ulceration. In a lesser concentration chloropicrin is a strong lacrimator, although less effective

than the true lacrimators, and the flow of tears is the first symptom noted. It was a frequent and only symptom observed in these patients treated at Edgewood Arsenal.

Screening smokes

White phosphorus, sulfur trioxide-chlorsulfonic acid, and titanium tetrachloride are some of the screening smokes.

A case report,[1] illustrated by a photograph, of a severe white-phosphorus burn resulting in blindness has already been published. Phosphorus was used extensively during World War II, both as a casualty and noncasualty agent. The protection given by the ordinary eyeshields against white phosphorus varies considerably. When a 11-mg. piece of phosphorus, dried on blotting paper, was placed on an eyeshield and ignited with a hot wire, penetration occurred in 10 seconds. On the other hand, on another occasion under similiar conditions, a 12-mg. fragment penetrated an eyeshield in 3.2 seconds (fig. 2). Even though the penetration time is rapid in some instances (when the smoke is disseminated from shells or bombs, the dispersal force may tend to diminish the penetration time even further), the protection afforded probably suffices to permit the lid reflex adequate time to act and protect the eye against a destructive burn.

On November 19, 1942, a white man, aged about 37 years, was treated for sulfur-trioxide-chlorsulfonic-acid burns of his left eye, left side of his face and neck, and left forearm after a "burster-well" in a leaking shell exploded suddenly. He ran immediately under a shower and his left eye and skin were thoroughly washed. The eye burned and lacrimated but did not otherwise particularly disturb the patient until about 24 hours later at which time the lids were so swollen that he was unable to see. Other than this swelling of the lids and conjunctivas, the eye appeared normal. The swelling subsided in four days and the skin burns healed in seven days.

The following case history stresses two important facts: (1) that a so-called noncasualty war gas may at a point of dispersal cause considerable damage and, (2) that it is potentially dangerous to give an eye patient a local analgesic for self-medication, even though it contains an antiseptic. The pain may be relieved but the pathologic processes may progress.

In February, 1943, in a southern camp,

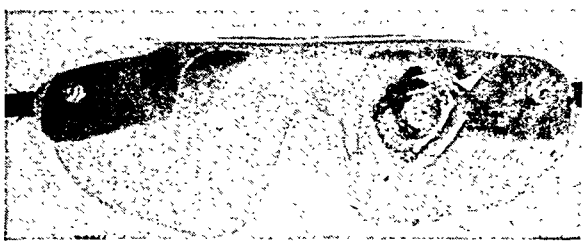

Fig. 2 (Uhde). Antigas eyeshield showing penetration made by a flaming 12-mg. fragment of white phosphorus in 3.2 seconds.

a master sergeant, aged 24 years, splashed titanium tetrachloride into his left eye while removing a cork from a bottle. The eye was irrigated immediately and for about five minutes with 2-percent sodium bicarbonate. A medical officer gave him an ointment of metaphen (1:3,000) with butyn (2 percent) with instructions to use it freely. Twenty-four hours later while en route to Edgewood Arsenal, the sergeant observed that his lids were severely swollen and that he had blurred vision with severe pain (relieved by the ointment), lacrimation, blepharospasm, and photophobia. Examination three days after the eye was contaminated showed severe inflammation of the lids and conjunctiva, numerous conjunctival and subconjunctival hemorrhages, central corneal ulceration, 4 mm. in diameter, which stained bright green with fluorescein and which extended into the stroma, haziness (infiltrates and edema) of most of the remaining corneal tissue, and reflex miosis. The aqueous was clear. The patient was placed in a dark room; the pupil was dilated with a mydriatic, and albucid (10 percent) was instilled every

four hours. The ulcer healed slowly, leaving a faint nebular scarring in the visual axis.

Incendiary agents

The incendiary agents produce a heat burn when brought in contact with the body. Some of the principal incendiary agents are thermite, white phosphorus, combustible oil, and combustible metal incendiaries.

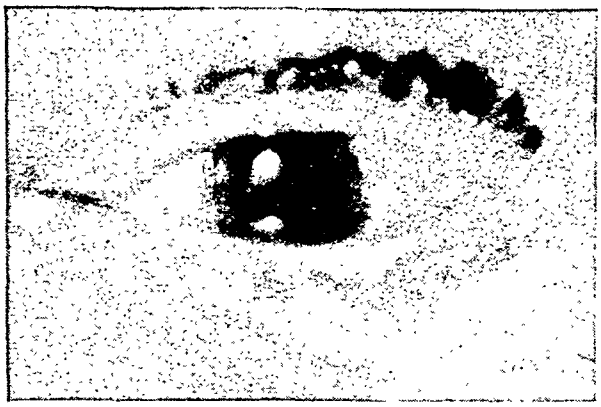

Fig. 3 (Uhde). Photograph of a human eye taken 24 hours after being burned with thermite. The patient was wearing spectacles which were covered with a thick layer of metallic-like matter after the accident. Photograph shows charred cilia and swelling of the lids and conjunctiva. There was bright-green fluorescein staining of the visual axis of the cornea with either a pale-green staining or haziness of the remaining corneal surface.

In February, 1943, a T/4, aged about 27 years, was treated for thermite burns of both eyes, neck, and both hands. He was drilling a hole into an experimental bomb which unexpectedly ignited. Fortunately he was wearing spectacles which were covered with a thick layer of metalliclike material after the accident. Examination showed burns of the face, neck, and hands, charred cilia (fig. 3), hyperemia, and chemosis of the lids and conjunctivas, bright-green fluorescein staining of the visual axis of the right cornea, with either a pale-green staining or haziness of the remaining corneal surface, and superficial punctate staining of the left cornea. After treatment with a mydriatic and sterile liquid petrolatum in a dark room for 24 hours, the corneal surface no longer stained and the epithelium appeared normal (6× loupe).

That the antigas eyeshields give considerable protection against the incendiaries was shown in the discussion on white-phosphorus burns and by the fact that an eyeshield resists the flame of a Bunsen burner for 3½ seconds (fig. 4).

The treatment and prognosis of an incendiary burn is that of any heat burn of the same degree and extent. The eye should be irrigated gently with normal saline, and a mild ointment or oil and a mydriatic should be instilled. The lids should be closed with a pad of dampened gauze immediately over them and then with a dry pad held with adhesive, since the best dressing for the cornea

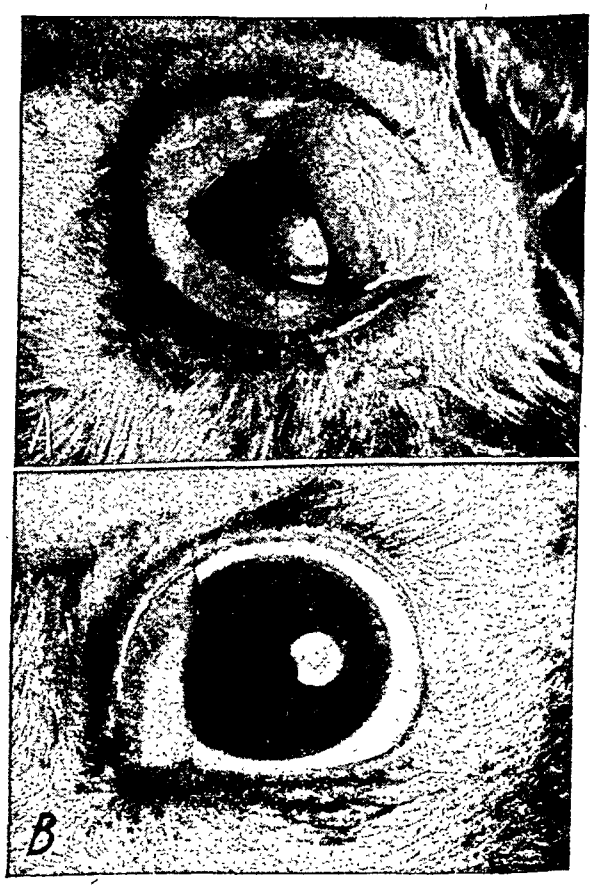

Fig. 4 (Uhde). (A) photograph of a rabbit's eye taken 24 hours after exposure to the flame of a Bunsen burner for 3½ seconds. (B) control eye showing protection given by an antigas eyeshield on exposure to the same flame for 3½ seconds.

is the lid. Cocaine or other local anesthetic should not be used, as anesthesia of the cornea might lead to damage.

Summary

Case reports of eye injuries due to splash burns from chloroacetaphenone, chloroacetophenone solution, bromobenzylcyanide, phosgene, white phosphorus, sulfur-trioxide chlorsulfonic acid, titanium tetrachloride, and thermite are presented. Treatment is discussed.

A PROCEDURE TO FACILITATE INTRACAPSULAR FORCEPS EXTRACTION OF INTUMESCENT CATARACTS*

LOUIS DAILY, JR., M.D., AND RAY K. DAILY, M.D.
Houston, Texas

The procedure consists in puncturing the lens capsule with a fine needle near the equator at the 12-o'clock position. A small amount of pultaceous cortex is thus permitted to escape, after which the capsule, no longer tightly stretched, can be picked up with smooth capsule forceps. While this procedure is not original, it was stumbled on independently by us. It has received scant mention in the literature available to us, and there are no articles concerning it in the American literature. Although our experience with it is limited to seven cases, the uniform success following its use, its simplicity, and its apparent lack of recognition justify, we believe, this brief discussion.

We fell on the procedure by accidentally pricking the lens capsule with de Wecker iris scissors in performing a peripheral iridotomy. To our surprise the wound in the capsule remained localized throughout the extraction, the capsule became relatively flaccid and was picked up easily with Arruga capsule forceps, and the extraction was intracapsular. In our next case of intumescent cataract, a Graefe knife was intentionally used to puncture the capsule; however, the incision enlarged itself and the lens could not be extracted in the capsule. Since then we have used a fine needle to make the puncture, with resulting intracapsular extraction in all of the seven cases so far attempted. Three of these extractions were done through round pupils.

DISCUSSION IN LITERATURE

Lindner[2] was probably the first to use the procedure. In 1942, he recommended the use of a Graefe knife to prick the capsule when the latter is very tense, allowing some cortex to escape so that the capsule may be grasped more easily with the forceps. That this article was not abstracted in English until 1946 is undoubtedly due to the inaccessibility of German publications during the war. Traquair,[7] in 1944, in discussing a paper on cataracts, mentioned that intumescent cataracts can be extracted in the capsule, if the capsule is pricked with a needle before an attempt is made to grasp it. Sedan and Sedan-Bauby,[5] in 1946, reported its use in seven cases, all successful. They, too stumbled on the procedure by accident, in almost the same way as we did. In performing a peripheral iridectomy they accidentally tore the capsule with fine-toothed iris forceps, with the same surprising result. They use the puncture only after they have failed to deliver the lens by the Smith technique.

That intumescent cataract is particularly difficult to extract in the capsule is well known. Elschnig,[1] who was one of the earliest proponents of intracapsular extraction with capsule forceps, stated that the intracapsular extraction is not suitable in intumescent cataract, or is successful in but a small percentage of cases. He was of the opinion that this is the only stage of senile cataract in which the operation should be postponed for at least several weeks until the anterior chamber is almost normal, or at least has become deeper. In the beginning of intumescence the capsule cannot be grasped. When the lens becomes dehydrated in the transition to maturity, it is easily grasped. He also stated that if an iridectomy is performed, the lens may be delivered in the capsule in a small percentage of cases by the Smith or Smith-Pagenstecher technique. Meller[3] in one of the most recent textbooks on surgery is still of the opinion that intracapsular extraction is contraindicated in in-

* From the Department of Ophthalmology, Jefferson Davis Hospital.

tumescent cataract. Our limited experience leads us to believe that this contraindication is not valid if the lens is punctured with a fine needle before being grasped with forceps. Moreover, the punctured lens may be delivered through a round pupil smaller than is otherwise required, by using combined traction and pressure.

The erisophake is considered suitable for intracapsular extraction of intumescent lenses. In this regard Ribeiro,[4] in an exhaustive article on suction extraction of cataracts, points out that for intumescent cataracts one should use a large suction cup and a low degree of suction. A small suction cup applied to a small area requires a greater amount of suction which will undoubtedly break the capsule. He also points out that the larger the suction cup, the more difficult it is to manipulate because it can easily include the edge of the iris and produce an iridodialysis. Spaeth[6] is of the opinion that regardless of the operator who is using the erisophake, there is a greater incidence of vitreous loss with this procedure, than with extraction using forceps. The puncture offers an alternative to the use of erisophake and permits extraction of intumescent lenses with forceps.

Operative technique

The technique is simple. No additional paraphernalia other than a sharp, fine-gauge (No. 25 or No. 26) needle is needed. The puncture is made just before the lens is to be grasped with forceps. The site of puncture is in the anterior capsule near the upper edge. It is made through a peripheral iridotomy, peripheral iridectomy, or through a total iridectomy. Some resistance is offered to the point of the needle by the lens capsule, and the lens is felt to move backward a little just before the needle penetrates the capsule. Once the capsule is punctured, the needle is at once withdrawn, and is followed by a small amount of milky-white fluid. The relaxed capsule is now easily grasped in its lower or upper third and the extraction completed by using traction combined with pressure. No attempt is made to seal off the hole in the capsule by grasping its edges with the lens forceps.

Sedan[5] states that Charles Thomas of Nancy told him in a personal communication that he had used this type of puncture, but had made it with a cystitome in the lower third of the anterior capsule and had then attempted to close off the wound by grasping its edges with the lens forceps. He succeeded in 8 of 12 cases.

We feel that the small wound in the capsule may act as a safety valve during the extraction particularly when it is being done through an intact sphincter with a not well-dilated pupil. In one case of ours this was strikingly illustrated. The capsule was punctured as described above, after an attempt to grasp it with forceps had been unsuccessful. As always, a milky-white fluid escaped from the wound in the capsule. The pupil in this case was round and narrow. Some resistance was felt in loosening the lens from the zonule and in pulling it into the rather small pupil, when suddenly all resistance was felt to disappear. It was thought at this point that the capsule had torn. The capsule was then drawn through the pupil and out of the eye by putting one forceps after another upon it in a hand over hand fashion as described by Verhoeff, and to our surprise, it emerged intact almost empty except for a thin yellow nucleus. This seems to indicate that the capsule and the solid portion of the lens which it surrounds may be extracted through a pupil of a diameter slightly greater than that of the solid portion of the lens, although considerable pultaceous cortex may be lost in the process.

The puncture is not indicated, of course, in lenses with senile sclerotic changes. In one case, we experimentally inserted a needle into a completely sclerosed lens. It felt like hard clay. Upon withdrawl of the needle nothing issued from the wound in the capsule. The capsule was easily grasped with forceps and the extraction was intracapsular. While the procedure has no advantage in a

sclerosed lens, in this particular case it did no harm. A large series of cases may demonstrate that the puncture does not prejudice the successful intracapsular extraction of any lens upon which it is performed.

We have had no complications following this procedure. The small amount of pultaceous cortex which ordinarily escapes from the wound in the capsule is probably pushed out of the eye ahead of the lens. We have not practiced routine irrigation of the anterior chamber after this kind of extraction and have had no iritis or other complications in the seven cases in which we have used it.

Summary and Conclusions

1. Puncture of the capsule of the intumescent lens near the equator at the 12-o'clock position facilitates intracapsular extraction with forceps.

2. No complications result from the use of this procedure.

3. Intracapsular extraction of intumescent cataract through a round pupil is made possible by this procedure.

NOTES, CASES, INSTRUMENTS

FIBRINOUS EXUDATIVE CYSTS OF THE IRIS

MAXWELL THOMAS, M.D., AND
RONALD BURNSIDE, M.D.
Dallas, Texas

Dramatic recoveries of iridocyclitis after the administration of penicillin have recently been reported, such as the case by Weizenblatt.[1] Other types of therapy having been simultaneously used, the effectiveness of the penicillin is not easy to evaluate. In the instance to be reported, arsenicals and bismuth used for syphilis had apparently produced an acute hepatitis, although causing both the blood and spinal serologic tests to be negative. The cysts, which subsequently appeared when the constitutional reactions of an acute hepatitis were in a process of subsiding, were inflammatory in character and responded to penicillin therapy.

It was suggested that the cysts arose from the anterior iris crypts at the site of the posterior synechias. Duke-Elder[2] described similar spontaneous cysts of exudative nature which may arise from clefts in the iris.

REPORT OF A CASE

A 24-year-old white man entered the hospital on September 14, 1946, complaining of general malaise, increased fatigability, and discoloration of the skin and sclera, which began four weeks before admission. Later, on October 17, 1946, he developed an iridocyclitis, complicated by the formation of fibrinous exudative cysts of the iris..

History. The previous history was unimportant except for the fact that, four months prior to entrance, in April, 1946, he had a penile chancre followed by a positive serologic test. He received injections of bismuth and an arsenic preparation, each once a week, up to the week before admission to the hospital; this included three weeks after the appearance of a generalized jaundice.

Family history. The family history was irrelevant except that the mother had died from an embolus from varicose veins of the legs. Past history was otherwise irrelevant.

Physical examination. A young white man, deeply jaundiced and not acutely ill, with no temperature, presented himself.

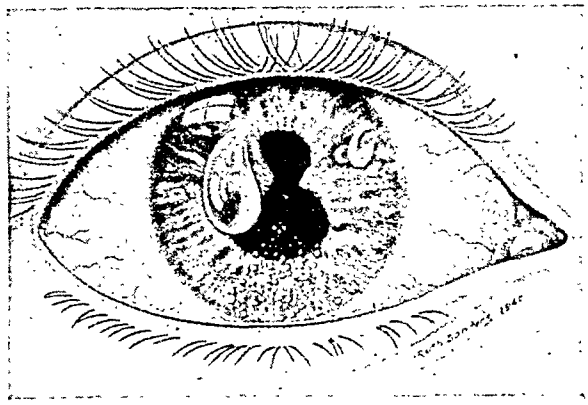

Fig. 1 (Thomas and Burnside). Fibrinous exudative cysts on the iris.

Conjunctiva and sclera are yellow, pupils equal, dilate and react to light and accommodation. Eyegrounds are normal in appearance. All systems were negative except for slight bilateral cervical and inguinal adenopathy. The abdomen was described as soft, no rigidity, but with slight tenderness in the right upper quadrant. The liver was palpated some two to three finger's breadth below the costal margin, although the edge was not distinctly felt. No other organs were palpable.

Treatment. Because it was assumed that the patient had an acute drug hepatitis from arsenic, he was given treatment including methionine, choline, high-carbohydrate, high-protein, and low-fat diet, brewer's yeast, liver extract, and bed rest.

Eye symptoms. Recovery proceeded uneventfully until October 16, 1946, when the patient complained of slight pain and diminution of vision in his right eye. No manifest refractive error was present and the

visual acuity was: O.D., 20/60; O.S., 20/20. Tension to finger palpation was normal.

On October 17, 1946, gross examination revealed a slight edema of the lids with purplish discoloration. The conjunctiva was edematous with the presence of moderate ciliary injection. The cornea was slightly cloudy. The pupil was irregular and fixed, about 3 mm. in diameter. A clear grayish-yellow, tear-drop appearing structure hung from the anterior surface of the iris at the 10-o'clock position over a definite nodule. At the 2-o'clock position, a nodule supporting a very small similar type of cystlike structure was present. After dilation of the pupil, two posterior synechias were noted at the 10- and 2-o'clock positions. Ophthalmoscopic study of the right eye was unsatisfactory due to the cloudy cornea and presence of inflammatory products in the anterior segment.

Biomicroscopic study revealed the cornea to be edematous throughout, with many irregular folds in Descemet's membrane. Numerous keratic precipitates of a dark-brown color covered the lower fourth of the endothelium of the cornea. The aqueous was filled with many cells and clumps of cells seemed to be moving freely. A moderate engorgement of the entire iris gave it a muddy appearance. At the sites of the synechias, the iris vessels were strutted over an iris segment which was definitely elevated.

Two pedunculated cysts appeared to rise from a small anterior iris nodule at the 10-o'clock position. A common stalk was the origin of both. The larger cyst had a thin, transparent, veil like, outer wall and was of grayish color with particles of uveal pigment and inflammatory cells adherent to it. This larger cyst was approximately 4.5-mm. long, 2.5-mm. wide, and its depth allowed its surface to be almost in contact with the cornea. A similar miniature cyst arose from the same nodule and over the larger cyst. Both hung across the base of the firmly fixed posterior synechias. At the 2-o'clock position and medial to the adjacent synechias was a small reddish nodule 1 by 1.5 mm., and overlying this was a small, half-moon shaped, transparent cyst with a wall similar to those previously described.

Therapy. Instillations of atropine and 10-percent neosynephrin failed to release the synechias or to dilate the pupil satisfactorily. This treatment was followed the next day by a subconjunctival injection, but the synechias held firm. Penicillin was started with 5,000 u. every three hours, and this was increased daily until 100,000 u. were given at each intramuscular injection. In 48 hours the cysts were reduced to half the original size. By October 24, 1946, eight days later, they had disappeared along with the synechias, following a repetition of a subconjunctival injection of atropine and adrenalin. Only a small indistinct nodule remained at the sites originally described. By November 1, 1946, no evidence of active pathologic processes of the iris was seen except a slight iris atrophy. A few keratic precipitates remained, but no free cells were noted in the aqueous.

Laboratory findings. Blood Wassermann and precipitation tests were negative. Spinal serology was negative and a colloidal gold test was 0000000000. Cell count showed three polymorphs per cm. First urine specimen: dark brown color; turbid; reaction acid; specific gravity, 1.011; albumin trace; sugar negative. W.B.C., rare; R.B.C., 2-3 (high-powered field), many granular casts, bile strongly positive, urobilinogen positive.

Feces: bile acids were negative. On September 28, 1946, cephalin cholesterol showed a flocculation of two plus. The icterus index fell from 135.6 on admission to 13.7 when dismissed on November 6, 1946. X-ray studies of the abdomen and chest were negative.

Comment

An unusual inflammatory cyst of the anterior chamber, associated with an iridocyclitis and causing little pain, was suspected of being luetic in origin because of the dramatic response to penicillin given systemically.

It was believed that the jaundiced state of the patient was due to liver damage produced by the administration of arsenicals, since cessation of the hepatitis began with the stopping of the arsenic therapy. Therefore, the iridocyclitis was probably due to a luetic infection, although the serologic tests on admission were negative. The large doses of penicillin supplied sufficient concentration to the site of the inflammation of the anterior chamber; and, even though large amounts of inflammatory exudate were present, an unusually rapid response occurred. This also suggests that, when anterior-segment inflammatory processes are sensitive to penicillin therapy, they have an excellent prognosis when the drug is given parenterally.

CLINIC FOR BINOCULAR PROBLEMS*

THREE EMMETROPIC PATIENTS TREATED WITH ANISEIKONIC GLASSES OVER 8- TO 10-YEAR PERIODS

PAUL W. MILES, M.D.
Saint Louis, Missouri

Aniseikonia usually arises when anisometropia or unequal astigmatism is corrected with ophthalmic lenses. The fact that it is measured occasionally in emmetropic patients with ocular symptoms which are otherwise inexplicable is of great theoretical interest. As suggested by Hughes,[1] the seat of the anomaly in these patients may be in the comparative density of retinal sensory elements in the two eyes, or in the neurologic processes in the ocular cortex. The following cases are cited as examples.

CASE REPORTS

CASE 1

S. B. W., a white woman, was first seen at the age of 15 years, on August 31, 1938. Her complaint was fatigue of the eyes after reading, movies, or riding in a car. After an hour's study, there was headache in the frontal region which could be relieved by resting her eyes one-half hour. The onset of this complaint was in 1935 following treatment for sinusitis. She had worn these glasses for 18 months without relief: R.E., −0.12D. cyl. ax. 180°, 20/15; L.E., −0.25D. cyl. ax. 5°, 20/15.

External examination and ophthalmoscopy were found to be normal. The subjective noncycloplegic refraction was: R.E., −0.25D. cyl. ax. 150°; L.E., −0.25D. cyl. ax. 40°. Diplopia tests for phoria were negative both distant and near.

Fusional amplitudes were: Distant: Divergence, 9/7$^{\Delta}$ (break and recover). Convergence, 10/8$^{\Delta}$. Vertical, ±2/1$^{\Delta}$ (+ is B.D. right). Near: Divergence, 21/16$^{\Delta}$. Convergence, 40/18$^{\Delta}$. Vertical, ±3/2$^{\Delta}$.

Tests for aniseikonia on the ophthalmoëikonometer without the refractive correction showed the need for magnifying the image of the right eye by 1.0% overall.

After wearing the prescription: R.E., 0.00D. sph. with 1.0% overall; L.E., 0.00D. sph., for seven weeks, she reported relief of her fatigue and headache.

In October, 1941, she returned stating that the glasses had done very well for two years, but since she had entered a secretarial school, she had begun to get headaches over the right eye after reading or when watching a movie.

Second examination. External and ophthalmoscopic examinations were normal. Visual acuity without glasses was 20/15 O.U. Keratometer readings showed: R.E.,

---

* From the Dartmouth Eye Institute, Hanover, New Hampshire.

42.37/10, 42.62/100, with a −0.25D. cyl. ax. 10°; L.E., 42.62/35, 43.37/135, with a −0.75D. cyl. ax. 35°. Subjective noncycloplegic refraction was: R.E., −0.25D. cyl. ax. 90°; L.E., −0.25D. sph. ⌒ 0.25D. cyl. ax. 35°.

Diplopia tests showed orthophoria for both distant and near vision. The fusional amplitudes had increased in three years to: Distant: Divergence, 12/10Δ. Convergence, 16/12Δ. Vertical, ±4/3Δ. Near. Divergence, 18/16Δ. Convergence, 24/20Δ. Vertical, ± 6/4Δ.

Tests for aniseikonia on the ophthalmo-eikonometer without refractive lenses showed: 0.25% overall combined with 0.25% ax. 90°. Tests on the space eikonometer[2] showed: ax. 90°: R.E., 1.0% ax. 180°: L.E., 0.75%; delta: −0.3° (which measurements correspond to an aniseikonic correction of R.E., 1.75% meridional, ax. 130°).[3] The patient was given the prescription: R.E., 0.00D. sph. with 1.5% ax. 135°; L.E., 0.00D. sph. which she reported in a letter of June 14, 1943, again relieved her complaints. On November 20, 1943, she returned to the clinic at the insistence of her father who thought she had been using her eyes too much. Her refractive and aniseikonic conditions were found to remain the same.

CASE 2

L. M. S., a white man, aged 33 years, was a gymnasium instructor. He was first seen in December, 1936. His chief complaint was headache in the frontal and occipital region of 12 years' duration. The headaches were almost continuous, although he had a few days relief at intervals. The headache had no apparent relation to physical fatigue or any activity. There was no train or car sickness. He would sometimes wake up with the headache, feeling physically exhausted. The headaches often interfered with rest at night. He did much reading in spite of his headache. He had tried wearing glasses (presumably plus for near) and also tinted lenses without relief. After one-half hour's reading, his eyes would tire and pull. Objects stared at seemed to fade in and out. There was photophobia, burning and lacrimation, blinking and blepharospasm when he tried to concentrate on a moving object.

History. Since the age of 11 years, he had had "sick headaches" with nausea and partial temporary field changes. These came once or twice a year, but had not occurred for the past three years. In 1930, the patient was treated for acute conjunctivitis with "the wrong prescription." He stated that due to this treatment, he had to keep the eyes bandaged for two weeks, and wear dark glasses for several weeks following.

The family history was negative except that his mother had had "sick headaches" all her life.

Examination. External and ophthalmoscopic examinations were normal. Keratometer readings were: R.E., −0.37D. cyl. ax. 160°; L.E., −0.12D. cyl. ax. 180°. Subjective noncycloplegic refraction showed: R.E., +0.25D. cyl. ax. 60°, 20/15; L.E., +0.25D. cyl. ax. 175°, 20/15. By the diplopia test, there was 1Δ esophoria for distant vision, and 5Δ exophoria for near. He was given a prescription for +0.75D. sph., O.U., which he wore for a week. He reported no relief whatever.

When tested on the ophthalmo-eikonometer, he was found to have slight left meridional aniseikonia:

R.E., +0.50D. sph., L.E., +0.50D. sph., with 1.0% magnification axis 180°. After wearing this prescription for a month, he reported that the eyes were more relaxed, and there was less blinking and smarting of the eyes.

Second examination. On reëxamination on April 27, 1937, he was found to be emmetropic, and tests on the ophthalmo-eikonometer without refractive lenses showed: R.E., 0.75% ax. 90°; L.E., 1.0% ax. 180°. He was given this prescription in fitover lenses over planos. These proved to be superior to his previous glasses, so he was given the prescription in permanent form.

On December 6, 1937, he appeared at a clinic seminar conducted by the late Dr. Bielschowsky. The patient reported that he was no longer aware of headaches at all. He had often checked himself to be sure the headaches were real, by temporarily removing the glasses. He had occasionally tried to read a few minutes without the glasses, but invariably suffered a headache. He was no longer annoyed by photophobia, burning of the eyes, or strain on watching moving objects. The reading required in his work no longer gave him such discomfort.

In commenting on the case, Dr. Bielschowsky said, "It is hard to understand how an anomaly can cause trouble some times, and can then disappear, and come back." (He meant prior to wearing the glasses.) "I think one has to assume that where nothing can be found but aniseikonia, one has to wonder if other factors have to be considered, such as physical fatigue, excitement, or worry, because if the aniseikonia would be the only anomaly we would not understand how there could be any free intervals at all."

Third examination. On February 1, 1946, the patient was again examined. He had been wearing the plano-aniseikonic glasses for nine years. His vision had remained good, but he was complaining of difficulty with reading. (Aged 42 years, this visit.) He complained that his migrainelike headaches had returned. There were premonitory flashing lights. In eight days, he had had five severe headaches. He was working long hours in spite of frequent colds and fatigue.

External and ophthalmoscopic examinations were normal. The keratometer reading was: R.E., 44.75, 45.50, with a −0.75D. cyl. ax. 180°. L.E., 44.75, 45.25, with a −0.50D. cyl. ax. 180°. The subjective refraction was: R.E., −0.50D. sph., 20/20+; L.E., −0.25D. sph., 20/20+. The dynamic crossed-cylinder test indicated that an add for near was required: +1.00D. sph., O.U. at 16 inches.

Diplopia tests showed orthophoria for distant vision, and 5$^{\Delta}$ exophoria for near. The ophthalmo-eikonometer with the above refractive prescription measured: R.E., 1.5% ax. 90°.

He was given a pair of glasses: R.E., −0.50D. sph. with 1.25% ax. 90° (in fitovers); L.E., −0.25D. sph., and an additional pair of fitovers for reading, consisting of +1.00D. sph., O.U.

On June 13, 1946, he reported that the glasses were quite satisfactory. There had been a few headaches since he received them, but they were not severe. Therefore, the above prescription was made up in permanent bifocal form.

CASE 3

G. K., a white man, was first seen at the age of 16 years, in December, 1936. His chief complaint was slow reading. He admitted some fatigue after prolonged reading, but seldom had headache or eye strain. He had been examined by an ophthalmologist three years previously, and had been given convergence exercises.

History. His past history was normal. He had a sister with squint, and a brother with myopia and color blindness. A complete physical examination of the patient was found negative. External and ophthalmoscopic examinations of the eyes were normal.

Keratometer readings were: R.E., 42.00, 42.25, with a −0.25D. cyl. ax. 180°; L.E., 42.12, 42.37, with a −0.25D. cyl. ax. 180°. The subjective noncycloplegic refraction was: R.E., +0.50D. sph. ⊂ +0.25D. cyl. ax. 180°, 20/15; L.E., +0.50D. sph. ⊂ +0.25D. cyl. ax. 180°, 20/15.

There was esophoria of 2$^{\Delta}$ for distant vision, and an exophoria of 2$^{\Delta}$ for near. Dominance was left eye, right hand. Tests on the ophthalmo-eikonometer without refractive correction showed: R.E., 1.75% ax. 90°; L.E., 0.75% ax. 180°. Next day the test was repeated and R.E., 1.75% ax. 90° was found, so he was given this prescription in a fitover over plano lenses.

After a month, he reported improvement in his reading, and less fatigue. He was

tested five times on the ophthalmograph, which is an instrument that photographs eye movements while reading unfamiliar material. This test is considered unreliable when used in this way, but it did seem to indicate improved reading while wearing the aniseikonic glasses.

Second examination. He was reëxamined in December, 1937. On tests with the ophthalmo-eikonometer identical readings were found. He stated that his glasses had helped him in his school work. His school registrar reported February 24, 1937: "G. K. is doing a good job. He tells me that he feels that his glasses are helping him appreciably. You will be interested to know that he says his reading speed has increased about 50 percent already. Although he is undemonstrative and rarely shows enthusiasm, he is greatly encouraged by this development."

On September 15, 1943, a letter was received from G. K. from an Army camp. He requested another pair of his plano-aniseikonic glasses. In January, 1946, he again wrote, stating that his glasses had worn out, and that he wished to get another pair of the same prescription.

SUMMARY

Three cases of aniseikonia in emmetropia are reported, showing relief of symptoms from 8 to 10 years each. Of these cases, one was studied by the late Dr. A. Bielschowsky.

USE OF THE GONIOLENS FOR DIAGNOSIS OF RETAINED FOREIGN BODY IN THE ANTERIOR CHAMBER

MERRILL J. REEH, M.D.
Portland, Oregon

It has been said that a great number of errors encountered in the practice of medicine are the result of omission rather than commission on the part of the physician. Frequently, because of shortage of time or mental inertia, one fails to use all of the facilities readily available in an effort to learn more about an eye. The following case is not in itself unusual and has undoubtedly been encountered by numerous ophthalmologists before, yet it serves admirably to emphasize the need for more frequent use of gonioscopy.

CASE REPORT

Mr. X., a young man, came to my attention on July 28, 1947, because of a red, moderately painful, irritable right eye. He stated that a foreign body had entered the eye about 14 years before while he was working on a farm repairing machinery. At that time he struck the wheel of a tractor with a dirty hammer and at the same moment felt something strike his right eye. Several days later an X-ray film was taken and revealed a foreign body in the globe. A cataract had also developed in the interim. An unsuccessful attempt was made to remove the foreign body with a magnet. The patient was told that the foreign body was nonmagnetic and was located behind the opaque lens in the vitreous chamber. The eye became quiet in due time. On a subsequent occasion, X-ray films of his eye

were taken in another city and he was again told that there was a foreign body in the globe. Gonioscopy was not employed at any time.

Examination now revealed a normal left eye with 20/15 vision. The right eye showed a 10-degree divergence. It was moderately injected, principally in the pericorneal region, more pronounced in the lower half of the globe. The pupil was about 3 mm. in diameter and reacted sluggishly to light. The lens was cataractous and about half absorbed. The slitlamp revealed epithelial edema (bedewing) in the lower third of the cornea. A small corneal scar was also visible. There was a slight flare with a few cells but no keratic precipitates. The tension was: R.E., 6 mm. Hg (Schiøtz); L.E., 17 mm. An X-ray film demonstrated a faint opacity in the region occupied by the anterior segment. With a large-size Troncoso goniolens* in position, the angle was studied by means of a loupe and a small flashlight. A small, black, oblong foreign body was found lying in the angle at the 6-o'clock position in such a manner that the opaque sclera prevented its direct visualization.

After the acute inflammation was brought under control, the foreign body and the remainder of the opaque lens were removed. A subsequent X-ray study showed that the faint opacity previously noted in the anterior-segment area had disappeared. The foreign body was found to be a small piece of organic material, either wood or weed stem. The eye healed uneventfully and the inflammation promptly subsided. Eight weeks after the removal of the foreign body the vision was correctible to 20/25.

Discussion

This foreign body, which was entirely invisible, was easily and accurately located with the aid of gonioscopy. If it had been permitted to remain, the eye might ultimately have been lost. Sympathetic ophthalmitis, while extremely rare, was always a threat as long as the eye remained irritable because of a retained foreign body.

CONGENITAL RETINAL FOLD WITH VITREOUS DISORGANIZATION*

A case report

I. J. Eisenberg,† M.D.
Philadelphia, Pennsylvania

In 1928, the first case of congenital retinal fold was reported by Ida Mann in the *Transactions of the Ophthalmological Society of the United Kingdom.* In 1936, six more cases were reported by her. In the same year, Weve reported eight cases of the same condition, which he called "Ablatio Falciformis Congenitalis." Other cases were reported by Ancona (1935), Kiewe (1936), Tillema (1937), Theodore and Ziporkes (1940), Van Manen (1941), and Gartner (1941).

This congenital defect is characterized by the presence of folds involving the inner layers of the optic cup (the retina without the pigment epithelium) which projects into the vitreous. From the cases reported, the general opththalmoscopic picture can be summarized by (1) the solid appearance of the fold, (2) branches of the retinal artery on the fold, (3) septumlike connections with the retina, (4) attachment anteriorly to the ora serrata, (5) strands passing to the lens near the equator, (6) clear vitreous and lens.

Case report

The case presented is that of a young girl, T. M., aged eight years, with a history of poor vision in the left eye discovered during a routine examination five months before be-

* Read at the meeting of the Eye Section, Philadelphia County Medical Society, April 2, 1947.

† Clinical Assistant, Wills Hospital, Clinic of Dr. Louis Lehrfeld.

ing seen by us in the clinic. Close questioning of a rather intelligent mother did not reveal any history of injury or inflammation involving her daughter's eyes.

History. The family medical history showed that the father had had a detached retina (spontaneous) with secondary glaucoma about 10 years ago, resulting in enucleation. Three other children in the family were all apparently normal. The child's past medical history told that she had had whooping cough at the age of three years, measles at four.

Examination. The adnexa were normal. E.O.M. appear to be normal. There was no evidence of nystagmus nor strabismus. The pupils were equal and reacted to light and accommodation. Vision was: O.D., 20/20; O.S., light perception (questionable).

The fundus examination showed the media of the right eye to be clear; the disc well defined and normal in color; the vessels normal. The lens of the left eye appeared to be clear; the vitreous was hazy with many fine dustlike opacities; the retina could not be visualized at this time. With a +12 lens, a large white area was seen between the 7- and 9-o'clock positions. At this time the large gray-white mass appeared to be extending anteriorly to the posterior part of the lens and near the ora serrata and posteriorly into the vitreous.

Under slitlamp examination, the cornea appeared to be normal; the anterior chamber was normal; X-ray studies of the orbit appeared normal, except for a small opacity near the posterior cortex at the center. The anterior vitreous showed fine opacities made up in the form of a reticulum. Strands were present which appeared to run from the mass horizontally and temporally near the posterior surface of the lens.

The mass transilluminated poorly; tension was normal; X-ray studies of the orbit showed no evidence of calcification.

Laboratory studies. The blood count was in normal range; Wassermann test was negative.

Course. Although no medication was prescribed, the patient was observed at frequent intervals. Within a period of about two months, although opacities were still present, the vitreous appeared to clear sufficiently so that a view of the retina was possible. An examination of the fundus with a +12 lens showed a large gray-white area between the 7- and 9-o'clock positions. The mass appeared to extend into the vitreous from the disc area and, anteriorly, to the posterior part of the lens and ora serrata. The area tapered off and appeared to fold into the retina. The temporal side of this mass presented a sharply demarcated surface seeming to fold under itself. Small minute blood vessels appear on its surface. Just posterior to the lens, strands could also be seen running horizontally from this mass, temporally. Inferiorly, when the eye was well dilated, a small grayish white mass could be seen near the ora serrata, which had, apparently, no connections with the larger mass.

Diagnosis. The differential diagnoses considered in this case were: A. Inflammatory causes—(1) cyclitic membrane, (2) retinitis proliferans, and (3) detached retina. B. Neoplastic causes—(1) retinoblastomata and (2) melanoma of the choroid. C. Congenital defects—(1) persistent tunica vasculosa lentis, (2) fibroblastic remains with Cloquet's canal, and (3) retinal fold.

The history, the ophthalmoscopic appearance, the clinical course, and the associated findings ruled out all the above etiologic factors except retinal fold.

Thus the solid appearance of the mass with the underfolding of the temporal surface, the extension from the disc to the ora serrata, strands passing near the lens, the exclusion of the other etiologic factors, and the lack of any specific history indicated that this was a congenital retinal fold. The partial disorganization of the vitreous may either be secondary or it may be entirely unrelated to this defect.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

March 3, 1947

DR. BENJAMIN FRIEDMAN, *president*

OFFICE PROCEDURES IN BACTERIOLOGY

DR. FREDERICK H. THEODORE spoke on this subject during the instruction period.

BETA IRRADIATION IN OPHTHALMOLOGY

DR. CHARLES E. ILIFF spoke of the various uses of beta irradiation in ophthalmology and illustrated his talk with slides and motion pictures. He said that beta rays possess the same qualities as other rays in the power of selective tissue destruction, but in contrast to gamma rays their penetration is shallow. In no single case has any damage to the lens been observed either clinically or experimentally.

Dr. Iliff said that excellent results have been obtained in the treatment of vernal conjunctivitis. Recurrences are less frequent, and when these do occur, are less severe. In anterior ocular tuberculosis, beta therapy seems to shorten the course and decrease the severity of the symptoms with less residual scarring of the cornea. Irradiation, though, did not prevent future tuberculous recurrences. Dr. Iliff said that small benign tumors of the lid and anterior segment can be easily and safely removed with excellent cosmetic results. In corneal scars, where vascularization is a prominent feature and where there is still activity, irradiation appears beneficial. In old calcified and dense scars, treatment is not successful. Superficial vascularization after keratectomies and keratoplasties can be controlled with beta therapy. Encouraging results were also obtained in the treatment of acne rosacea keratitis. Dystrophies, sarcoid, lupus erythematosus, pemphigus, punctate keratitis, and corneal ulcers due to pyogenic infections, are not improved by beta rays, and may be made worse by their use.

UVEITIS WITH HYPOPYON AND RECURRENT GENITO-ORAL OPHTHOSIS (BEHCET'S SYNDROME)

DR. HELEN O. CURTH presented the case of a 27-year-old man, with left postoperative anophthalmos and almost complete loss of vision of the right eye. These findings are the end results of recurrent attacks of uveitis. Two years after the onset of the disease, the patient showed hypopyon. The patient also suffered from recurrent genital ulcerations and recurrent oral aphthae. This syndrome has been described by Behcet. Various kinds of local and systemic treatment proved futile. Dr. Curth said that patients with only two manifestations of the triad are considered abortive cases of the disease. A girl with recurrent genital and oral aphthae was also shown. These two patients did not show erythema nodosum, which is frequently seen in patients with Behcet's syndrome.

Dr. Curth, in discussing the differential diagnosis, mentioned other systemic diseases with manifestations in the eyes and on the skin and mucous membranes, such as Reiter's and Stevens-Johnson disease. Dr. Curth concluded that close collaboration of ophthalmologists and dermatologists may prove of great value in the investigation of these diseases.

Discussion. Dr. Charles A. Perera, described the left eye of the first patient. An iridectomy was performed in July, a cyclodiathermy in September, and enucleation in October. Microscopic studies of the globe showed a surgical coloboma of the iris

superiorly and necrosis of the inferior ciliary body resulting from the cyclodiathermy. The underlying pathologic processes included polymorphonuclear exudate in the lower anterior chamber, plasma-cell and lymphocytic foci in the iris and remaining uveal tract, posterior synechia, complicated cataract, complete detachment of the retina following contracture, subretinal hemorrhage, perivascular infiltration of the optic nerve, and phagocytic cells containing blood pigment on the inner surface of the retina and in the optic-nerve head. This eyeball, then, was the seat of a chronic recurrent uveitis and intraocular hemorrhages, followed by the development of a cataract and secondary glaucoma. Dr. Perera said that there was no clue to the etiology, which is believed to be a virus infection by some authors and an allergic reaction by others.

Sarcoid simulating Mikulicz's disease and Parinaud's syndrome

Dr. Isadore Givner presented two cases of sarcoid, one simulating Mikulicz's syndrome and the other simulating Parinaud's oculoglandular syndrome. The first case was that of a colored woman, aged 35 years, with generalized skin nodules a diffuse swelling of the parotid glands, and an enlargement of both lacrimal glands. Tuberculin tests up to 1:100 mg. O.T. were negative. Typical findings of sarcoid appeared in the lung and phalanges. Biopsy of a nodule showed masses of epithelioid and giant cells. No caseation and very little round-cell infiltration were present.

The second case was that of a 15-year-old white boy, who presented a round granulomatous growth on the under surface of the left upper lid of a week's duration. The left preauricular gland was enlarged. Mantoux test, 1:100,000, was positive. Biopsy of the granulation tissue disclosed naked tubercules, typical of sarcoid.

Dr. Givner emphasized the importance of biopsy in suspected cases. He felt that the findings of a positive tuberculin test are in keeping with the trend of considering sarcoid a special type of tuberculosis.

Discussion. Dr. Raymond E. Meek said that anyone who makes a diagnosis of Boeck's sarcoid is to be congratulated. It means keeping in mind this condition and also means careful observation and investigation to establish the diagnosis. Dr. Meek said that Dr. Givner deserves much credit for discovering these two cases and presenting them.

Recognition of sarcoid has a practical aspect in the treatment of uveitis. Many ophthalmologists feel that remote foci of infection are the most important causes of endogenous uveitis, while syphilis, tuberculosis, and other systemic diseases are recognized as causes, but are less important. The usual recognized causes of granulomatous uveitis are syphilis, tuberculosis, brucellosis, sarcoid, lymphogranuloma venereum, and certain fungus infections, according to Alan C. Woods, in his lecture on "The Influence of Hypersensitivity on Endogenous Uveal Disease." (Am. J. Ophth., 30:257-274 (Mar.) 1947.)

Dr. Meek said that he felt that the problem of sarcoid may be of great importance in the treatment of uveitis. Once the problem of the etiology of sarcoid is solved, a new clue may be found for the prevention and treatment of this obstinate affection of the eyes. Woods said, "Nothing can be said of sarcoid, for the specific agent, whatever it may be, has never been isolated and the etiology of the disease is a complete mystery." Dr. Meek concluded by saying that we must continue our efforts in finding the cause of this disease.

Silent dacryocystitis

Dr. Frederick H. Theodore said that routine irrigation of the lacrimal passages in such a manner as to be able to examine the washings will frequently reveal the presence of an otherwise "silent" dacryo-

cystitis. This occurs in some cases with patent lacrimal passages and the complaint of persistent unilateral conjunctivitis. The examination of the washings is accomplished by having the patient sit with his head forward, so that the irrigating fluid comes out through the nose and is caught in the receptacle. The following observations are made: (1) the degree of patency, and (2) the character of the washings—whether shreds, pus, or mucus are present. Cultures and smears may be taken of this washing.

Dr. Theodore mentioned a number of cases of severe unilateral conjunctivitis which had persisted for months. The tear sac in each case had been declared normal because the irrigation had been done with the patient's head backward. By this method, the character of the washings cannot be observed. Treatment by frequent irrigation of the sac was followed by cure. Cultures of both the conjunctivitis and the mucus, revealed the same toxic organisms.

Dr. Theodore concluded that these observations suggest the existence of a subclinical, beginning mucous dacryocystitis, which may go on to frank dacryocystitis if untreated; therefore, the early diagnosis of this condition is of great value.

Dr. George Stine, *presiding*

Central choroiditis

Dr. Fritz Nelson presented a 26-year-old woman who suddenly, a few weeks previously, noticed a spot before her right eye after some domestic excitement. Central vision was measured at 5/100, and refraction revealed a −1.00D. of myopia. Funduscopy presented an area of edema around the macula extending to the disc. There was a crescentric, bright area above the fovea which might have represented either a folding of the retina or a subretinal hemorrhage. Under routine symptomatic treatment, vision improved to 5/15, although the fundus appearance remained the same. A Kahn test was normal, as were the blood count and a complete physical examination. No satisfactory diagnosis had been made.

Discussion. Dr. James Strong said that, although the history was of such short duration, it is most likely that the condition had existed a much longer time and had merely been brought to attention by the excitement. Dr. Leonard Swigert said he had noticed what he felt was pigment formation in the area, so that he deemed it to be a central choroiditis of not too recent origin. Dr. Nelson, in closing, said that the fact that the patient had suddenly noticed a scotoma seemed to indicate the condition to be acute since she would have noticed this before had it been present.

Microphthalmos

Dr. John C. Long presented a 2½-year-old girl with congenital, bilateral microphthalmos. Her prenatal, postnatal, and general history were entirely normal. No other member of the family had ever presented any ocular disease. Examination revealed severe microphthalmos with almost total opacification of both corneas. Vision consisted of light perception in the right eye only. The corneas measured 4.5 mm. in the right eye, and 3.5 mm. in the left. Ocular movement seemed normal and the child seemed physically and mentally normal in all other respects. The mother was of the opinion that both eyes had become larger during the past year.

Plastic and reconstructive surgery of the eyelids

Dr. George A. Filmer presented a com-

prehensive paper on this subject generously illustrated with kodachrome slides of patients in the Eye Department of the U. S. Army Beaumont General Hospital which served as a reconstructive eye center. The most frequent repair job called for was the repair of skin cicatrices. These could often be done by the simple "Z" plasty along the line of the scar. When this failed, a full-thickness skin graft was employed. These grafts were taken from the other eyelid, the retroauricular fold (which source proved exceedingly satisfactory) or the supraclavicular region. A proper pressure dressing must always be applied to these.

In revision of the lower lid at the inner canthus, a pedicle of "Z" flap around the canthus was most used. This often extended from the side of the nose well down over the upper portion of the cheek. If this failed or was not feasible, a skin graft was employed. At the outer canthus, the "Z" flap was also employed whenever possible. An external canthal tarsorrhaphy or the Kuhnt-Szymanowsky repair techniques were used. If too much damage had been done, a fascialata transplant was used as a sling around the whole lower lid.

Revisions of upper lids were accomplished by the routine methods of notch repair, by "Z" flaps, or by skin grafts. Eyebrow grafts were taken from the temple or the retroauricular fold. Eyelash grafts were best taken by vertical sections through the eyebrow. For controlling the slant and appearance of these lashes, the ordinary cosmetic eyelash curlers were recommended. For reconstruction of either lid, the regular Hughes reconstruction technique was employed. If this failed, then sliding flaps, pedicle flaps, and whole-thickness skin grafts were used.

DR. HOWARD F. HILL, *presiding*

OCULAR PROPTOSIS

This subject was discussed by DR. DERRICK VAIL of Chicago in the paper of the evening. The classification of the types of proptosis, correlated with the etiology, signs, and symptoms, and the profuse number of illustrative slides made a very instructive and interesting paper.

Dr. Vail classified ocular proptosis into two main subdivisions: (1) apparent proptosis, and (2) true proptosis. In apparent proptosis, the protrusion of the lids without edema may be a result of fat, familial feature, or asymmetry of face; while protrusion of the lids with edema may be due to ocular causes such as iritis and glaucoma, or due to an inflamed lid caused by chalazion, hordeolum, abscess, lacrimal abscess, frontal sinusitis, periadenitis, trauma, insect stings, trichinosis, and so forth.

In true proptosis, the protrusion may be rapid with edema of the lids, as seen in glaucoma, iridocyclitis, panophthalmitis, cellulitis of the orbit, serous or purulent tenonitis, caverous sinus thrombosis, hemorrhages due to trauma or spontaneous hemorrhage associated with scurvy, anemia, rickets, hemophilia, and so forth. Gradual proptosis without edema may be congenital due to malformation of orbit, an encephalocele, and so forth; it may be due to ocular enlargements as seen in high myopia, buphthalmos, melanoma of choroid perforating posteriorly; or it may be associated with third-nerve paralysis with loss of muscle tone, or after a tenotomy. Unilateral proptosis with lateral displacement may be due to a mucocele or neoplasm from the sinus, exostosis of the orbit wall, meningioma, periostitis of orbital wall, complication of nasal surgery, em-

physema of the orbit, and so forth. Unilateral proptosis with central displacement may be observed in Graves's disease, in paradoxial exophthalmos, in vascular conditions such as arteriovenous aneurysm, varicose orbital veins, cirsoid aneurysm of orbit, or nevi, in association with tumors of the optic nerve. Unilateral proptosis with central displacement is also due to cysts of the orbit, either congenital such as encephalocele, congenital coloboma of choroid and dermoid, or acquired cysts such as the exudative type, traumatic epithelial inclusion, or parasitic. It is observed also with neoplasms either of benign type, such as plexiform neuroma, or of malignant type, primary or secondary.

Binocular exophthalmos may be due to familial congenital malformation, tower skull, Graves's disease, paradoxial or ophthalmoplegic exophthalmos, sarcoma of ethmoid, bilateral sinusitis, neurofibromas, myasthenia gravis, cavernous sinus thrombosis, Mikulicz disease, cranio-orbitofacial malformations such as hereditary craniofacial dysostosis (Crouzon's disease), multiple xanthomatosis (Schuller-Christian disease), and so forth.

Discussion. In the discussion that followed, Dr. Frederick Verhoeff spoke of the difficulties in making a diagnosis in cases of proptosis. He described a case of meningioma in a girl, aged five years, which went around the optic nerve but did not invade the papilla. He said that at the time there was considerable discussion as to whether the lesion was primary in the orbit or not. He felt that if it does occur, it must be very uncommon and that it was wise, in individual cases, to believe that it was not primary. He also mentioned that he has noted errors in making a diagnosis of neurofibroma of the optic nerve when glioma is present and has heard of some cases of glioma associated with neurofibromatosis elsewhere.

Dr. Edwin B. Dunphy added another type of proptosis to those mentioned by Dr. Vail, namely intermittent exophthalmos, usually occurring in an adult when he holds his breath, bends over, or during some athletic event. One eye will come forward as much as 5 to 8 mm. and then recede into the orbit. He had seen several cases, one supposedly due to varices in the orbit which filled up. He tried injecting urethane solution without success in this case.

Dr. H. Frederick Stephens asked about the effect of the meningiomas on the optic foramen and their surgical approach.

Dr. Vail (in closing) said that diagnosis will tax one's ingenuity to the utmost, requiring a most careful history, X-ray examination, including the optic foramina and sinuses as well as the orbit, and examination of the appearance of the orbit, including listening with the stethoscope. He agreed with Dr. Verhoeff that probably gliomas of the optic nerve have been mistakenly called neurofibromas. He mentioned a case of a 10-year-old child who had right ocular proptosis with slight limitation of movement with the characteristic pigment changes of neurofibromatosis in the skin. The child's grandmother had the same skin changes plus typical neurofibromatosis nodules on the entire body. He also has seen the intermittent exophthalmos described by Dr. Dunphy, and said that he believed most hemangiomas of the orbit also show the same type of exophthalmos eventually. He described a case with this type of hemangioma in which the exophthalmos with recurrent subconjunctival and subcutaneous hemorrhages disappeared entirely after insertion of radon into the orbit. In regard to the effect of a meningioma on the optic foramen, he said that he believed that study of the literature, as well as experience, would bear out the impression that one does not get an enlarged optic foramen in the presence of proptosis suggestive of an intraorbital tumor without having intracranial involvement. Therefore he agreed with Dr. Dandy that the real approach is always through the intracranial route and never through the orbital route. Serious

complications may occur using the orbital route, and the frontal approach is hazardous for some time after the orbital approach has been used unsuccessfully.

Reporter.

SOCIEDAD OFTALMOLOGICA DE MADRID

March 21, 1947

The Millard-Gubler syndrome

Dr. Casero presented this subject with reference to a patient who showed the syndrome in an anomalous manner.

Discussion. Dr. Marin Amat said that the symptoms presented in Dr. Casero's case—right hemiplegia, with paralysis of the left external rectus muscle and paresis of the right inferior facial—do not fall within the classical mold of the Millard-Gubler syndrome (alternate inferior paralysis) in that the hemiplegia is on one side and the paralysis of the external rectus (sixth cranial) and of the facial (seventh cranial) on the opposite side, with a lesion in the protuberance of the pyramidal tract before decussation (central neurone) and of the roots of the sixth and seventh cranial nerves beyond their origin in their respective nuclei (peripheral neurones).

In his opinion, this clinical incongruity might be explained by a poor interpretation of the neurologic examination and failure to differentiate between the deviation of the mouth to the right and a right facial paresis (antagonistic symptoms), or perhaps, failure to locate a lesion in the cerebral peduncle and in the protuberance.

The most acceptable explanation is that this is a case of one of those rare crossed (alternate) paralyses limited to the sphere of innervation of the cranial nerves.

Dr. Carreras said that it is evident that the case presented by Dr. Casero is one of a protuberance syndrome, but that it is not a pure example of the syndrome of Millard-Gubler. The lesion is, naturally, in part in the inferior protuberance, since only this localization can explain the simultaneous involvement of the fibers of the pyramidal fasciculus and the root fibers of the sixth pair of the same side. However, in order to explain the syndrome shown by the patient one must surmise that the same lesion extends sufficiently upward to involve the aberrant fibers of the pyramidal bundle which go to the facial nucleus of the opposite side. Thus can be explained the fact that the facial paresis is contralateral instead of ipsolateral, as in the typical Millard-Gubler syndrome. It is also necessary to assume that the lesion extends only to a slight depth in the body of the pons; otherwise, it would involve nerve structures which would greatly increase the symptomatology of the case.

Let us hope that the operation which the patient is soon to undergo will clear up the doubts which we still have with reference to the nature of the lesion. I believe it is a tumor, perhaps a glioma. The papillary edema, which was not present at first, supports the belief in a tumor.

Retinal detachment with cystic formation

Dr. Casero presented the case of a 16-year-old boy, emmetropic, who showed cystic formation in the retinas of both eyes with bilateral detachment. There was a history that two months before the detachment the patient was hit on the forehead. For this reason the author described the lesion as traumatic, since it was possible that the blow was a contributing factor in loosening the retina and causing a detachment. But undoubtedly there had been previously a degenerative cystic process in both retinas.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

FUNDAMENTAL RESEARCH IN OPHTHALMOLOGY

In an article in the April 11, 1947, issue of *Science,* entitled "Fundamental Research in the Clinical Specialties," V. Everett Kinsey, biochemist at the Howe Laboratory of Ophthalmology of Harvard University, analyzes with exceptional acumen the problems connected with basic research in ophthalmology. A discussion of this aspect of ophthalmology seems particularly timely in view of the recent establishment of two new foundations for basic research in ophthalmology on the Pacific Coast.

Kinsey made a survey of the status of fundamental research in the clinical specialties at some of the larger universities and found the situation to be in general unsatisfactory. Research programs were found to be handicapped by inadequate funds and by the fact that neither the well-qualified department heads nor the unpaid clinical staff members were in a position to devote sufficient time to them. The current practice of assigning faculty members from basic-science departments to clinical departments,

and vice versa, with salaries and duties divided, was found to be more often unsatisfactory than satisfactory. Kinsey calls attention to the fact that the number of investigators working in any given field is frequently pitifully small. Glaucoma, for example, is one of the principal causes of blindness in individuals past middle age and yet in the United States at the present time not more than three investigators are devoting half or more of their time to it. He concludes that as a result of these half-way measures the amount of fundamental research in the clinical fields is extremely small and that even if sufficient funds were to be made immediately available few departments would have either the personnel or the programs ready to take advantage of them.

Kinsey then considers the various possibilities for expanding research in the clinical fields. He discusses the advantages and disadvantages of special laboratories for the study of specific diseases, and of special research institutes in which researches relating to a number of specialties could be performed. He concludes, however, that the soundest plan is to establish laboratories in connection with specific clinical departments in the medical school and to staff them with well-trained full-time workers. The principal function of each of these laboratories should be to develop the fundamental aspects of the clinical specialty concerned and to make them available to the postgraduate student. Kinsey states that the experience of the Howe Laboratory indicates that this type of research unit is effective. He feels that although fundamental discoveries have in the past been made by isolated workers devoting their leisure time to research, there is every reason to believe that the coöperative effort of individuals with different backgrounds and training inevitably yields the best results. He believes that research of this kind is essentially a full-time job if facilities and personnel are to be utilized efficiently and if the quality of the work is to compare favorably with that in other branches of science.

In Kinsey's opinion the first step in establishing a research laboratory is to obtain the services of an able director. He believes that in general the head of the clinical department should not also be the director of the laboratory since he hasn't the time for what should be a full-time job in itself. The clinical department head, moreover, is likely to be interested preëminently in the practice of medicine and to lack the scientific background which would qualify him to direct research. He concludes that both positions are of such importance that a parallel administrative organization such as obtains at the Howe Laboratory is to be preferred to a vertical administrative organization.

An important secondary function of the research laboratory should be the postgraduate teaching of the basic sciences as applied to the medical specialty concerned. Kinsey believes, however, that in no case should this teaching function be allowed to occupy over a quarter of the staff's time. He discusses in detail the question of the academic standing, remuneration, and tenure of the laboratory staff and expresses the opinion that the system of rank should be comparable to that of career men in other academic fields rather than to that of the clinical department. In the latter, outstanding physicians, devoting only a small fraction of their time to the medical school, may hold relatively low rank. In order to avoid the appearance of discrimination, the titles of the laboratory staff should be different from those of the clinical staff, for example, "professor of ophthalmological research" rather than "professor of ophthalmology." If capable men are to be obtained and retained, salaries must compare favorably with those in basic-science departments and industrial-research laboratories and reasonable tenure must be assured.

The objection may be made that if the basic scientist devotes the time and effort necessary to familiarize himself with both the medical and laboratory aspects of a

specialty, he may not be able to maintain the same proficiency in his basic field as the more specialized worker. Kinsey refers to the saying that such a man may be neither fish nor fowl but answers the objection by pointing to the example of the biochemist who is both biologist and chemist. He believes that this "hybrid" has contributed more to the knowledge of biochemistry than either the biologist or the chemist and suggests that in the future the great contributions to the advancement of knowledge in scientific medicine may well come from another hybrid who might be called the "medical scientist."

This article of Kinsey's comes at a time when the importance of the basic sciences in relation to ophthalmology is becoming more and more widely recognized. In this connection the role of the American Board of Ophthalmology in stimulating basic-science teaching and, indirectly, basic research should not be overlooked. Nevertheless, the position of the full-time investigator in ophthalmology is frequently not an entirely happy one. Workers devoting virtually their entire time to ophthalmologic problems have complained of relative isolation and of the fact that their specialization has precluded, or at least handicapped, the possibility of their returning to the basic-science departments. They have found, moreover, that their chances of advancement are poorer than they would be in comparable positions in the basic-science departments; in the latter there is of course always the possibility of becoming a department head.

As ophthalmologic research laboratories increase in number the factor of isolation will be reduced and it is to be hoped that the new laboratories will be organized in such a way as to provide adequate rank and remuneration. Kinsey's suggestion that the research laboratory be separated administratively from the clinical department has much in its favor, and the Howe Laboratory testifies to the effectiveness of this method. On the other hand there are several institutions, notably the University of Pennsylvania and Johns Hopkins University, in which the vertical type of administration has functioned exceedingly well. This is clearly due to the fact that the department heads in these institutions have been outstanding basic investigators as well as clinicians. Unfortunately this happy combination must be considered most unusual. Whatever the administrative set-up, however, there is no doubt but that in the future our specialty will be advanced in direct proportion to the output of the "medical scientist," working either alone or in coöperation with the clinical ophthalmologist.

Phillips Thygeson.

CRITICISM OF THE AMERICAN BOARD OF OPHTHALMOLOGY

Some workers in the field of education for the practice of ophthalmology may have felt concern as to certain parts of the address delivered by President Alan C. Woods at the annual meeting of the American Academy of Ophthalmology and Otolaryngology in October, 1947. Yet frank and understanding criticism in any field of human activity is desirable, and often serves the very admirable purpose of leading to improvement in method. On the other hand it is always proper to inquire whether the criticism is well founded; in other words one function of the critical faculty is to criticize the critic.

The American Board of Ophthalmology, founded 30 years or so ago, represented the carefully studied conclusions of as fine a group of stalwarts as the field of medical education has ever known. It would have been strangely superhuman if that group's judgments and procedures had been entirely free from error or doubt or beyond improvement. It must also be recognized that no large and greatly varied mass of conditions is ever uniformly well met by any set of regulations. But the quality that perplexes us in President Woods's address is that it seems at times to present criticisms which,

if taken too seriously, might endanger the whole fabric of the Board's endeavors.

What have been the main purposes of the American Board of Ophthalmology?

It has been repeatedly emphasized that no such Board could demand or achieve uniform perfection in the would-be specialist's scientific knowledge of his subject; but that the Board's desire should be to determine whether the specialist possessed such proficiency as to render him a safe practitioner of ocular diagnosis, therapeutics, and surgery. It is obvious that in the minds of different examiners there may exist appreciable variation as to what constitutes such proficiency, and it cannot be doubted that such variation has worked at times to the advantage or prejudice of individual candidates. But in a general way such broad conception of the Board's requirements has fitted the needs of the public as to the practice of ophthalmology.

The Board had to realize the existence not only of varying intelligence and training among its candidates, but the basic fact that teaching institutions throughout the country were not of uniform efficiency, but emphasized in unequal degree the significance of different phases of the subject of ophthalmology, now this, now that, according to the strength or weakness of individuals or teachers or equipment. Certain outstanding educational groups have shown a tendency to prepare students to assume the capacity of teachers rather than of private practitioners, and have therefore required exceptionally lengthy periods of internship or residency. But to make this system widespread might have a dangerous tendency to defeat the general educational purpose, by encouraging the existence of great numbers of uncertified, and therefore of poorly rather than well-trained specialists.

Woods objects, as others have objected, to the Board's requirement of a minimum of one year of internship in a general hospital. This problem has given rise to much debate. But, taking into account the still inevitable inequalities of method and efficiency in general and technical education, and the variations in human personality, the rule is probably much more frequently wise than foolish. Woods objects that the system wastes precious time. What system of training in a clinical institution does not waste precious time? How large a proportion of the activities of a student nurse is free from this accusation? How much of the time of an intern or resident in the great institution over which Woods presides at Baltimore is completely exempt from such a criticism? The important question with regard to the preliminary or general hospital internship is whether it makes the practitioner of ophthalmology better able to understand the relation of ophthalmology to general medicine, and not only the technical but the human problems of the patients' lives; and again it must be remembered that the American Board exists primarily not to create research and laboratory workers but to satisfy the clinical needs of the general community.

The presidential address further takes exception to the tendency to make the certificate of the examining board a condition for appointment or promotion in general or hospital staffs. This condemnation is even extended to include the action of the United States Veterans' Administration in requiring that persons appointed to its attending or consulting staffs be diplomates of the Boards representing their specialties, and also in granting a 25-percent increase in salary to members of its full-time staff who obtain certification.

But we cannot escape the truth that human nature very generally needs incentives for the performance of desirable acts. At the inception of the American Board for Ophthalmic Examinations (the original name of the present Board of Ophthalmology) this fact was recognized through adoption by the American Ophthalmological Society of the rule that future candidates for its membership must have received the Board's certificate; and by the American Academy of

Ophthalmology and Otolaryngology of the rule that candidates for membership must possess the certificate either of the Ophthalmologic or the Otolaryngologic Board. It is also true that these requirements have been a great stimulus to the success of the activities of those Boards. Are we now to dispense with this kind of incentive?

It is curious that, in considering weaknesses associated with the working of the examining boards, the Woods presidential address does not call even passing attention to the fact that the certificate of membership in the American Academy of Ophthalmology and Otolaryngology fails to indicate upon which Board certificate the approval for membership in the Academy is based. Yet the certificate of membership in the Academy is displayed in thousands of offices all over the country as one of the criteria of efficient training, and the certificate of the Board of Otolaryngology, usually rated as rather easier of attainment, will undoubtedly be sought by many Army and Navy veterans in preference to the certificate of the Board of Ophthalmology, whose greater emphasis upon basic and theoretic knowledge has aroused more fear and trembling among candidates.

There is at least the merit of frankness in the reminder that some 12 years ago the Medical Board of the Johns Hopkins Hospital adopted a resolution to the effect that the Board was opposed "to the principle that certification by any of the specialty boards should be a condition of appointment or promotion to any position on the staff of the Johns Hopkins Hospital"; and that the secretary of that Board was requested to notify such other hospitals as he deemed proper of the action of the Board in this instance. This was a rather unpleasant slap at standardization! As regards the principle involved, we are assured (in the presidential address) that the American Board of Ophthalmology does not appear to have recanted in any way, and the writer says: "To this activity of the specialty boards Dr. Chesney has applied the adjective 'pernicious.' In this I fully agree with him."

Yet surely in this country, with its peculiar balance between Federal and State constitutional rights, some such measures aimed at professional standardization are not only permissible but desirable; and the principle of advantage pertaining to the certificates of the specialty boards is a valuable step in the direction of such standardization. Is it not possible to retain the advantages of this principle and practice, without serious disadvantages? Would the writer favor some elaborate system of control through the Federal Government, under a general scheme of socialization?

Woods's fear that research institutions may suffer from the application of any such general principle or rule is surely exaggerated, because the good sense of the examining boards is bound sooner or later to recognize any such special exemptions as may prove necessary in the case of research workers. Equally exaggerated, it may well be argued, is the further pronouncement that the present policies of the national societies lie "squarely across" the pathway along which ophthalmology must henceforth develop. And surely it can be said that, subject to recognized standards of excellence, "the national societies" already comply with Woods's desideratum that they "open their ranks, without distinction or the creation of different classes, to all medical men or scientists whose primary interest lies in the field of ophthalmology." But it is hardly to be denied that a scientist cannot be regarded as an ophthalmologist unless he has a basic and adequate understanding of the clinical problems of ophthalmology, such as is demanded by the American Board.

W. H. Crisp.

OBITUARY

DR. LOUIS STORROW GREENE (1872-1947)

On November 12, 1947, during his sleep, Dr. Louis Storrow Greene was called to his reward which he richly deserved. He had been at work most of the day in his office and after dinner had conducted a meeting of the vestry of his church until after midnight.

LOUIS STORROW GREENE

He had a heart block, and was completely unconscious of the approach of the end of his life when he retired.

Dr. Greene, while of Virginia ancestry, was born in Columbus, Georgia, November 19, 1872. He was the youngest son of Anne Appleton Storrow and William Spencer Greene. His father, at that time, was a construction engineer of railroads: hence his early education was in the deep south, Alabama, and later in Virginia. His premedical work was at the University of Virginia from which he was graduated in medicine in 1895. He spent the next two years in New York doing postgraduate work at Charity Hospital and the New York Eye and Ear Infirmary.

In 1897, he came to Washington and associated himself with Dr. William H. Wilmer with whom he remained in the practice of ophthalmology until 1915. During these years, he taught diseases of the eye at Georgetown University Medical School. He served as ophthalmologist to the National Medical Advisory Draft Board during World War I; and was ophthalmologist to the Episcopal Hospital Aviation Unit.

He was associated in various capacities on the staff of the Episcopal Eye and Ear Hospital, being the last of the staff that began service in the present hospital. He was a senior surgeon at the time of his death.

Dr. Greene was a member of the American Medical Association, District Medical Society, Washington Ophthalmological Society, French Society of Ophthalmology, and of the American Ophthalmological Society, of which he was president in 1936.

Dr. Greene was a sound ophthalmologist, well rounded in the practice of his art. He was a very skillful surgeon and a keen diagnostician. His advice was often sought by younger colleagues as a consultant. His great joy was in selecting younger men and helping them start their medical careers: many of them owe their more rapid advance in their practice to his support and encouragement.

He was a loyal friend and a delightful companion. His vacations were often spent in hunting and fishing trips, on many of which I accompanied him. He had a keen sense of humor, was adept in the verbal passage of arms, in which he usually bested his adversary although he never left a sting behind.

His religious life was full, for he was a strong lay worker in his chosen church, the

Protestant Episcopal. He was senior warden at the time of his death.

He was married in 1903 to Miss Louise Packwood Burke who survives him together with two children, a son and a daughter. John W. Burke.

CORRESPONDENCE

An ocular test for penicillin susceptibility (dermatitis venenata)

Editor,
American Journal of Ophthalmology:

It has been my observation that, as the years roll by, people in the United States are getting more and more allergic. In this short report I do not wish to discuss allergy and its many vague and not yet understood ramifications, but briefly to call attention to one of our most modern drugs and to suggest an ocular test which may be of benefit.

I wish also to warn against the promiscuous use of this relatively new drug which is a most valuable adjunct to our pharmacopeia and which, as we all know, has proved its worth when used with reason and some caution.

When any new drug is discovered and is found worthy in certain pathologic conditions, we are sometimes fooled into the belief that we have a panacea for all the ills to which the flesh is heir. The medicine I wish to discuss briefly is penicillin. From the literature I am receiving, I find that penicillin is being used for almost every known ailment from treatment of the vagina with vaginal suppositories to treatment of the eyes with ophthalmic ointment.

In my own practice I have known and seen three cases whose reactions were far from those desired. Two cases for which the drug was given were of indefinite corneal infiltrations whose etiology could not be positively established, and one was a case of lid infiltration which later developed a Vincent's angina. The patients were all given "big shots" of penicillin. Two of the patients developed urticarial and vesicular eruptions while the other acquired a general diffuse desquamation which took some time to cure. One of the patients died.

I know that some cases are emergency ones and, when it is a matter of life or death, minutes count. There is no time to test the patient's reactions. But in those cases where time is not so valuable, and the intradermal or small dose injections have been tried, I wish to offer the following simple ocular test as an added precautionary measure and a safe way to determine the susceptibility of the patient to the drug.

The test is as follows. One eye is selected; the other used as a control. Penicillin ophthalmic ointment (calcium) is instilled in the lower cul-de-sac of the eye three times a day; the excess of the ointment is wiped off with sterile cleansing tissues. The eye should not be washed either before or at any time after the instillation of the penicillin. A positive reaction is manifested on the 4th or 5th day by a thickening of the lids, with a brawny desquamation and intense itching. If the finger is gently passed over the skin of the lids there is a sensation as if the finger were passed over very fine sandpaper. The upper lid is usually more intensely affected than the lower lid. Strangely enough the conjunctiva and cornea are unaffected, the reaction being confined exclusively to the skin of the lids.

This test, I believe, will assist materially in diagnosing the susceptibility of individuals to penicillin. Since sensitivity to penicillin is usually manifested by skin lesions, it is my opinion that this test would be a very good indication of general sensitivity. In those cases which showed skin-lid reactions, the conjunctiva and cornea were positively *not* affected.

New York, New York.

BOOK REVIEWS

THE OCULOROTARY MUSCLES. By Richard Gordon Scobee, M.D. St. Louis, C. V. Mosby Co., 1947. 359 pages, clothbound, illustrated. Price, $8.00.

This is the first textbook on the extraocular muscles in the past 11 years and one of the most effective that has been written on the subject. A difficult and controversial division of ophthalmology is logically and clearly handled and, perhaps equally important, the book is interesting and readable. The underlying philosophy owes much to the work of the late F. Bernard Chavasse, a writer on the subject who has not received the attention that he has deserved.

Scobee's monograph begins with anatomic and physiologic studies. Photographs of an ophthalmotrope are utilized to indicate the attachments and functions of the oculorotary muscles. Diagrams aid materially in the interpretation. The concepts of muscle action are so well given as to relieve the obscurity engendered by the tables of straight and tilted blocks depicted in most texts. The 2nd to the 6th chapters deal with additional fundamentals of ocular deviations, such as the underlying neuromuscular mechanisms and elementary laws governing the action of the oculorotary muscles. Section II covers the latent deviations, the etiology, as well as prescriptions, and is separate from the rest of the book. Section III contains a discussion of the manifest deviations, and Sections IV and V deal with the diagnosis and treatment of the deviation. One of the best chapters is that on the "Analysis of the Case" wherein is described the routine employed by the writer.

Almost every ophthalmologist is interested in the surgical treatment of squint because, in many cases, surgery is necessary for a cure whether or not orthoptics or spectacles, or both, have been employed, and furthermore most ophthalmologists are interested in surgery. The chapter on the surgical principles indicates that the author believes in the theory followed in orthopedic practice of weakening the antagonistic muscles in cases of underactivity of a muscle rather than direct attack on the affected muscles. He does not advocate any specific surgical technique, being satisfied with the enunciation of the general principles of corrective surgery. He points out convincingly the importance of proper handling of the check ligaments after having previously clarified their anatomy. A careful study of the book is the best argument for a complete analysis of each muscle case including the findings on the operating table when surgery is indicated. From a perusal of the earlier chapter one can analyze the muscle or muscles at fault in a given case and treat the patient intelligently and individualistically. The findings under anesthesia must be used as the final criterion as to the surgery to be undertaken.

This splendid monograph will help ophthalmologists to an understanding of the modern concepts about the extraocular muscles and may lead them to abandon the indiscriminate recess-resect operations which have tended to be the only procedures employed by many ophthalmic surgeons.

The book is compact and well printed on good paper, with many excellent cuts and photographs that illustrate the text effectively and aid in the interpretation of otherwise difficult ideas. This is an outstanding contribution to ophthalmic literature.

Lawrence T. Post.

HEADACHE. By Louis G. Moench, M.D. Chicago, The Year Book Publishers, 1947. 207 pages, 55 illustrations. Price $3.50.

The author divides the subject into chapters dealing with pathologic anatomy and physiology of headache; headaches from intracranial pathology, spinal puncture and ventriculography; cranial nerve neuralgias; headache of ocular origin; headache of nasal origin; headache from pathology in the neck; headache from systemic disorders;

histamine headaches; migraine and headaches of emotional origin.

The first chapter opens with the statement that "no understanding of headache is possible without a comprehension of the pain-sensitive structures of the head and the disturbances which bring about their stimulation." Illustrated by excellent line drawings the various sensitive structures are discussed and the regions to which the pain is referred outlined. Of particular interest to the ophthalmologist is the frequency with which pain from stretching or irritating arteries is referred to, or behind, the eye. For example, the intracranial segment of the internal carotid artery, when stimulated, refers pain behind the eye and low in the temporal region. The middle cerebral artery and the sensitive proximal portion of the anterior cerebral artery refer the pain in and behind the eyes.

The chapter on ocular headaches consists of 11 pages in which the various ocular headaches are discussed briefly. For the small space devoted to this subject it would seem that too much emphasis has been placed on aniseikonia.

The book presents an excellent exposition on the underlying mechanism of headache together with a discussion of the areas to which the pain is referred.

The makeup of the book, the paper and the binding are all good.

Frederick C. Cordes.

CENTRAL AND INDIRECT VISION OF THE LIGHT-ADAPTED EYE. By Viggo Clemmesen. Acta Physiologica Scandinavica, 9:1-206 (Supplement 27), 1947.

This monograph with an extensive bibliography is written in English and has a summary in Danish. It is a report of the author's extremely thorough and capable investigation of indirect vision which he carried out because knowledge of the subject seemed rather deficient.

The first chapter is devoted to an analysis of the visual sense on the basis of the literature and for this purpose the subject is divided into light sense and physiologic resolving power. The first factor is measured by the discrimination factor and the second is not dealt with, in order to keep the investigation within manageable bounds. Under the heading, physiologic resolving power, an account is given of the possibilities of exact localization of image point in the monocular field, as well as the importance of optical factors, especially the resolving power of the optical system of the eye and the anatomic structure of the fovea. A functional unit is defined as the number of cones which are connected to the same optic ganglion cell through a conducting neurone. At the fovea the functional unit must consist of at least one cone. In the second chapter indirect vision is considered under the same headings.

In the second part the author describes his own investigations which consist of comparative sense-physiologic experiments on central and indirect vision. Experiments on the following functions are recorded: the minimum separable, perception of movement, form sense, aligning power, and discrimination of thickness of line.

The discrimination of thickness of line must be interpreted as a function of the intensity discrimination (light sense) when the object exceeds a certain minimum size. The minimum separable for objects illuminated from before may also serve as a measure of light sense.

Physiologic resolving power is measured by the minimum separable for luminous squares of threshold brightness on an unilluminated ground, or by the minimum separable for an unilluminated square on a luminous ground of threshold brightness. Perception of movement of a luminous point on an unilluminated ground can be used as a measure of physiologic resolving power and so can the form sense under certain conditions and with certain reservations.

The aligning power is of a complex nature. It is a function of physiologic resolving power and of the intensity of discrimination.

The physiologic resolving power yields information on the retinal structure and is, therefore, of the greatest interest for comparisons of central and indirect vision. Indirect vision begins to act at a distance of 2.7 inches from the center of the visual field; even at this small eccentricity the minimum separable is larger than at the center. The physiologic resolving power decreases rapidly with eccentricity irrespective of the structural limits in the retina (rod-free area). The size of the functional unit increases with eccentricity up to three degrees in the horizontal meridian and two in the vertical. Outside these eccentricities the units are no longer functionally separated, and it must be assumed that the nerve impulse spreads through horizontal neural connections. The variation in size of the functional unit within the fovea is caused by variations in the diameter of the cones and outside this area not only by the variations of the distances between the cones but also by the number of cones connected with each nerve fiber.

This necessarily brief glance into this very interesting monograph cannot hope to do more than suggest the pleasure that any reader who is interested in physiologic optics will derive from studying the original.

F. H. Haessler.

HANDBOOK OF OPHTHALMOLOGY. By Ignacy Abramovicz. Warsaw, Poland, Scientific Publications of the Medical Institute, 1947. 580 pages. Price, not listed.

Abramovicz, formerly professor of ophthalmology at the Medical School of Vilno, is at present director of the ophthalmological department of the Medical Academy at Danzig. This handbook evinces a mastery in condensing the entire domain of ophthalmology into a brief survey for the medical student and in selecting for more significant description those areas of ophthalmology, orientation in which is of greatest value to the general practitioner.

It is essentially a practical treatise, compiling massive data based on factual foundations and making no pretense to include the newer data or even to point out the directions of research. The chapters on trachoma, and ocular injuries are quite comprehensive. For the rest, the book follows the traditional pattern of devoting the first chapters to the anatomy, physiology, and embryology of the eye, with a special chapter on this domain in the newborn and infants. Refraction and motor anomalies are covered in some detail, and ocular surgery is completely left out.

The chapters devoted to ocular diseases present accurate, balanced, dependable descriptions, made more persuasive by profuse and excellent illustrations. The book contains 256 illustrations, some of which are reproductions from the literature, and 14 plates of fundus photographs in color; the illustrations are particularly numerous in the chapters on diseases of the orbit, lids, lacrimal apparatus, and the cornea. The printing is unusually good for publications received from this part of Europe. It was done in Sweden, as a contribution of the Swedish government to the cultural progress of Poland. While there is nothing new in this handbook, it undoubtedly represents a significant contribution to the ophthalmologic needs of Poland, for to our knowledge there was no handbook of a similar nature in the Polish language.

Ray K. Daily and Sylvan Brandon.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjuctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Gát L. **Topographic study of the insertions of the rectus muscles.** Ophthalmologica 114:43-51, July, 1947.

Post mortem measurements of the width in equatorial direction and the distance from the corneal margin of the insertions of the rectus muscles revealed very considerable individual variations. The results are presented statistically.

Peter C. Kronfeld.

Nordmann J., and Stoll R. **The pigment cells of the choroid of the chick embryo.** Ophthalmologica 114:99-102, Aug. 1947.

In the chick embryo the chromatophores of the choroid make their first appearance on the tenth day after fertilization. The development of the chromatophores appears to be related to that of the ciliary nerves and independent of the pigment epithelium of the retina.

Peter C. Kronfeld.

Sudakevitch, T. **The variations in the system of the trunks of the posterior ciliary arteries.** Brit. J. Ophth. 31:738-760, Dec., 1947.

The variation in the anastomoses of the ophthalmic artery and its importance has not been emphasized in the literature. The ophthalmic artery may start as one or two trunks. Should the ophthalmic artery start from only the external carotid then anastomoses are essential and important for the functions of the eye. The role of the ophthalmic artery is not chiefly concerned with the central retinal artery, but mainly with the ciliary arteries. A definite order of branching of the long posterior ciliary arteries for sustaining a favorable correlation in the system of the ophthalmic artery from the hemodynamic point of view is very important. Most frequently, the first branch is the medial one of the long posterior ciliary arteries, with a common trunk with the central retinal artery.

In cases showing embryonic interruption in the trunk of the ophthalmic artery a variation was seen in the usual order of branching. Here, the medial branch of the long posterior ciliary artery was found in the second part, after the lacrimal artery. When this occurred na-

ture provided anastomoses and accessory branches. In some cases the posterior ciliary arteries may take part in the anastomoses themselves, making junction with the first and second parts and forming a new collateral way toward the posterior ciliary and neighboring arteries.

Intracranial interruptions of the ophthalmic arteries are of embryonic origin. The definite osseovascular correlation which develops in the narrow intracranial space in front of the optic canal is of extreme importance for normal eye function. (28 figures.) O. H. Ellis.

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Missiroli, Giuseppe. **Allergometric investigations on patients suffering from probable tuberculous ocular disease.** Boll. d'ocul. 26:171-178, March, 1947.

Continuing former investigations concerning the degree of cutaneous reaction to a tuberculin brand called "M.D.C. Terr." (Boll. d'ocul., Jan. 1947), the author compared the cutaneous reactions to this tuberculin in 17 patients affected by recurrent vitreous hemorrhages and in 11 patients with sympathetic ophthalmia. While in the latter group, most patients did not react to the 1 to 50,000 dilution—only one patient did—the patients with recurrent vitreous hemorrhages had positive cutaneous reactions even to dilutions of 1 to 100 million; 14 of these 17 patients reacted to dilutions of 1 to 100,000 and less. This seems to confirm the opinion of Stock and Axenfeld who, in 1909, postulated the tuberculous etiology of the recurrent vitreous hemorrhages. (1 table, 36 references.) K. W. Ascher.

Panzardi, Domenico. **Penicillin in the prophylaxis of postoperative infections of the eyeball.** Boll. d'ocul. 25:501-519, Oct.-Dec., 1946. (See Section 5.)

Reiser, K. A. **The problems of intraocular tuberculosis.** Klin. Monatsbl. f. Augenh. 112:1-12, May, 1947.

Intraocular tuberculosis has been a controversial subject because of the lack of sure diagnostic findings in the diseased eye. Many different diseases of the bulbus show similar clinical characteristics. Pathologic findings from the acute stage of the inflammatory process are scarce because the eyes are enucleated after, and not during, that stage, because of complications like secondary glaucoma. Therefore, the pathologist finds only the end result of the inflammatory process. Tubercle bacilli are only rarely found in these enucleated eyes and the histologically evident granulation tissue is not as pathognomonic as it once was thought to be. The clinical proof of the presence of a primary tuberculous focus is very difficult and frequently impossible, the Mantoux skin test is unreliable, a focal eye reaction after injections of greater doses of tuberculin is dangerous and, likewise, not foolproof and X-ray findings in the chest of persons with and without tuberculous eye disease are often identical. Serum reaction of the blood for tuberculosis as well as the isolation of tubercle bacilli from the blood are equally problematic. In spite of these uncertainties the author has no doubt of the existence of a true metastatic tuberculosis of the eye. He discusses four stages of investigation to make the diagnosis with certainty. The first stage embraces the general physical and laboratory examinations of the usual kind. A definite diagnosis is only rarely achieved and this stage usually ends with the diagnosis "uveitis of unknown etiology." During the second stage the findings are reviewed after removal of all possible foci of infection and after evaluation of the further course of the disease including resistance or response to treatment. At this point a diagnosis can often be made with probability. The third step embodies observa-

tion of long duration, sometimes after treatment in a sanatorium. Occasional hints of small, old tuberculous flare-ups in other parts of the body, recurrent attacks of the eye disease, changes in location of the ocular inflammatory process within the same eye and, again, evaluation of the therapeutic result are the considerations which make a diagnosis of clinically certain ocular tuberculosis possible. The fourth diagnostic stage is the positive proof of an active tuberculous lung process. The latter is found through repeated X-ray observation of seemingly inactive scars and glands over a long period of time. One then finds minute changes which correspond to caseous processes. The positive finding of bacilli in an enucleated eye belongs also to this last diagnostic part. The author states that, contrary to the old theories, lung tuberculosis and eye tuberculosis are actively co-existent in the same individual and that the disease in the two organs is only quantitatively, but not qualitatively, different. Max Hirschfelder.

Scholz, R. O., Cowie, D. B., and Wilde, W. S. **Studies on the physiology of the eye using tracer substances. Parts I and II.** Am. J. Ophth. 30:1513-1526, Dec., 1947. (3 tables, 3 figures, 9 references, discussion.)

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Bonhomme, C., and Ferrié J. **Changes in the lacrimal gland of the rabbit after the injection of pilocarpine.** Ophthalmologica 113:316-318, May, 1947.

Under the designation of apical ergastoplasm the authors describe and depict certain transient histological changes that occur in the cytoplasm of the secretory cells of the lacrimal gland under the influence of pilocarpine.

Peter C. Kronfeld.

Davson, Hugh, and Quilliam, J. P. **The effects of nitrogen mustard on the permeability of the blood-aqueous humour barrier to Evans blue. An instance of the influence of a lesion in one eye on the susceptibility of the other.** Brit. J. Ophth. 31:717-721, Dec., 1947.

The authors found that Evans blue injected intravenously does not appear in the aqueous of normal rabbits. After a solution of nitrogen mustard was instilled into the conjunctival sac of one eye the permeability of the blood-aqueous barrier was increased. Evans blue appeared in the anterior chamber of that eye and a ciliary injection appeared in the untreated eye. Solutions of different toxicity were used and the results showed that instillation of a high concentration of nitrogen mustard in one eye potentiates the action of a mild solution in the other eye by the reflex dilatation of the iris vessels.

O. H. Ellis.

Fischer, F. P. **Lens metabolism and cataract.** Ophthalmologica 114:1-9, July, 1947.

Fischer reviews and tries to integrate some of the more recent work concerning the metabolism of the normal and cataractous lens. The two principal views concerning the pathogenesis of cataracts are: lens opacities result from disturbances of either the carbohydrate and mineral metabolism or from the internal respiration of the lens. Fischer shows that these two views are not irreconcilable. The various phases of the carbohydrate metabolism are represented in a rather complex diagram. "The cataractous lens is an asphyxiated lens." Peter C. Kronfeld.

Leopold, I. H., and Adler, F. H. **Specific treatment of ocular burns due to Lewisite (Beta-Chlorovinyldichloroarsine).** Arch. Ophth. 38:174-181, Aug., 1947.

An effective antiarsenical agent, BAL

(2.3-dimercaptopropanol), was discovered and developed during the war years. It has been shown not only to be an effective therapeutic agent against arsenical war agents but also to be of value in the treatment of the various types of arsenical poisonings encountered in civilian practice.

The drug is irritating and produces ocular damage if used in concentrations greater than five percent or if repeatedly applied. It is recommended that it be applied once after the initial application. BAL is very effective in preventing severe ocular damage from Lewisite when applied promptly. It also has a specific effect on ocular lesions due to methyldichloroarsine, ethyldichloroarsine and phenyldichloroarsine and it has slight beneficial effect on lesions due to mustard gas (diethyl sulfide). The solvent and method of application is discussed in some detail. Apparently the use of 5-percent BAL in a special ointment base is most practical for military use.

John C. Long.

MacDonald, A. D. **Mydriatics: some developments.** Practitioner 158:413-417, May, 1947.

All mydriatics of the belladonna group —atropine, homatropine, euphthalmine, and hyoscine—have the common feature that paralysis of accommodation is of shorter duration than the accompanying mydriasis. The mydriasis is not maximal and can be increased by the use of sympathomimetic drugs. Eumydrine, also a member of this family, differs in that the effect on accommodation is more prolonged. The sympathomimetic mydriatics, including adrenaline and ephedrine produce no cycloplegia and do not increase the ocular tension. Cocaine, a local anesthetic, has a definite mydriatic effect and enhances the mydriatic effect produced by atropine.

The antispasmotic drugs such as papaverine, syntropan and benadryl, have little mydriatic effect. There is a short discussion of the methods of investigation of drugs for the mydriatic effect, and of the history of attempts to synthesize mydriatic drugs. In these investigations it has been found that certain choline esters are powerful mydriatics, of shorter duration than atropine. One choline ester, used increasingly at present, is dibutolin. Thus far these choline esters have been used infrequently, usually as substitutes for atropine. Benjamin Milder.

Olcott, C. T. **Experimental argyrosis. III. Pigmentation of the eyes of rats following ingestion of silver during long periods of time.** Am. J. Path. 23:783-792, Sept., 1947.

Ocular pigmentation due to the deposition of silver can be recognized during life and at autopsy in rats after ingestion of silver salts for long periods. The amount of pigmentation is directly related to the duration and intensity of the treatment. The zone of greatest pigmentation in the eye is the homogeneous layer of Bruch's membrane of the choroid and its continuation as the basal membrane of the epithelium of the ciliary body. Theodore M. Shapira.

Rosso, S. **The effect of acetylcholine shock on ocular tension and the retinal arterial pressure.** Rassegna ital. d'ottal. 16:357-369, Sept.-Oct., 1947.

After reviewing the effects of convulsive treatment in schizophrenia by various other means, Rosso reports his observations after the injection of acetylcholine. In a group of 35 patients, aged 20 to 35 years, he studied particularly the variations of the general arterial pressure in relation to the behavior of the retinal vessels. In the second group of 16 patients he reports the relation of the general arterial pressure to that of the retinal arteries and to ocular tonus. Shock was

induced by the intravenous injection of 0.50 gm. of acetylcholine bromide, dissolved in distilled water. The average results were as follows: a fall of general systolic pressure of 20 mm. of Hg and a 10 mm. fall in the diastolic pressure; the retinal arterial pressure fell about 10 percent and showed rather marked oscillations, but returned to normal more rapidly than the general arterial pressure; there was a contraction of the central retinal artery of brief duration; the average fall of intraocular pressure was 5 mm. Eugene M. Blake.

Stutterheim, N. A. **Peripheral and central disturbances of the visual fields. An aspect of di-ophthalmology.** Brit. J. Ophth. 31:721-730, Dec., 1947.

The author discribes in detail his observations on three patients in whom functional contraction of the visual fields of both eyes was present with diminished central vision, combined with various other symptoms of severe eyestrain. The condition is called astheno-vergence. Treatments using the kinetic principle rapidly cleared the condition.

O. H. Ellis.

Valerio, Mario. **Wetting agents in ophthalmology, with particular regard to their uses in ocular sulfamidotherapy.** Ann. di ottal. e clin. ocul. 72:428-436, July, 1946.

By experiments made on rabbits, Valerio found that therapeutic concentrations of sulfonamides can be obtained in both the vitreous and the aqueous if a wetting agent is used, whether the sulfonamides are administered by iontophoresis or in an ointment.

Since the anesthetic percaine (nupercaine) is a very efficacious wetting agent he recommends its use in ½-percent solution with 2-percent epinephrine for maximal mydriasis in examination of the fundus. Harry K. Messenger.

Van Dyke, H. B. **Autonomic nervous system and action of drugs important in ophthalmology.** Arch. Ophth. 38:145-153, Aug., 1947.

This is a general review of the pharmacology of the autonomic nervous system with special reference to the eye. For the purposes of the discussion, the older view that transmission of impulses depends on humoral agents, such as acetylcholine and substances closely related to epinephrine, has been adopted. The summary includes a very valuable outline of the action of the various ophthalmic drugs used for their action on the autonomic nervous system. John C. Long.

Vidal, F., Malbrán, J. L., and García Badaracco, J. **Neurocapillary test in experimental aniridia.** Arch. de oftal. de Buenos Aires 21:105, April-June, 1946.

The authors studied the action of carbaminoylcholine chloride in experimental aniridia and partial iridectomy in the cat. The drug produces a rapid fall in the intraocular pressure in both eyes which later increases gradually and is lower in the operated eyes. These lower values are believed to be due to the reduction of the dialyzing vascular area. (Bibliography.)

Plinio Montalván.

4

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Angius, T. **Research on accommodation.** Rassegna ital. d'ottal. 16:370-376, Sept.-Oct., 1947.

The author devised and describes apparatus for measuring the near point of accommodation of each eye separately. With it he measured the power of accommodation of 1160 healthy young adults from 19 to 26 years of age and with normal vision. The normal power of accommodation for ages 19 to 20 is 11 D, and from 21 to 26 is 10 D. These values are

higher than those of Donders and close to those of Duane. (1 Figure.)

Eugene M. Blake.

Bucalossi, Antonio. **A subjective method for the study of the refracted light-bundle of the eye and the determination of the refraction.** Ann. di ottal. e clin. ocul. 72:385-407, July, 1946.

The refraction of the eye can be determined by viewing a white object on a black background through a filter, half of which is of red glass and the other half of green, so placed in front of the eye that the line of separation between the two colored fields passes through the center of the pupil. An object thus viewed generally appears to be of the color resulting from the fusion of the two colors of the filter and to be surrounded by colored zones or bands which vary according to the refraction and aberration of the eye. Six diagrams for interpreting the numerous variations are given.

Harry K. Messenger.

Cotlier, I. **Subjective astigmatoscopy in the determination of astigmatism.** An. argent. de oftal. 7:119-124, Oct.-Nov.-Dec., 1946.

Subjective astigmatoscopy is based on the examination of a point of white light which is seen as a diffusion line by an astigmatic eye. To perform the test the author utilizes a subjective kinescope in which a line of light is employed to determine the principal meridian of astigmia, by an apparent subjective lengthening or shortening of the constant source of linear light. Additional blue or red filters may be used for further refinement, especially in cases with hypermetropia. Lenses are then placed before the eye until the dispersion and lengthening effects due to the astigmia are made to disappear. (2 figures, bibliography).

Edward Saskin.

Cross, A. G. **Contact lenses.** Practitioner 158:406-412, May, 1947.

This survey of the present status of contact lenses includes a brief description of their history from the original blown glass lenses to the present plastic contact lenses. The author discusses the advantages, cosmetic and industrial, of contact lenses. Indications for use include asymmetric ametropia, keratoconus, corneal irregularities due to scarring, and monocular aphakia. In addition, therapeutic indications include lagophthalmos and neuroparalytic keratitis. Eyes with recurrent erosions and trichiasis have been benefited by contact lenses. The cosmetic indications are discussed.

The author describes Zeiss lenses, and describes the method of individual fitting of contact lenses. Tolerance to contact lenses varies greatly. The author feels that with cut plastic lenses it is possible to insure at least four hours a day of comfortable wear. He emphasizes the importance of careful selection of candidates for the wearing of contact lenses.

Benjamin Milder.

Duke Elder, Sir Stewart. **Eye strain.** Practitioner 158:377-382, May, 1947.

The author defines "eye strain" as the effort of the visual apparatus to clarify vision by ineffectual adjustments. Among the factors which cause eye strain, the author emphasizes faulty illumination and the fineness of the work done. More important, however, are ocular defects which produce eye strain. Chief among these are error of refraction and presbyopia and also accommodation, convergence, muscular impairments and aniseikonia. Eye strain is commonly the result of efforts to compensate for relatively small ocular defects. The more ready appearance of asthenopic symptoms in people who are subject to other strains and stresses, both physical and psychic, is emphasized. Treatment is principally

optic, but the author warns against the indiscriminate correction of errors of refraction which are not producing symptoms. Benjamin Milder.

Foddis, Antonio. **Concerning central scotomata encountered in certain secondary cataracts.** Boll d'ocul. 26:87-97, Feb., 1947.

In the 1943 volume of the same journal (no. 8-10, p. 479) Focosi discussed the visual disturbances observed in certain cases of secondary cataract; the present paper is devoted to a mathematical analysis of the phenomenon. (4 figures.)

K. W. Ascher.

Fuchs, Adalbert. **Myopia inversa.** Arch. Ophth. 37:722-739, June, 1947.

In occasional eyes changes occur at the disc which resemble the nasal conus of myopia but which are something quite different. In these cases, on the nasal side of the optic nerve one finds changes which look exactly like those on the temporal side of the optic nerve in cases of high myopia, namely, large atrophic zones of the choroid (circumpapillary atrophy), which extend toward the nasal side more than toward the temporal side. As such eyes are myopic, the author proposes to call these changes "myopia inversa." The distribution of the vessels is nearly always inverted. Pronounced supertraction of the temporal margin of the disc is not ordinarily present. Fourteen cases of this condition are described in detail with sketches of the disc.

John C. Long.

Iribas, Gregorio, **Contact lenses in ophthalmology.** Arch. Soc. oft. hisp.-amer. 7:797-807, Aug., 1947.

No new viewpoints on contact lenses are presented. The author prefers fitting with Obrig's trial set of plastic lenses. He finds individual molds of the eyeball unnecessary. The mathematical data on the computation of the refractive correction from the data furnished by the trial-case refraction, the measurement with the ophthalmometer, and the distance between the correcting lens and the anterior corneal surface are presented.

Ray K. Daily.

MacDonald, J. G. **Spasm of accommodation.** Supp. New Zealand, M.J. 1947, pp. 39-42, 1947.

Spasm of accommodation simulates myopia, gives rise to annoying blurring of vision, and should be treated by the daily use of atropine. Irwin E. Gaynon.

Maione, Mario. **The action of simultaneous multiple luminous stimuli on the retinal function. (Experimental researches.)** Ann. di ottal. e clin. ocul. 72: 467-490, Aug. 1946.

Maione performed a series of experiments designed to elucidate the functional relations between various parts of the retina. Using double targets (red-green, red-white, green-white) specially calibrated with respect to luminous intensity he found that the extent of the visual field for a given color is reduced when the target presents simultaneously another stimulus of the same luminous intensity. In a second group of experiments he found that a luminous stimulus on one part of the retina weakens the action of a simultaneous luminous stimulus on another part. With a special device he studied the variation in macular visual acuity when the periphery of the retina is stimulated, and found that the more in-

tense the peripheral stimulus the less the central visual acuity.

As a working hypothesis Maione considers the retina to possess a definite energy potential, the discharge of which upon the optic nerve is determined by the characteristics of the stimuli.

Harry K. Messenger.

Moron-Salas, José. **Two problems in refraction.** Arch. Soc. oft. hisp.-amer. 7: 741-755, Aug., 1947.

Moron-Salas discusses aniseiconia, and the use of the cross cylinder. For the diagnosis of aniseiconia, he uses the Maddox eiconometer which is described in detail. Size glasses are not available in Europe, and the author attempts to equalize the size of the retinal images by the thickness and position of the lenses. The enlargement of the image increases in direct proportion to the thickness of the lens, and inversely to the radius of curvature. The apparent size of the object increases if the lens is placed with its concave surface towards the eye, and diminishes if the lens is placed with the convex surface towards the eye. In cases of unilateral myopia the aniseiconia can be reduced by reducing the distance of the correcting lens from the eye.

The use of cross cylinders is described, and attention is called to the possibility of error, pointed out by Williamson Noble, caused by the fact that vertical lines are seen more distinctly if the vertical meridian of the eye has the strongest refraction. To avoid this error the author suggests that in using the cross cylinder, patients be asked to look at letters or numbers in which curved lines predominate, such as, 3, 6, 8, 9, o, c, and g. (3 illustrations, 1 table.) Ray K. Daily.

Pannevis M. **The brightness of positive after-images.** Ophthalmologica 113:280-289, May, 1947.

The purpose of this study was to follow and define the course of positive after-images by measuring their brightness. These measurements are made by "projecting" the after-image onto a screen the brightness of which can be varied and measured. If the screen is brighter than the after-image the latter immediately changes from light to dark. This phenomenon is only an induced change in brightness and not a change from a positive to a negative after-image. The decrease in brightness, that is, the fading of a positive after-image can be expressed by a relatively simple formula. Peripheral after-images (following stimulation of a peripheral retinal area) are less intense and fade out more quickly than central ones. The area of a central scotoma often proves incapable of producing after-images. During the recovery of central vision the more peripheral portion of the scotomatous area regains its capacity of producing after-images sooner than the more central portions.

Peter C. Kronfeld.

Park, G. E. **Reading difficulty (dyslexia) from the ophthalmic point of view.** Am. J. Ophth. 31:28-34, Jan., 1948. (2 tables, 9 references.)

Weidmann W. **The sharpness of the subjective visual images.** Ophthalmologica 114:33-43, July, 1947.

The various physiological aberrations and imperfections of the emmetropic eye lead to a degree of blurring of the retinal images that is comparable to that produced by an ametropia of about 2 diopters. Nevertheless, the subjective visual images are sharp and there is no subjective awareness of the fact that the retinal images consist of or, at least, are outlined by diffusion circles. With a simple experimental arrangement the author has studied the effect of partly overlapping diffusion circles (DC) upon the subjective

impression. If two DC of different brightness overlap partly on the peripheral retina, no summation of the two stimuli occurs in the area of the overlap. Instead, the stronger (brighter) stimulus suppresses the weaker one. Barely eccentric DC suffer the same fate if they overlap partly with a central (macular) DC. Similar rules apply to colored DC: The more brightly colored DC extinguishes the weaker stimulus in the area of the overlap. Summation occurs only if two DC of the same color and brightness overlap. Another consequence of the physiological interactions between DC or double stimulations of retinal areas is the apparent enlargement by the radius of the DC of any bright object seen against a dark background, due to the suppression of the darker DC. These phenomena account for the subjective sharpness of visual images.

Peter C. Kronfeld.

5

DIAGNOSIS AND THERAPY

Bailliart, P. **Reflections on ophthalmoscopy.** Ann. d'ocul. 180:449-456, Aug., 1947.

The redness of the normal fundus depends on the quantity and quality of its reflected light which enters the observer's eye. The choroid, including its vessels and pigment, acts as a colored screen which absorbs most light except red. The interposition of fluids or solids between the choroidal screen and the transparent retinal screen changes the fundus color values in retinal detachment. Monochromatic light including red-free causes the nerve fibers, interstitial tissues and vessels to appear more distinct and of a different color because these tissues are less permeable to light of short wave length.

In the ordinary electric ophthalmoscope, the observer uses a wide range of wave length. Retinal pigment epithelium loss increases distinctness because of the increased light which penetrates the choriocapillaris, the reflected color appearing brighter. Absence of the choriocapillaris renders only the larger vessels and interspaces visible with a variable amount of pigment which may appear gray, black or brown. Detached pigment epithelium migrates to the nearest retinal vessels, following the course of the interstitial intra-ocular fluid which is from the choroid to the vitreous. The fundus appears more dull and slightly opaque after the absorption of pigment from the retinal pigment epithelium.

Magnifications of 10 to 14 diameters are afforded by direct ophthalmoscopy. The central retinal artery is about 90 μ in diameter and vessels as small as 20 to 30 μ are visible under favorable conditions. The normal granular appearance of the fundus is ascribed to the hexagonal shape of the cells of the pigment epithelium, about 15 to 30 μ in diameter. The crystalline appearance frequently observed in perimacular exudation is caused by the increased fluids in the underlying choriocapillaris. In estimating fundus depth lesions are best aligned with the blood vessel planes. The larger vessels are in the nerve fiber layer and the smaller vessels extend to the internal granular layer. Pigment epithelium lesions are external to the retinal vssels. In myopia tension causes the retinal pigment layer to reflect more light and the fundus to appear more transparent and the details more distinct. The partial or total loss of the pigment epithelium tends to make the fundus appear lighter and brighter. Unfortunately, quantitative and qualitative changes in the interstitial fluids of the fundus, which play an important part in disease, cannot be studied in histologic sections. The fundus in life and death is quite different. Only with the ophthalmoscope can the cellular and interstitial tissues in health and disease be observed and interpreted.

Chas. A. Bahn

Boyd Law, T. **Intraocular infection and penicillin.** M. J. Australia 2:298, Sept. 6, 1947.

The author presents one case of a woman who had unilateral cataract surgery; the ultimate result was a slight prolapse of the pillars of the iris which was treated with trichloracetic acid. Visual acuity was 6/12 with correction. When next observed 14 months later there was an infection of the anterior chamber of the eye which had gained access along one of the prolapsed pillars. Intramuscular injections of penicillin were given, first 50,000 units and then 15,000 units every 4 hours, penicillin drops were instilled in the eye (1,000 units per millilitre) every 15 minutes for 5 hours, then every hour, and atropine was instilled. The eye did not respond. A kerotome incision was made and some of the penicillin solution was used to wash out the anterior chamber with a lachrymal syringe. This was repeated the next two days. Intramuscular injection of penicillin was continued until she received 1,000,000 units and penicillin drops were instilled several times daily. The eye responded rapidly and the patient was discharged 17 days later.

When next examined five months later, the pupil had contracted slightly, the eye was free of inflammation, and the lens capsule in the pupillary area was only slightly more dense than before the infection. A discussion was done and, through the gap obtained, a good view of the fundus showed no evidence of any damage in the posterior segment of the eye. Corrected visual acuity was 6/24.

Theodore M. Shapira.

Grignolo, Antonio. **Vivicillin for eye affections.** Boll. d'ocul. 26:179-188, March, 1947.

In 1944, Enoch and Wallersteiner described the inhibitory action on penicillin-resistant microorganisms of an antibiotic they called vivicillin, a suspension of living filaments of Penicillium notatum. A similar, possibly even identical, preparation was obtained from B. babudieri from the Instituto Superiore di Sanita in Rome and was used for treatment of blepharitis ulcerosa as well as squammosa, of catarrhal and of purulent conjunctivitis, of pseudomembranous, angular, and lymphatic conjunctivitis, keratitis, corneal ulcers, dacryocystitis, iridocyclitis, infected ocular wounds and postoperative infections. The application was either local, in drops, eye bath, or compresses, or general, by intramuscular injection. Excellent results were obtained in ulcerous blepharitis, which recurred nevertheless. Conjunctivitis caused by streptococci, staphylococci, Morax-Axenfeld diplobacilli, and infected wounds of the eye responded favorably. Lymphatic keratoconjunctivitis, dakryocystitis, gonorrheal conjunctivitis, Koch-Weeks conjunctivitis, corneal ulcers, and iridocyclitis did not respond to this therapy.

K. W. Ascher.

Panzardi, Domenico. **Penicillin in the prophylaxis of postoperative infections of the eyeball.** Boll. d'ocul. 25:501-519, Oct.-Dec., 1946.

The writer reports in tabulated form the results obtained in 55 intraocular and 25 extraocular operations on eyes in which the cultures had shown the presence of the staphylocci, streptococci, the micrococcus catarrhalis, the pneumococcus, the xerosis bacillus, the Morax-Axenfeld diplococcus and the Koch-Weeks bacillus. The use of penicillin in collyrium or ointment every four to six hours for one to three days destroyed the germs of the conjunctiva more completely than any other drug. Even after this short treatment cultures were sterile for 4 to 8 days which is long enough to prevent secondary infection of the wound. The tolerance of the eye to penicillin was good

for the duration of the postoperative treatment. However, the prophylaxis of surgical infections can be completed by the internal use of a sulfamide a day before and the two days after operation. (Bibliography.) Melchiore Lombardo.

Seidenari, Renato. **An ophthalmoscope lamp for retinal detachment.** Ann. di ottal. e clin. ocul. 72:491-494, Aug., 1946.

For facilitating the finding of retinal tears Seidenari presents a simplified electric ophthalmoscope for examination of the fundus by the indirect method. The light source is much more powerful than in the ordinary electric ophthalmoscope. Chromatic aberration is almost completely eliminated by the use of two condensing lenses with an interposed diaphragm.

OCULAR MOTILITY

Martínez, Luis, Jr. **A case of fixed strabismus.** Am. J. Ophth. 31:80-81, Jan., 1948. (2 figures.)

McGuire, W. P. **The surgical correction of paresis of the superior oblique.** Am. J. Ophth. 31:65-77, Jan., 1948. (6 figures, 49 references.)

Smith, James W. **The problem of strabismus in childhood. With special reference to convergent strabismus in infancy and early childhood.** Am. J. Ophth. 31:85-89, Jan., 1948. (7 references.)

Verhoeff, F. H. **Problems concerning convergence.** Tr. Am. Acad. Ophth. pp. 15-19, Sept.-Oct., 1947.

If each eye moved independently, bifixation would be a simple matter if and when it became advantageous, and a special convergence mechanism would be unnecessary. The two eyes move precisely together as though mechanically connected, though the exact manner of the operation of this function is practically unknown. When an eye is directed downward and inward by the conjugate mechanism without the help of convergence, it undergoes relative extortion. When the inward movement is produced by the convergence mechanism, the eye undergoes intorsion. Convergence is, therefore, accomplished by the internal rectus muscles together with reduced innervation or inhibition of their antagonists. An eye can move further inward by conjugate action than by convergence. After maximal symmetrical convergence has been obtained through bifixation of an object in the midline, one eye at a time can be turned still further inward by carrying the fixation to the left for the right eye and vice-versa for the left, while bifixation is still maintained. Convergence is more restricted than conjugate motion because the convergence mechanism has only the internal rectus to turn an eye whereas the conjugate mechanism has in addition the help of the other ocular muscles, notably the superior and inferior rectus muscles. The other factors involved are: insufficient inhibition of the external rectus and the utilization of two different physiologic mechanisms, each with its separate muscle fibers and/or innervation.

Convergence is primarily involuntary although more or less voluntary control is frequently acquired, but is not used in ordinary vision. Convergence can seldom be disassociated from accommodation. The convergence necessary for bifixation is normally accomplished through accommodation, distance sense, and disparateness of the fixation object images. These factors cannot be completely disassociated. The deviation of an occluded eye when viewing a distant object through a concave lens proves that accommodation causes convergence. The distance sense hampers the convergence effect of accommodation because the fixated object con-

tinues to appear distant. The effect of nearness can be demonstrated by looking with one eye occluded at a near object through a convex lens which prevents accommodation. The occluded eye converges, but far from enough, although the convex lens makes the object appear nearer than it actually is.

When the convergence effect of accommodation is the same for each eye separately, it is probably also the same when both eyes are used. This is not true for the distance sense because the distance of the near object does not appear the same with one eye occluded as with both eyes open. The effect of disparate images can be studied with a stereoscope or with two dots on a card. When these approach each other by convergence, or relative divergence, with strong attention the two images unite and stay united without effort on the part of the observer. Thus the effect of accommodation or distance sense on convergence cannot be completely nullified.

Conscious concepts of depth are not produced by disparate images but unconsciously there may be depth perception which is associated with convergence or divergence. Binocular fixation is inversely proportionate to the image differences and in very near vision produced by efforts of accommodation and distance sense. In ordinary vision, convergence is involuntary and is produced partially by a sensory factor which is entirely subconscious.

Perlia's nucleus is involved in convergence but its method of function is not understood. Apparently it equalizes stimuli to the internal rectus muscles. Perlia's nucleus is apparently connected with the probable centers of pupillary contraction and accommodation. The association between convergence and accommodation is, generally speaking, hereditary and not acquired. In many patients with convergence strabismus since infancy, accommodation causes increased convergence. There is apparently no divergence center. Chas. A. Bahn.

7

CONJUNCTIVA, CORNEA, SCLERA

Arriaga Cantullera, José. **Sulfanimides and trachoma.** Arch. Soc. oft. hisp.-amer. 7:787-796, Aug., 1947.

The author reviews the literature, and reports his own investigations. One study comprises a group of 34 children in the first and second stages of trachoma treated in an orphanage. They were given a sulfa preparation internally, and a sulfa ointment locally. At the end of 20 days, 19 were discharged as cured, and the other 15 were treated for ten days longer; at that time they too were clinically cured. Reexamined at the end of one year, 30 were found cured, with smooth tarsal conjunctiva, and pale eyes. Two had follicles, without subjective symptoms and two had no follicles, but presented signs suggestive of trachoma, such as lacrimation, conjunctival congestion, and abnormalities in the tarsal vessels. In summary, 19 patients were cured with 30 to 40 grams of the drug, and 15 required from 45 to 55 grams. In an ambulatory group of patients treated in the same manner, the results were inferior to those obtained at the orphanage, which seems to indicate that other factors, such as hygienic surroundings, or proper nutrition play a part in the results obtained.

Another investigation concerned the effect of Irgafen, a sulfa preparation which, because of its affinity for blood plasma, produces a higher blood concentration with smaller doses. It was used in 60 patients in various stages of trachoma. The dose of Irgafen was half of that used with the other sulfa drugs. Of Irgafen 20 grams were administered during a period of three weeks; 10 grams were given in the first week, and after a week's interval 10 grams were given during the third

week. Tabulated data show that 68.33 percent of the patients were cured, and 21.24 percent improved. One patient, who failed to respond to the continuous administration of 40 grams of the drug, was given a subconjunctival injection of Irgamid. The injection was so painful, and the reaction of the lids so marked, that the patient did not return for further therapy. Seen three months later she was found cured. One patient was sensitive to sulfa drugs, and the treatment had to be abandoned. Arriaga concludes that the sulfa drugs act not only on the trachomatous complications and secondary infections, but exert a direct curative effect on the trachomatous process itself. (Bibliography.) Ray K. Daily.

Casari, G. F. **A case of aphthous conjunctivitis.** Rassegna ital. d'ottal. 16:377-385, Sept.-Oct., 1947.

A 38-year-old woman developed aphthae of the oral and vaginal mucosa, together with a polymorphous cutaneous erythema and a bilateral acute conjunctivitis. The condition was recurrent, but healed completely. The etiology was considered to be a tuberculous allergy.

Eugene M. Blake.

Colombo, G. L. **Rickettsial corpuscles in numular conjunctivitis.** Ann. d'ocul. 180: 470-474, Aug., 1947.

In a previous article the author reported the observation of rickettsial bodies in three cases of epidemic numular conjunctivitis, which term is preferred to epidemic keratoconjunctivitis.

The condition was exceptionally frequent in Italy during 1946 and was observed especially in returned prisoners from Germany and India. The characteristic symptoms include spontaneous pain, inflammation and swelling of the preauricular glands as well as catarrhal conjunctivitis with marked edema and follicculosis especially in the semilunar fold and caruncle. The inferior conjunctiva is usually more inflamed and contains more follicles. The conjunctiva of the upper lid is relatively normal. In this respect this conjunctivitis differs from another rickettsial disease, trachoma. The exudation is catarrhal.

The technique used for biologic cellular examination includes grattage after cocainization. The scrapings containing the epithelial cells are placed on several slides, and after fixation in ether and methyl alcohol are stained with Giemsa-Romanowski stain. The epithelial cells have violet nuclei and rose-pink protoplasm, while the rickettsial bodies are blue. The rickettsial bodies vary from 2 to 3 μ and the grouped masses from 200 to 300 μ in size. The latter appear as triangular caps on the nuclei or slightly separated as single or divided groups.

The author has not observed similar findings in conjunctival inflammations caused by other rickettsial diseases, which include trachoma, conjunctivitis of the new-born, and swimming pool conjunctivitis. The clinical differences strongly suggest that several types of the rickettsial group are involved. All differ from bacteria in morphology, in staining reaction, and chemically, in their agglutinin, precipitin, and amboceptor reactions. Clinical and pathological differences between the bacterial and rickettsial diseases are more or less marked. The conjunctival exudates in the latter consist almost exclusively of small monocular leucocytes.

The presence of rickettsial bodies has been observed by the author in numerous cases of numular keratoconjunctivitis which is considered a pathologic and clinical entity. Chas. A. Bahn.

Coverdale, Howard. **Ocular lesion associated with dendritic ulcer.** Supp. New Zealand M. J. p. 31, 1947.

Ten cases are presented illustrating the

association of dendritic ulcer with herpes facialis, superficial punctate keratitis, disciform keratitis, keratitis profunda, and iridocyclitis. Irwin E. Gaynon.

Godfrey-Smith, R. A. **Reiter's syndrome.** M.J. Australia 2:574-575, Nov. 8, 1947.

The author adds another report to the growing list of cases of Reiter's disease, a syndrome that consists of non-specific urethritis, polyarthritis and cojunctivitis. The association of this syndrome with bacillary dysentery has been suggested. F. H. Haessler.

Grossmann, E. E. **Treatment of corneal ulcer with blood and blood plasma.** Arch. Ophth. 37:779-781, June, 1947.

The cornea is avascular and derives its nourishment by dialysis from the perilimbal plexus. For this reason, healing of corneal infections may become sluggish and prolonged. It is also notable that frequently lesions of the cornea clear up only after vascularization has occurred. In view of the lack of an adequate nutrient supply system in the cornea, it would appear logical to apply the needed nutrient elements directly to the cornea in the form of drops of either whole blood or plasma. Gratifying results have been obtained when blood was used in paste form in several cases of indolent decubitus ulcers and in infected wounds. Six cases of corneal disease are briefly described, in which treatment consisted of the application of either blood plasma or whole blood. Good results were obtained. John C. Long.

Jayle, G. E. **Transfixing grafts of the cornea in the infant and adolescent.** Arch. d'opht. 7:148-155, 1947.

Jayle reviews the history of corneal grafts from the time of von Hippel in 1888 to the present time. He concludes that the current success of the operation as contrasted with earlier failures is due to minor changes in technique, to improvement in anaesthesia and akinesis, and to the great improvement in control of bacterial infection, rather than to any fundamental changes. The author then describes in detail his own operative technique and offers two illustrative cases to show the indications for operation and the handling of complications. Among all the possible complications he stresses the relative importance of glaucoma and advocates trephining for its control and even as a means of prophylaxis in certain cases. He notes that successful grafts are possible even in the very young. Phillips Thygeson.

Klauder, J. V. **Treatment of interstitial keratitis with particular reference to the results of penicillin therapy.** Am. J. Syph., Gonor. and Ven. Dis. 31:575-599, Nov., 1947.

Seventy-two patients with interstitial keratitis were treated with penicillin.

The addition of penicillin to the therapy of interstitial keratitis does not give results superior to other forms of treatment, such as fever-chemotherapy without penicillin and no treatment eliminates the devastating effect of the disease. (5 tables, references.) Bennett W. Muir.

Scuderi, G. **Leishmaniasis of the eyelid associated with keratitis.** Rassegna ital. d'ottal. 16:335-356, Sept.-Oct., 1947. (See Section 15.)

Shuttleworth, F. N., and Benstead, J. G. **Primary meningococcal ophthalmia.** Brit. M. J. pp. 568-569, Oct. 11, 1947.

Attention is drawn to the importance of recognizing the meningococcus as a primary cause of conjunctivitis.

Two cases in Leeds school children are described. One patient was eventually treated with local application of sulfacetamide and the second with penicillin with

good results. Some aspects of the literature are discussed.

Theodore M. Shapira.

Stern, H. J. **Acute ocular manifestations of riboflavin deficiency.** Ophthalmologica 114:103-106, Aug., 1947.

A white woman, 52 years of age, presented herself in the Eye Clinic of the Hadassah University Hospital in Jerusalem because of redness, burning and itching of both eyes of several days' duration. Her diet had been very low in riboflavin for many months. Ophthalmological examination revealed marked congestion of the bulbar conjunctiva and of the marginal vascular plexus of the cornea. From the latter fine radial vessels invaded the subepithelial layers of the cornea for as much as 3 mm. The peripheral rim of the cornea was slightly edematous. Under riboflavin treatment by mouth (5 mg. three times daily) the eye improved dramatically.

Peter C. Kronfeld.

Vancea, P. **Electrometric variations of the tissue pH in trachoma.** Arch. d'ophth. 7:156-160, 1947.

Vancea reports on the variations in tissue pH observed in 16 cases of trachoma before and after treatment, as recorded by the ionometer of Brehmer. He found the normal tissue pH values to vary from 7.90 to 8.10 according to the part of the conjunctiva studied. In contrast, the average pH of the 16 trachomatous conjunctivas of the upper cul-de-sac measured 7.42; in the same individuals the average pH of the unaffected bulbar conjunctivas was 8.01. After follicular expressions the pH of the trachomatous conjunctivas rose to an average of 7.95 which is considered normal. Vancea concludes that under the influence of trachoma virus there occurs an acidification of the affected tissues which disappears under treatment. This return to normal pH precedes the actual healing of the disease.

Phillips Thygeson.

Venco, Luigi. **Considerations on the various phases of the process of union of homoplastic corneal transplants.** Ann. di ottal. e clin. ocul. 72:513-545, Sept., 1946.

From his clinical observation of 67 homoplastic transplants Venco distinguishes five phases or stages in the union of the implant with the recipient cornea. These phases arise at varying intervals after the keratoplasty and vary greatly in their severity. Complications, whether operative or postoperative, are excluded from consideration.

The first phase ("hydration of the implant") occurs invariably. At the first dressing both the implant and the recipient cornea are found to be opalescent and obviously swollen. The hydration usually disappears, at least macroscopically, within the first ten days.

The second phase ("inflammatory reactions") includes the usual phenomena of ocular inflammation which may vary greatly but usually subside in 10 to 20 days. These are linked with the process of cicatrization of the corneal wound, with the interaction between the implant and the surrounding tissue, and with the "ergic" status or reactive capacity of the individual. Vascularization of the recipient cornea is more or less constant in this stage, but ordinarily the newly formed vessels do not extend into the implant.

The third or "postvital" phase occurs in 18 to 24 days and seems to mark the limit of the survival of the implant, which henceforth is subject to new metabolic relations. Union between it and the cornea has been established. The phenomena which occur in this stage are of capital importance for the success of the keratoplasty and are attributed to the inevitable regressive processes of autolysis and autodigestion of dead tissue. In this phase the implant may become vascu-

larized and more or less opaque, and the changes are reversible only in part. The larger the implant the more severe these regressive changes are likly to be. Venco believes that frequent instillations of dilute hydrogen peroxide are of value in combating the tissue anoxia in this stage.

The fourth phase, which is inconstant, comprises various "tissue phenomena" attending the gradual transformation undergone by the implant in its new seat. These changes, manifested clinically by vascularization or loss of transparency, are usually not attended by inflammation and may occur months after the keratoplasty. In general, if the transplant is successful at the end of a year it is likely to continue so, barring those changes included in the fifth phase.

The fifth phase of "remote disturbances," is likewise inconstant, but frequently occurs because the implant behaves as a locus minoris resistentiae. The implant is prone to be affected by dystrophies, inflammations, and other morbid processes. (50 references.)

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Campos, Raffaele. **A case of choroidal angioma with ossification of the lamina vitrea.** Boll. d'ocul. 26:145-170, March, 1947.

A 12-year-old boy with an angioma (nevus flammeus) of the right side of his face was admitted for the purpose of an extraction of his right lens for traumatic cataract. When five years old he was hit in that eye and this trauma caused an apparently uncomplicated traumatic cataract. Uncertain light projection was the only suspicious sign, and a linear extraction was performed with abundant hemorrhage. Bleeding continued and the eye was enucleated 16 days after the extraction. Four weeks after the enucleation of the right bulbus, an inflammation, most probably sympathetic ophthalmia, developed in the left eye. This inflammation healed within seven weeks under local mydriatic and dionine treatment, with application of leaches, and chinophenyl and urotropin injections followed by mercury ointment as for secondary lues. Blood Wassermann and tuberculin tests were negative. An extensive description of the histopathologic findings is supplemented by six photomicrographs. Near the optic nerve head of the enucleated eye, uveal angiomatosis with fibrous and bony tissue formation was noted. Degenerative processes of the lamina vitrea such as Kuhnt-Junius disease and angioid streaks are discussed. (36 references.)

Lees, V. T. **A case of metastatic osteosarcoma in the choroid.** Brit. J. Ophth. 31: 713-716, Dec., 1947.

The author presents a case of the first recorded instance of metastatic osteosarcoma in the eye. The occurrence of intraocular metastatic sarcoma is unusual. The postmortem specimens showed such a distinctive cell pattern of trabeculae of osteoid tissue with the tumor cells in the interstices, that it was possible from that alone to diagnose bone sarcoma without reference to the history of osteosarcoma of the knee for which amputation had been performed. O. H. Ellis.

Lemoine, P. **Acute iritis and allergy.** Arch. d'opht. 7:161-166, 1947.

The author notes that there has been an increasing tendency to consider allergy as a cause of ocular inflammations of uncertain etiology. He then reviews the theories of the mechanism of allergy, with particular reference to the liberation

of histamine, and suggests that allergy may be concerned in acute iritis and that it may indeed be the cause of the initial symptoms in the majority of cases in spite of primary involvement with an infectious agent. On the basis of this hypothesis Lemoine subjected 30 patients to antiallergic therapy consisting of a series of intravenous injections of hyposulfate of sodium. He kept a control group on the customary local therapy alone. In the group treated antiallergically there was rapid diminution in inflammation, relief from pain, and rapid improvement in vision. No signs of intolerance to the drug were noted. From 9 to 12 injections were usually administered. He concludes that the therapeutic results obtained favor his hypothesis. Phillips Thygeson.

Samuels, B. **The problem of sympathetic ophthalmia.** Irish J. M. Sc. pp. 610-621, Oct., 1947.

The etiology, pathology, pathogenesis, diagnosis and treatment of sympathetic ophthalmia is discussed. Secondary glaucoma in the sympathizing eye should be treated by repeated paracentesis.

Irwin E. Gaynon.

Sédan, J. **Large unilateral stromal hypoplasia of the iris.** Ann. d'ocul. 180:466-469, Aug., 1947.

This constitutional anomaly usually involves the lower part of iris and the pupil is round. In the case reported the temporal quadrant of the iris was hypoplastic and the pupil was flat on the temporal side.

A dark brown triangular area, in the temporal quadrant of an otherwise blue iris, was observed in a Polish woman aged 23 years. The brown area was practically level with the remaining iris and contained several concentric folds. The temporal pupillary flatness persisted in mydriasis. Otherwise both eyes were structurally and functionally normal. This type of pupillary flatness is usually traumatic. No change had been observed in the iris and pupil by several ophthalmologists who had examined the patient since birth. The lesion is probably congenital and not progressive. (1 figure.)

GLAUCOMA AND OCULAR TENSION

Chandler, P. A., and Johnson, C. C. **A neglected cause of secondary glaucoma in eyes in which the lens is absent or subluxated.** Arch. Ophth. 37:740-771, June, 1947.

A form of secondary glaucoma in aphakic eyes and in eyes with dislocated lenses is discussed, in which the causative factor is apparently a block between the anterior and the posterior chamber. This block may arise from a membrane partly or wholly inflammatory, from the herniation of vitreous through the pupil acting as a plug, or from adhesion of the iris to an intact hyaloid membrane.

Treatment consists of the re-establishment of communication between the chambers by the use of a mydriatic, by discission of a pupillary membrane, by transfixion of the iris or by iridectomy. Treatment should be begun early before permanent peripheral anterior synechias are formed. A block of the pupil by vitreous in an aphakic eye, or one with posterior dislocation of the lens, with resultant increased pressure in the posterior chamber, is the probable cause of large accumulations of vitreous in the anterior chamber. In aphakic eyes in which the pupil is completely blocked by a membrane, it is advisable to do preliminary transfixion of the iris before undertaking

a discission of the membrane. Fourteen illustrative cases are presented.

John C. Long.

Cristini, Giuseppe. **The action of Roentgentherapy on the sympathetic centers of the medulla in glaucoma.** Riv. oto-neuro-oftal., 22:124-147, March-April, 1947.

Nine cases of glaucoma are reported in patients 41 to 70 years of age. Seven of the patients were male. The vision, tension, conditions of the fundus, the condition of the fields, and their changes after treatment are given in detail. A resume of the result obtained is given with a discussion on the effect on three cardinal symptoms of glaucoma: hypertension, optic atrophy and campimetric changes. It is concluded that irradiation of the medullary sympathetic centers and the ciliospinal center of Budge leads to results as satisfactory as after treatment now used in similar cases. (16 figures, bibliography.) Melchiore Lombardo.

François, J. **Glaucoma and cataract.** Ann. d'ocul. 180:457-465, Aug., 1947.

Cataract may cause or be caused by glaucoma, or their co-existence may be coincidental. The probable duration of each is measured in part by changes in the visual fields and the pupils which are important diagnostically.

In chronic glaucoma with beginning cataract a preliminary iris inclusion operation is preferred. The lens extraction can follow if and when the attendant risks are justified.

If an eye that has been operated upon for chronic glaucoma has an operable cataract, the decision to remove the cataract depends upon the surgical risks involved. Obviously, higher risks are justified if necessary to afford or maintain slight sight. Intracapsular extraction, especially if preceded by capsular micropuncture, is less apt to be followed by secondary uveitis. Suction, even in the hands of those who can use it efficiently, has the disadvantage of requiring a deeper anterior chamber than forceps. Generally speaking, when vision in the better eye is reduced to 20/100 because of cataract, lens extraction is advisable. Interference with a filtering scar in a lens extraction is usually ill advised; incisions should be lateral or inferior to the filtering scar.

In chronic glaucoma with operable cataract, if tension is reasonably low a lens extraction with a complete iridectomy usually involves the least risk. The two stage operation has the disadvantage of double exposure to both trauma and infection as well as their complications such as uveitis, vitreous loss, and lens dislocation. Only the removal of the lens, because of the reduction of the volume of the intraocular contents may permanently reduce the tension. If tension is above 35 mm. Hg a two stage operation is preferred with a minimal interval of six months between operations.

In co-existent glaucoma and cataract, miotics usually must be supplemented sooner or later by surgery. The earlier the surgery is done the better and operations which may have to be repeated, such as cyclodialysis, cyclodiathermy, iridectomy, and sclerotomy should be avoided. Surgery with filtering cicatrices and iris inclusion is preferred to operations of the Elliot and Lagrange type. Surgery should be directed against glaucoma primarily and secondarily against cataract. Cataract extraction in very hard eyes can only result in grave complications, such as extensive vitreous loss and intraocular hemorrhage. Intracapsular extraction is usually preferable if efficiently conceived and performed. Three illustrative cases are presented. Chas. A. Bahn.

Mulock Houwer A. W. **Leucoma adherens and glaucoma.** Ophthalmologica 113:303-308, May, 1947.

Mulock Houwer reports a case of secondary glaucoma after gonorrheal keratoconjunctivitis in a native of the Dutch East Indies. The upper-temporal sector of the cornea was very thin and ectatic (apparently a keratectasia after a large gonorrheal ulcer). Two tags of pigmented tissue with fringes projecting into the anterior chamber were attached to the posterior surface of the ectatic portion of the cornea. Mulock Houwer interprets these findings as follows: in the large ulcer that occupied the upper-temporal sector of the cornea, a small perforation occurred. Because of the presence of posterior synechias the iris prolapse remained very small. After an absence of the chamber for several days the corneal perforation became water tight, the chamber was restored and the anterior synechias broke, leaving only tags of iris tissue on the posterior surface of the cornea. During the absence of the chamber peripheral anterior synechias formed, and gave rise to secondary glaucoma. The author's main point is that the peripheral and not the central anterior synechias are the cause of secondary glaucoma after corneal perforation.

Peter C. Kronfeld.

Mulock Houwer A. W. **The pathology and therapy of corneal fistulas.** Ophthalmologica 113:309-315, May, 1947.

The article is based upon the author's very extensive experience with cases of corneal fistula following severe keratoconjunctivitides (mostly gonorrheal) in natives of the Dutch East Indies. His conclusions are very similar to those of Kronfeld (Am. J. Ophth. 23:1014, 1940) based on the latter's experiences in North China. The main fact to be kept in mind is that the fistulous eye depends upon the fistula for maintenance of a normal intraocular pressure. The normal outflow channels have been closed and the fistula has become the safety valve of the eye. The fistula can only be closed by giving the eye other channels of outflow. This is best accomplished by one or two cyclodialyses after which the fistula usually becomes obliterated. Kronfeld prefers Wootton's combined iridectomy and cyclodialysis followed by excision and keratoplastic repair of the fistula.

Peter C. Kronfeld.

Natale, Amadeo. **Evaluation and mechanism of the destructive effect of ocular hypertension.** Arch. d'opht. 7:129-147, 1947.

This complete and well documented review of the subject of the pathogenesis of glaucoma does not lend itself well to abstracting. The review considers first the clinical significance of increased intraocular pressure and the methods of measuring it. The relation of intraocular pressure to venous and arterial pressures and to the pressure of the spinal fluid is considered. Natale concludes that the figures commonly given for the intraocular pressure are too high. He notes the lack of correlation between the degree of pressure rise and the visual functions. Next in order are considered angioscotometry and its significance, the theories of the origin of the aqueous, provocative tests, and the significance of extraocular nervous factors and such other extraocular factors as hypertension and edema. Gonioscopy and aqueous veins are also discussed and, finally, the diagnostic value of observations on the papillomotor reflex.

Phillips Thygeson.

Redslob, Edmondo. **The treatment of hydrophthalmia.** Ann. di ottal. e clin. ocul. 72:449-454, Aug., 1946.

The treatment of hydrophthalmos must generally be surgical. The operation of choice is a perforating diathermy coagu-

lation of the ciliary body, as described by Vogt, which requires less precision than the usual decompressive procedures and can be done rapidly under local anesthesia. Hydrophthalmos is frequently a manifestation of hereditary syphilis and general anesthesia may be fatal because of dysfunction of the liver. Redslob employs a simpler technique than Vogt's: he makes a series of eight diathermy punctures around the limbus, two in each quadrant, 2 mm. from the cornea. He does not incise the conjunctiva but makes each perforation through both conjunctiva and sclera, with a needle about one millimeter long, which is applied for one or two seconds. When the needle is withdrawn a trace of clear liquid (watery vitreous) may be seen to exude. This augurs well for the success of the operation. He thinks that the operation is effective not only because it inhibits the secretion of the aqueous but also because it produces a kind of fistulization.

Redslob has used this method in about 50 cases of glaucoma of every kind, and has not observed the least complication. On the day following operation the tension may be elevated, but two or three days later it falls and may remain at a normal level or even lower. The operation has proved ineffective in hemorrhagic glaucoma, but in simple glaucoma the results are excellent.

Harry K. Messenger.

Reese, A. B. **The significance of the base pressure in primary glaucoma.** Am. J. Ophth. 31:25-27, Jan., 1948.

Talbot, Craeme. **Alternative operations to corneo-scleral trephining in treatment of glaucoma.** Supp. New Zealand M. J. pp. 37-38, 1947.

Cyclodialysis may be done in eyes with chronic simple glaucoma when the tension is below 40, in aphakia, and when the disease is not quite controlled with miotics. Delayed re-formation of the anterior chamber is seldom met with in cyclodialysis. Cataract formation and late infection is reduced in cyclodialysis in comparison with trephining.

CRYSTALLINE LENS

Clapp, C. A. **Some medico-legal aspects of traumatic cataract.** South. M. J. 40: 998-1000, Dec., 1947.

Fifteen percent of 300,000 eye injuries each year are associated with lens opacities. Penetrating wound and contusion cataracts should be observed for a minimum of three months to be sure the opacity is complete. If complete loss of vision is present, the cataract should be removed. Concussion cataract may be diagnosed by the rosette formation. Malingering should be tested for.

Irwin E. Gaynon.

Focosi, Marcello. **Answer to the note of Dr. Foddis concerning the central scotomas produced by changes in the posterior lens capsule of aphacic eyes.** Boll. d'ocul. 26:98-102, Feb., 1947.

A patient operated on for senile cataract by extracapsular extraction, with round pupil, had 10/10 corrected vision; one year later, corrected vision was only 3/10 and a relative central scotoma for red was present. This scotoma disappeared after discission of the secondary membrane and vision returned to 10/10. The author asked Professor Vasco Ronchi for an explanatory discussion which is reprinted in extenso. Ronchi agrees with the explanation previously given by Focosi that the central scotoma in these cases is due to a deterioration of the retinal image, attributable to the irregular opacification of the posterior lens capsule.

K. W. Ascher.

François, J. **Glaucoma and cataract.** Ann. d'ocul. 180:457-465, Aug., 1947. (See Section 9.)

Jones, Edgar. **Comments on hypoparathyroidism and cataract formation.** Am. Practitioner 2:167-169, Nov., 1947.

Lack of parathyroid hormone allows calcium in the aqueous to penetrate the lens capsule which results in the formation of cataracts after exposure to ultraviolet light. This may occur after thyroidectomy. Two cases are reported. One patient did not wear glasses and developed bilateral cataracts. The second patient wore glasses which presumably gave protection against exposure to ultraviolet light and did not develop cataracts.

Irwin G. Gaynon.

Stallard, H. B. **Cataract.** Practitioner 158:383-393, May, 1947.

The etiology of cataract is discussed briefly. Important factors are the biologic effects of senescence, local disturbances in the metabolism of the lens that result from specific diseases and the effect upon the lens of such general metabolic disturbances as vitamin deficiencies and endocrine dysfunctions. Lens changes occur in 96 percent of persons over 60 years of age. The degree to which the patient is incapacitated in relation to his particular type of work is the factor which determines when operation should be performed. Unilateral mature cataracts should be kept under observation and operation performed at the first signs of onset of hypermaturity. The author advocates the use of corneo-scleral sutures to close the wound. Ninety-six percent of patients operated on for cataract recover useful vision. Benjamin Milder.

Pittar, C. A. **Intracapsular cataract extraction.** Supp. New Zealand M. J. pp. 13-17, 1947.

A method of intracapsular cataract extraction is described. The author uses keratome and scissors section, peripheral iridectomy, and extraction and seals the conjunctival flap to the episcleral tissues by forming a coagulum with plasma.

Irwin E. Gaynon.

Vos, T. A. **"Extraction en carré" of secondary cataracts.** Ophthalmologica 113: 319-320, May, 1947.

The author describes the following method for the partial extraction of secondary cataracts: a central square "window" is cut into the secondary cataract by means of two discission knife-needles. First, the two vertical sides of the window are cut with a discission knife introduced through the temporal part of the limbus. With another needle-knife introduced at 6 o'clock the two horizontal cuts are made. Finally, the square piece is removed through a small keratome incision from below. "The greatest advantage of the method is that traction on iris or ciliary body is avoided." The author does not state how many times he has used this method or what his results have been. Peter C. Kronfeld.

Wolfe, O. R. **Twenty years experience with the Barraquer technic of cataract extraction.** J. Internatl. Coll. Surg. 10:398-403, July-Aug., 1947.

A conjunctival flap, keratome section and enlargement of the incision is made with scissors. Conjunctival sutures are placed in the 10, 12 and 2 o'clock positions. The Barraquer vacuum forceps is applied to the lens capsule. The lift on the lens is made forward toward the center of the cornea, while counter pressure is made just below the limbus on the vitreous thereby performing a combined extraction. The erisphake is the best means of grasping the capsule in intumescent and immature cataracts.

11
RETINA AND VITREOUS

Bjork, Stina. **Haemodynamic factors and retinal changes in hypertensive diseases.** Acta. Med. Scan. suppl. 175, pp. 1-165, 1946.

This monograph summarizes a study on 228 patients of three years' duration. In an attempt to uncover information about the origin and development of the hypertensive diseases, the patients were divided into two major age groups, from 14 to 40, and from 41 to 65.

The study consisted of a blood pressure measurement (after Korotkoff) and an analysis of the circulation (after Broemser and Wezler-Boger). The eye examination consisted of a measurement of vision and a refraction, ophthalmoscopic examination, measurement of the caliber of the retinal vessels (after Lobeck) and determination of the diastolic pressure of the central retinal artery (after Bailliart).

The 117 patients with essential hypertension, were found to have a narrower arterial caliber than the 59 with normal circulation. There was no significant difference in the caliber of the vessels in essential hypertension with and without retinopathy. The 34 patients with nephritis with or without retinopathy did not show a significant difference in arterial caliber when compared with normal subjects. The 11 patients with diabetes mellitus with hypertension and retinopathy did not show any significant differences in the factors which determine blood pressure when compared to findings in patients showing the same retinal picture with hypertension alone. The seven cases of thrombosis of the central retinal vein with hypertension show the same haemodynamic factors as cases of essential hypertension without fundus changes.

The author feels that the recording of the diastolic pressure of the central retinal artery yielded no information of importance beyond that obtained by recording the diastolic blood pressure in the brachial artery.

The development of fundus changes is due to a disturbance of nutrition in the retina. This is brought about by the early loss of elasticity of the large vessels arising from the heart. The appearance of a gradual increase in the total peripheral resistance with a simultaneous decrease in the cardiac output then causes a gradual diminution of the blood supply to the retina, with a local anoxemia. (18 figures, 18 tables.) H. C. Weinberg.

Couadau, A., and Planques, P. **Ophthalmoscopy in malignant arterial hypertension.** Rev. oto-neuro-oftal. 22:27-31, March-April, 1947.

In individuals over 50 years of age with chronic essential hypertension there are found the usual permanent lesions due to changes in the arteriolar and capillary walls, marked elevation of retinal arterial tension, and spasmodic exudative lesions such as hemorrhages, exudates, and edema. Occasionally one finds central vein thrombosis and almost total spastic arterial closure. In malignant arterial hypertension the eye changes occur between 25 and 50 years of age. Here the dangerous prognostic picture is neuroretinitis, in addition to hemorrhages, exudates, and spastic arterioles.

Edward Saskin.

De Ruyter, J. **The pathogenesis of lesions involving the ganglion of the optic fascicle.** Ophthalmologica 113:276-279, May, 1947.

The author's main point is that in a number of diseases which have been designated as retrobulbar neuritis the lesion is actually in the ganglion cell layer of the retina and not retrobulbar. If it were retrobulbar it should not be called neu-

ritis because the optic nerve is not a nerve, and also because the pathological process is usually not inflammatory. It has been definitely established that in methyl alcohol intoxication in man the multipolar ganglion cells of the retina are primarily affected. In tobacco and ethyl alcohol poisoning as well as in luetic optic atrophy the primary site of the lesions in the third neuron may also be in the ganglion cell layer of the retina. The author tries to correlate this apparent vulnerability of the ganglion cells with their ascorbic acid content (the other retinal layers containing practically no ascorbic acid). "In case of the development of a lesion of the optic fascicle due to tabes, we will try to improve the defective cell respiration by putting the required vitamins at the disposal of the cells. It must still be elucidated if ascorbic acid gives better results than the vitamins of the B group." Peter C. Kronfeld.

Doucet, P. **Softening of the retina in sectors and its relation to detachment.** Arch. d'opht. 7:167-170, 1947.

Doucet considers the various theories of the origin of retinal detachment, including traction by vitreous strands and retinal holes due to cystoid degeneration and choroidal atrophy. Cases have occurred in which white retinal streaks with obliterated vessels and atrophy of nerve tissue have been noted. The author reports two observations illustrating this type of retinal change. In his first case a man of 33 years with 16 diopters of myopia gradually lost vision in the right eye over a period of several years. There was a large flat detachment of the retina that involved the area about the macula, with a sector-like vascular disturbance and gross retinal lesions that consisted of spots of retinal atrophy.

In the second case a man of 37 years with a history of active tuberculosis had a detachment in the left eye following a tuberculous iridocyclitis with multiple iris tubercles. The detachment was sector-like in character and had a single radial tear at 2 o'clock. This was closed by operation. After operation the lesion could be seen to be essentially a degeneration of the retina consecutive to an incomplete arterial thrombosis. The area of retinal disturbance continued to increase, however, and the detachment later recurred.

The author concludes that in both these cases an arterial lesion was at fault, resulting in multiple lenticular plaques of retinal atrophy. He believes that arteritis unquestionably plays a role in the production of certain cases of retinal detachment. Phillips Thygeson.

Fischer, F. P., and Moorrees, H. G. **"Camp eyes" and solar retinopathy.** Ophthalmologica 114:10-15, July, 1947.

During 1945 and 1946 two types of disturbances of central vision made their appearance in the Dutch Eye Clinics: (1) the cases of "camp eyes" in persons that had been released from the Japanese camps for civilians and prisoners of war in the Dutch East Indies and had returned to Holland, and (2) cases of solar retinopathy in residents of Holland who during the partial solar eclipse of 1945 had exposed their eyes to an excessive dose of sunlight.

Fischer and Moorrees were struck by the similarity between the two diseases. Fischer had had considerable experience with severe cases of solar eclipse retinopathy (results of the eclipse of 1912) and Moorrees had been an internee in one of the Japanese camps for Dutch civilians on Java from 1942 to 1945. There he had daily contacts with early and advanced stages of "camp eyes."

The permanent residues of both diseases are very similar indeed. The central area is riddled with small scotomas which produce annoying metamorphopsia, but are compatible with a visual acuity up to

20/40. Ophthalmoscopically, the pigmentation in the macular region is irregular (most noticeable in red-free light), and the normal reflexes are absent.

The question arises how a fairly diffuse macular lesion such as is entailed in solar retinopathy can lead to multiple small scotomas which break the central area up in many little islands. To answer this question, Fischer and Moorrees invoke the theory of Hartridge according to which the retinal cones are normally arranged in clusters.

"Camp eyes" is undoubtedly a disease of undernourished people living in the tropics. Malnutrition of the same or greater severity such as must have prevailed in many parts of Europe did not produce "camp eyes." Since life in the Dutch East Indies entails more exposure to sunlight than life in Central or Western Europe, the authors feel justified in attributing the retinal damage in "camp eyes" to the action of the tropical sun upon a tissue that has become sensitized to light by a dietary deficiency such as is present in pellagra. The authors thus consider "camp eyes" primarily a retinopathy and not an optic nerve lesion. Treatment is effective only in the earliest stages of the disease. Peter C. Kronfeld.

Jona, S., and Camerini, R. **Therapy of retinitis pigmentosa by irradiation of Budge's ciliospinal center.** Riv. oto-neuro-oftal., 22:66-84, Jan.-Feb., 1947.

The writers consider spasm and hyaline degeneration of blood vessel walls to be important factors in the pathogenesis of retinitis pigmentosa. They report various means to control spasm and mention the surgical procedures upon the cervical sympathetic system. They tried inhibition of the cervical sympathetics by irradiation. In five out of seven patients of the same family the treatment was followed by an improvement either in visual power or in visual field. A hyaline degeneration of vessel walls was excluded in the five patients. It is the writers' opinion that irradiation therapy has the advantage over surgical therapy that it may be repeated. (Bibliography.)

Melchiore Lombardo.

Katzin, H. M., and Blum, John. **Transplantation of vitreous. A preliminary report.** Brit. J. Ophth. 31:760-766, Dec., 1947.

The authors review the literature on transplantation of the vitreous and report the results of experiments of vitreous transplant in rabbit eyes. The vitreous can usually be successfully transplanted. This is better than replacement with saline. It is, however, not without complications such as retinal detachment, traumatic cataract and fibrous tissue proliferation. Vitreous haze, thought to be due to alteration in physico-chemical properties of the injected vitreous, was present in a high percentage of the transplants, but usually cleared completely. Oxilia, Efisio. **Vascular anomalies of the retina: prepapillary arterial loop.** Ann. di ottal. e clin. ocul. 72:408-427, July, 1946.

A case is described and pictured of a prepapillary arterial loop of three spiral twists projecting two millimeters from the retina into the vitreous in the left eye of a 42-year-old woman. One limb arises from the disk, and the other is connected with a vessel on the retina. The distribution of the vessels, which are moderately tortuous, is irregular. The lower nasal quadrant is supplied at least in part from

the superior nasal branch of the central retinal artery, and a cilioretinal artery is present on the temporal side.

Oxilia reviews the literature on congenital vascular anomalies of the fundus since 1858, and of four hypotheses prefers that advanced by Little in 1881, according to which the loop is due to the exaggeration of the tortuosity of a single retinal vessel during the period of development.

Harry K. Messenger.

Redslob, E. **The pathogenesis of retinitis pigmentosa.** Ophthalmologica 113: 290-302, May, 1947.

Redslob reports the case of a female infant, 14 months of age, who shortly after vaccination against smallpox lost most or all the sight in both of her eyes. The pupils were in the state of amaurotic fixation. The fundi showed severe retinal ischemia. After six weeks of treatment with vasodilators and arsenicals the vision returned and the pupils resumed their normal activity. The discs, however, remained pale, the retinal vessels markedly narrowed and the eyegrounds retained the appearance of "pallor" that made Redslob think of arterial spasm in the choroid in addition to the retinal angiospasm. Ten years later he saw the child again. According to the parents, she had developed normally, had learned to read and write and did well in school. She herself complained of poor vision at night. Her corrected central vision was 0.5 in each eye, the visual fields were tubular and the fundi showed the picture of a typical advanced pigmentary degeneration of the retina.

Redslob reviews the theories concerning the pathogenesis of pigmentary degeneration of the retina. He concludes that these degenerations must be divided into two main groups, the so-called independent forms which are not due to heredity but to injuries, infections, intoxications; and the second group in which heredity is the basis of the retinal degeneration as well as of the associated neurological and other disturbances. The case reported in the paper belongs to group one.

Stearns, S., Friedman, E., Lugitch, M., and Hoffman, S. H. **Lipemia retinalis.** New England J. Med. 238:16-17, Jan. 9, 1948.

This, the sixty-third case of lipemia retinalis to be reported, occurred in a four and one half-year-old girl. There was an associated diabetic acidosis and a blood cholesterol of 1010 mg. per 100cc. The pupils were equal and active and the lenses were clear. In each eye the fundus was pale and the vessels were cream-colored ribbons. Arterioles and veins were indistinguishable.

OPTIC NERVE AND CHIASM

Levin, S., Trevett, L. D., and Greenblatt, M. **Syphilitic primary optic atrophy.** New England J. Med. 237:769-772, Nov. 20, 1947.

This is a review of 54 cases seen at the Boston Psychopathic Hospital during the years 1921-1944. Gradual visual loss was the first manifestation of trouble in 63 percent. The serologic reactions in untreated cases is negative only rarely. Pupillary abnormalities were present in 49 out of 51 (Argyll-Robertson in 36 of these). Tabetic features were mild, and no patient had marked ataxia. Visual fields showed moderate irregular constriction. The spinal fluid generally was strongly abnormal (Group III, paretic type). Without treatment there was frequent visual loss of 1/200 or less in both eyes within twelve months, which empha-

sizes the need for prompt treatment. Chemotherapy is no guarantee that optic atrophy will not occur. Treatment does not necessarily improve vision, but there is hope that it will keep it from deteriorating. The optic atrophy may respond well provided treatment is started soon enough. Artificial fever is an important addition to therapy. (1 table, 1 figure, references.) Bennett W. Muir.

McLean, J. M., and Ray, B. S. **Soft glaucoma and calcification of the internal carotid arteries.** Arch. Ophth. 38:154-158, Aug., 1947.

In 1932 Knapp reported cases of atrophy of the optic nerve with shallow cupping, defects of the visual fields which tended toward altitudinal hemianopsia and persistently normal tension. He was able to demonstrate roentgenographically the calcification of the arteries at the base of the brain in all 10 cases. The authors report a similar case in a man aged 61 years. The patient had had various diagnoses of glaucoma in spite of low intraocular pressure and had had an iridectomy done in one eye. Roentgenograms of the skull were normal and failed to disclose any unusual sclerosis of the carotid arteries. An exploratory craniotomy was done. Both optic nerves were longer than usual and ran up over the internal carotid arteries. Both nerves appeared atrophic. At the point where the nerves crossed the arteries they were flattened in ribbon-like fashion. The internal carotid arteries beneath were sclerotic, and each had a calcified plaque in its wall directly under the nerve. On direct observation, these calcified plaques could be seen hammering against the optic nerves with each pulse beat. It was felt that nothing constructive could be done. The patient made an uneventful recovery with no change in the visual status. John C. Long.

Salgado Benavides, E. **A contribution to the study of the non-pathologic optic papilla.** Arch. Soc. oft. hisp.-amer., 7:756-770, Aug., 1947.

Eleven physiologic variations of the optic disc are described and illustrated; they include a disc with an epipapillary membrane projecting above its level; an apparent folding of the nasal over the temporal portion of the disc, produced by a thin membranous formation, over the physiological excavation of the disc, perforated by the retinal vessels; myelinated nerve fibers; hyaline membranes enveloping the central vessels; and unusually large excavations, one of which approaches the size of a coloboma of the disc. A case of a papilla, in which the excavation is divided into two portions by a vertical band of fibrous tissue is, according to the author, the third case of this type to be reported in literature. Ray K. Daily.

NEURO-OPHTHALMOLOGY

Bachstez, E., and Baumgärtel, K. **Sources of error in the examination of the pupil.** Wien. klin. Wchnschr. 59:666-669, Oct. 10, 1947.

For the attainment of consistency and uniformity in the results of pupillary examination it is necessary not only to avoid gross errors of method but also to bear in mind the complex factors that determine the behavior of the pupils. It is the latter especially with which the authors concern themselves.

Ideally the source of light and the spot on the retina that is illuminated should be constant and the retina should be in a known state of adaptation. It is essential that the retina be dark-adapted, that the patient look into the distance to com-

pletely relax accommodation, that each eye be tested separately, and that the light fall on the fovea. Contraction to light is a true reflex, convergence contraction is an accompanying movement similar to the narrowing of the pupil when the lids are pressed together.

The dilatation which follows contraction should not be disregarded. Inhibition of the sphincter can be brought on by fear, surprise or a sudden thought. Redlich's symptom (widening of the pupil when the hands are firmly pressed together) is an example of this kind of inhibition. The sensory reflex can come from the region supplied by the trigeminal nerve and from other parts of the body, notably the skin. Auditory stimuli and the phases of respiration also act on the state of the pupil. A "paradoxical reaction," i.e. light seeming to dilate the pupil is always due to one of these outside causes.

A number of examples are cited to show how errors in diagnosis arise. The pupil is never in a state of rest. The evaluation of pupillary findings is most difficult in neurologic patients because of the many neuro-vegetative disturbances to which such patients are subject.

Cojazzi, L., and Sala, O. **Researches on the interference between the optokinetic nystagmus and caloric and postrotatory ones induced simultaneously in man.** Riv. oto-neuro-oftal. 22:50-65, Jan.-Feb., 1947.

The writers report the phenomena of interference which manifest themselves in man after optokinetic, caloric and postrotatory nystagmus are provoked. Normal individuals were examined. The optokinetic nystagmus was induced by the rotation of a cylinder with white and black stripes set in motion electrically with constant speed. For the caloric stimulation they used Veits's method and for the rotatory Buys-Fischer's. The optokinetic nystagmus constantly inhibited a provoked vestibular nystagmus of opposite direction and replaced it. The suppression of the labyrinthine nystagmus lasts as long as the optokinetic stimulus in an opposite direction is active; if the latter ceases the vestibular nystagmus reappears with its former characteristics. The normal phasic development of post-rotatory nystagmus is not at all modified by the interference of the optokinetic. When the calorific nystagmus has subsided for one or two minutes a "facilitation" is instituted for the optokinetic nystagmus towards the side to which the preceding caloric nystagmus had been directed. (Bibilography.)

Ferrata, Luigi. **Ocular changes in Paget's disease.** Ann. di ottal. e clin. ocul. 72:557-565, Sept., 1946.

A 53-year-old woman affected with Paget's disease for four years had diminution of vision, decrease of normal winking, exophthalmos, neuroparalytic keratitis (hypesthesia, loss of epithelium, and opacities), and papilledema with possible optic atrophy. These manifestations are all ascribed to mechanical factors arising from extensive osteitis deformans at the base of the skull. There was marked narrowing of the sphenoidal fissure. (References.)

Harry K. Messenger.

Focosi, M., and Maggioni, G. **Ophthalmoplegic hemicrania of Charcot from aneurism of internal carotid artery.** Boll. d'ocul., 25:537-551, Oct.-Dec., 1946.

A boy, six years of age, had vomiting without nausea in the early morning followed by intense headaches, especially in the right fronto-orbital region. This condition lasted for one day and was followed by ptosis of the right upper lid. The eyeball deviated outward, and the excursions of the eyeball inward, upward and downward were abolished. The pupil was

dilated and the accommodation was paralyzed. These symptoms gradually disappeared. A few months later they reappeared and arteriography of the brain revealed a round dilatation of the internal carotid artery in the clinoidal region. The etiology, pathogenesis and location of the lesion are discussed at length. (4 figures, bibliography.) Melchiore Lombardo.

Hughes, E. B. C. **The visual fields in indirect injury of the optic nerves.** Tr. Ophth. Soc. U. Kingdom. 65:35-46, 1945.

Visual field defects were found to fall into distinct groups in indirect injuries to the optic nerve, the so-called typical group and those of widely different types.

Indirect injuries of the optic nerve usually present instantaneous loss of vision, and appearance of primary optic atrophy in about three weeks, with minimal recovery in the first four weeks. The visual field defect involves the inferior part of the field of the affected eye. The depression field occasionally spreads to the upper half of the field. The upper nasal quadrant was least frequently affected by this depression. Three cases presented arcuate scotomata of the nerve fiber bundle which seemed to be associated with vascular lesions of the optic nerve.

In the operative treatment of these cases one must consider the removal of bone fragments, collections of blood within the nerve sheath, and local subdural haematomata. (8 figures.)

Beulah Cushman.

Lijó Pavia, J. **Retino-hypophysary syndrome. Treatment with gonadotropine. Four new cases.** Rev. oto-neuro-oftal. 22:5-9, Jan.-Feb., 1947.

This paper represents further investigation of a previously reported syndrome that embraces an unusual ophthalmoscopic picture, diminished central vision, atypical alterations of the visual fields, radiographic changes in the sella turcica and improvement with hormonal therapy. The present series consists of three women in the menopause and one male child eight years of age. There were sector defects and macular changes with typical sellar thinning. The central vision was always subnormal, ranging from 0.2 to 0.7. Hormonal injections were followed by only slightly improved vision but resulted in an increase in the sense of well-being. (4 figures.) Edward Saskin.

Lutt, C. J. **Denial of blindness and Argyll Robertson pupils without syphilis.** Bull. Los Angeles Neurol. Soc. 12:189-191, Dec., 1947.

The author reports an interesting case of denial of blindness with the clinical symptoms of meningovascular syphilis. The latter was unverified. At autopsy it was found that the pupillary immobility to light was due to a vascular lesion in the mesencephalon. The nystagmus and the cerebellar ataxia were explained on the basis of cerebellar softening and blindness was clearly due to softening of both occipital lobes following occlusive vascular changes. As not all patients with cortical blindness have the delusion that they can see, this was ascribed to the mental state of the patient, who confabulated and showed visual agnosia before becoming completely blind. This case confirmed the fact that the clinical symptoms of meningovascular syphilis are not a specific manifestation of the spirochete, but of the anatomical site of the lesions.

O. H. Ellis.

Marín Amat, M., and Marín Enciso, M. **Visual symptoms as the first subjective manifestations of hypophyseal tumors.** Arch. Soc. oft. hisp.-amer. 7:815-817, Aug., 1947.

A report of the data in a case of supracellar tumor with blindness and optic atrophy of the right eye, and one-sixth

visual acuity and incomplete optic atrophy of the left eye is presented. (2 illustrations.) Ray K. Daily.

Marmion, D. E., and Sandilands, J. **Opsoclonia: a rare ocular sign in polioencephalitis.** Lancet 2:508-509, Oct. 4, 1947.

A description is given of a case of probable polioencephalitis exhibiting a bizarre type of nystagmoid movement of the eyes. It is suggested that this is probably identical with that previously described under the name "opsoclonia" by Orzechowski in 1927.

Theodore M. Shapira.

Marucci, Luigi. **The psychic restitution of the pupillary reflex when fatigued to light, as studied with the pupillographic method of Loewenstein and Borsotti.** Ann. di ottal. e clin. ocul. 72:546-556, Sept., 1946.

A series of pupillograms is shown in which the restitution of the light-fatigued pupillary reflex occurs when the subject is stimulated psychically, as by a loud and unexpected noise. The pupillograms of patients with various neurologic and ocular disturbances are also shown, whereby the diagnostic and prognostic importance of this psychic restitution is demonstrated. The phenomenon is found to be dependent on the integrity of the sympathetic nervous system. (14 figures.)

Harry K. Messenger.

Nielsen, J. M. **Sensory perception through vision, a synesthesia.** Bull. Los Angeles Neurol. Soc. 12:195-196, Dec., 1947.

The author reports a case of epilepsy in a young adult following an injury at two years of age to the right occipital lobe. Her aura was the appearance of a large dark object in her blind left field. In this homonymous hemianopic field the presence of objects and a faint light were "felt" with either eye—a sensory response, a form of synesthesia. It was thought that the impulse reached the right thalamus and registered as a tactile impression. O. H. Ellis.

de Ocampo, Geminiano. **Latent nystagmus following head injury.** Arch. Ophth. 37:775-779, June, 1947.

A man, aged 24 years, a Filipino veteran of Bataan, received an injury to the left occipitoparietal area from fragments of an artillery shell. Eight months later it was observed that with the eyes in the primary position for far vision, there was no definite nystagmus. With the eyes right, spontaneous, transient, jerky horizontal nystagmus of both eyes to the right was present. With eyes left, a similar nystagmus, of lesser intensity, was noted. Caloric tests showed vestibular hyposensitivity, but the rotatory test revealed a stronger or longer state of irritability on the right side.

Various theories of the causation of nystagmus are discussed. The peripheral sensory stimuli and the state of stability of the lower coordinating centers, as well as the balance of the innervating influence of the higher voluntary and involuntary centers, must be considered as a whole in the explanation of the mechanism of latent nystagmus, and probably of all nystagmus. John C. Long.

Rubino, A. **"Arachnitis," "Endocraniosis" and Opticochiasmatic arachnoiditis.** Riv. oto-neuro-oftal. 22:85-102, March-April, 1947.

A married woman, 37 years of age, had had headaches since girlhood and, for the previous ten years, gradually failing vision. At the examination the vision of the right eye was found to be reduced to the recognition of hand movement and of left eye to 1/50. There was optic atrophy, the discs had slightly indistinct margins, the retinal arteries were contracted and

the veins enlarged. Absolute upper hemianopsia and absolute central scotoma were present in the right eye. In the left eye the hemianopsia was relative, and the central scotoma was relative for white and absolute for colors. Radiography showed a thickening of the skull especially in its frontal region, a calcification left of the midline and signs of chronic pansinusitis. The Pirquet reaction was strongly positive. A diagnosis of optico-chiasmatic arachnoiditis with meningo-endocraniosis was made. At the operation a right frontal flap was made. A marked thickening of the bone was found, the dura was found to be very thin and adherent to the bone. The optic nerves were reduced to half-normal size. The anatomic-clinical and etiopathologic relation that occurs between optico-chiasmatic arachnoiditis and primary arachnitis as well as endocraniosis is discussed. This is the third case reported in the literature. A classification of the various clinical forms of optico-chiasmatic arachnoiditis of the group of meningo-endocranioses is proposed. Melchiore Lombardo.

EYEBALL, ORBIT, SINUSES

Bianchi, G. **Two cases of cavernous agioma of the orbit.** Rassegna ital. d'ottal. 16:317-334, Sept.-Oct., 1947.

Two cases of cavernous angioma of the orbit are reported. The difficulty of exact diagnosis of the nature and site of such tumors is pointed out. The author recommends a comparison of the white blood cells found in the general circulation with those obtained by exploratory puncture of the angioma. The latter is characterized by a definite increase in the eosinophiles and basophiles, and the presence of immature cells. Histological examination of the tumors confirmed these findings. Accumulation of lymphocytes appear to initiate the formation of the fibrous tissue of the tumor. The lumen of vessels showed an increase of white cells and a decrease of the red. Good results were obtained in each case by removal of the tumors through Krönlein incisions. (5 figures.) Eugene M. Blake.

Hope-Robertson, W. J. **Pseudotumour of the orbit.** Supp. New Zealand M. J. pp. 18-30, 1947.

A pseudotumour of the orbit in a 43-year-old man is described. The pathology, differential diagnosis and treatment is discussed and a plea is made for biopsy as an aid to diagnosis. (5 figures.)

EYELIDS, LACRIMAL APPARATUS

Bloch, F. J. **Minor anomalies in position of the eyelashes.** Arch. Ophth. 37: 772-774, June, 1947.

Aberrant eyelashes may grow upward either subcutaneously or subconjunctivally. The subconjunctival growth is much the more important as the cilium may pierce the conjunctiva and rub upon the cornea. Both of these anomalies are explained on a mechanical basis. The sprouting cilium encounters an obstacle and is bent backward. Two cases are reported, one of cilium incarnatum externum and one of cilium incarnatum internum. John C. Long.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Elmer Cleo Ambrose, Trenton, Missouri, died October 15, 1947, aged 55 years.

Dr. Louis Storrow Greene, Washington, D.C., died November 12, 1947, aged 74 years.

Dr. Oscar Wentworth King, Coral Gables, Florida, died October 16, 1947, aged 63 years.

Dr. Albert Howell Mann, Texarkana, Arkansas, died October 16, 1947, aged 48 years.

Dr. Elmer Eason McKeown, Denver, Colorado, died October 7, 1947, aged 67 years.

Dr. Joel Whitaker, Indianapolis, Indiana, died October 13, 1947, aged 70 years.

ANNOUNCEMENTS

AMERICAN BOARD EXAMINATIONS

The American Board of Ophthalmology announces that practical examinations will be given in Baltimore from May 20 to 25, 1948, and in Chicago from October 6 to 9, 1948.

Written qualifying tests will be held annually, probably in January of each year. Applicants for the January, 1949, written qualifying tests must be filed with the secretary, Dr. S. Judd Beach, Cape Cottage, Maine, before July 1, 1948.

DIRECTORY SUPPLEMENT AVAILABLE

A supplement of diplomates from January, 1947, to January, 1948, will be sent gratis to all purchasers of the directory of the American Board of Ophthalmology. This supplement is arranged alphabetically and geographically. No biographic material is included.

Diplomates are urged to keep the executive office, Cape Cottage, Maine, informed of all changes of address, so that the files can be kept up-to-date.

ARMY POSITIONS OPEN

The U. S. Army Medical Corps now has a number of excellent positions which can be filled by physicians who have completed their formal board requirements (residence phase) but who need one or two years of practice limited to their specialty. Seven openings in eye, ear, nose, and throat have been announced; and three openings in ophthalmology. Eligible physicians are asked to communicate with The Surgeon General, U. S. Army, Washington 25, D.C., giving the following information: name, address, age, nationality, marital status, dependents, with age of each, medical school and graduation date, internship and date, specialty and geographic location desired, contemplated length of service, and details of prior military service.

MISCELLANEOUS

CINCINNATI HAS EYE LABORATORY

The department of ophthalmology of the University of Cincinnati College of Medicine is establishing an eye laboratory under the direction of Dr. Donald J. Lyle. At present the work of the laboratory is concerned with the examination of eyes for diagnosis and the preparation of specimens for study and collection. Physicians of Ohio, Indiana, and Kentucky will have access to the services and facilities of the laboratory which is temporarily located in Pavilion A of the Cincinnati General Hospital. The Eastern Hills Lions Club made the first gift to support the laboratory.

FUCHS'S "HISTOPATHOLOGY OF THE EYE"

The second volume of *Histopathology of the Eye* by Adalbert Fuchs is now available. It can be obtained from the publisher, Franz Deuticke, Helferstorferstrasse 4, Vienna, Austria. The price is $17.00.

SOCIETIES

BETTER VISION INSTITUTE

The increased radio activity for 1947 was outstanding among the reports at the meeting of the Better Vision Institute in New York on January 16. A total of 524 radio stations throughout the United States and Canada have requested the new series, "Eyes on the Ball."

Another significant 1947 project was the development of a new series of 24 educational brochures covering every aspect of eye science and service intended for the use of professional persons and for distribution to schools, libraries, and museums.

MEXICAN SOCIETY FORMED

The Sociedad de Oftalmologia de Guadalajara (Mexico) was organized on November 27, 1947, for the development of scientific investigation in ophthalmology, improvement of the members, and the development of measures for prevention and cure of blindness. The honorary president of the new society is Dr. Enrique Avalos; Dr. Elias Mendoza Gonzalez is acting president; Dr. Manuel Romo, vice-president; Dr. Antonio Diaz Geurrero, treasurer; and Dr. L. Nuñez Leal, secretary.

READING MEETING

Dr. William J. Hertz of Allentown, Pennsylvania, spoke on "Office Procedures in Ophthalmology and Otorhinolaryngology Based on 40 Years' Experience," at the January 21 meeting of the Reading Eye, Ear, Nose, and Throat Society.

Cleveland Ophthalmological Club

At a recent meeting of the Cleveland Ophthalmological Club, the following officers were elected: Dr. John E. L. Keyes, president; Dr. George King, vice-president; and Dr. Roscoe J. Kennedy, secretary-treasurer.

During the fall and winter months, the club has had many interesting programs. At the September meeting, Dr. John M. McLean, New York, spoke on "Vertical Factors in Strabismus." This lecture was illustrated with many excellent slides showing various conditions encountered and the results obtained.

Dr. Alson E. Braley, New York, was the guest speaker at the November meeting. His paper was on "Virus Diseases of the Cornea."

Residents in ophthalmology from the Cleveland hospitals were guests of the club at the January meeting. They presented the following interesting and instructive program: "Sturge-Weber Disease: A Case Report," Dr. Luebert Docter; "Use of Di-isopropyl Fluorophosphate in Selected Cases of Glaucoma," Dr. J. H. Graham; "Cataract Associated with Myotonic Dystrophy: A Case Report," Dr. H. H. Hardesty; "Zonular Cataract: A Case Report," Dr. J. I. Moreland; "Eale's Disease: A Case Report," Dr. Howard Possner; "Oculoglandular Tularemia Treated with Streptomycin: A Case Report," Dr. J. E. Springer.

Chinese society celebrates founding

The Chengtu Eye, Nose, Ear, and Throat Society celebrated its tenth anniversary on December 20, 1947. Dr. T. H. Lan, professor of biochemistry, West China Union University, was the guest speaker. He spoke on "Biochemistry of the Blood in Patients Suffering from Malignant Tumors." The history and progress of the organization were reviewed by Dr. K. C. Lang and Dr. E. Chan.

N.S.P.B. conference

The 1948 conference of the National Society for the Prevention of Blindness will be held at the Radisson Hotel, Minneapolis, Minnesota, April 5 to 7.

Brooklyn program

At the 103rd regular meeting of the Brooklyn Ophthalmological Society, Dr. Charles E. Iliff presented a paper on "The Use of Beta Irradiation in Ophthalmology." The discussion was by Dr. Ira I. Kaplan. The following were presented for election to membership: Dr. David A. Anderman, Dr. Martin Bodian, Dr. Regina Gilroy, and Dr. Charles Labriola.

Research Association meeting

The Association for Research in Ophthalmology, Inc., will hold its annual meeting in Chicago on June 21 and 22. The place of the meeting will be Thorne Hall, Northwestern University Medical School, 303 East Chicago Avenue.

Personals

Dr. Dunphy appointed Williams Professor

Dr. Edwin B. Dunphy has been named the Henry Willard Williams Professor of Ophthalmology at Harvard University. This is one of the older chairs of ophthalmology in American universities. Dr. Dunphy's predecessors and their years of office are: Dr. Oliver Fairfield Wadsworth, 1899-1903; Dr. Miles Standish, 1909-1914; Dr. Alexander Quackenboss, 1920-1923; Dr. George Strong Derby, 1923-1931.

Dr. Dunphy succeeded Dr. J. Herbert Waite as executive head of the department of ophthalmology at Harvard University Medical School in 1940, as clinical professor of ophthalmology. Dr. Dunphy continues as executive head of the department, with the new title Henry Willard Williams Clinical Professor of Ophthalmology.

Lectures in Chicago

Dr. Adalbert Fuchs gave a series of lectures at the University of Illinois, Chicago, on January 30 and 31 and February 1.

Dr. Post gives Gifford Lecture

Dr. Lawrence T. Post of St. Louis presented the fourth annual Sanford R. Gifford Memorial Lecture to members and guests of the Chicago Ophthalmological Society, at the Murphy Memorial Auditorium, Chicago, on January 26. The subject of his address was "Practical Considerations in the Diagnosis and Treatment of Strabismus."

Cleveland newcomer

Dr. Russell Nichol has recently opened offices for the practice of ophthalmology in Cleveland, Ohio. Dr. Nichol was formerly a member of the staff of the Eye Institute, College of Physicians and Surgeons, Columbia University, New York.

Professor Lindner speaks at Gill

On the evening of February 24, Prof. Karl Lindner, chief of the eye clinic, University of Vienna, Vienna, Austria, spoke at the Gill Memorial Eye, Ear and Throat Hospital, Roanoke, Virginia. His subjects were: "Therapeutics on Diseases of the Eye," and "New Eye Operations."

SOME CONFUSING FACTORS IN THE DIAGNOSIS OF PARALYSIS* OF THE VERTICALLY ACTING MUSCLES†

THE JACKSON MEMORIAL LECTURE

FRANCIS HEED ADLER, M.D.
Philadelphia, Pennsylvania

During his career, Dr. Edward Jackson wrote over 600 articles. The list of subjects covers the entire field of ophthalmology. Beginning in 1882, the first paper listed in his bibliography is "A Comparative Study of the Action of Certain Mydriatic Alkaloids," and the last entry, in 1926, is entitled "What Is Cancer?" This should allow any Jackson Memorial lecturer plenty of freedom in the choice of a subject, even if he wished to confine himself to one of Dr. Jackson's interests. I have elected to discuss some of the difficulties encountered in diagnosing vertical ocular muscle paralyses. I find some of Dr. Jackson's best writing and many of his original ideas are contained in his papers on strabismus. Everyone interested in operations on the ocular muscles should read his paper on the "Principles Controlling Operative Interference in Squint," published in the *Transactions of the Section on Ophthalmology* of the American Medical Association in 1902, and "Operations on the Extraocular Muscles," published in the *Ophthalmic Record* of 1923. Both of these papers are splendid, and each would today make a truly great Jackson Memorial Lecture, as in fact they did when Dr. Jackson himself presented them in his characteristic style and in that unforgettable voice of many decibels.

Paralysis of a lateral or medial rectus muscle seldom causes any difficulty in diagnosis. The signs and symptoms generally follow those described in the textbooks. This is not true of paralysis of the vertically acting muscles. Although textbooks describe the typical strabismus, the theoretic diplopia fields, and the characteristic reactions to the embarrassment, such as face turning and head tilting, which one should encounter for each muscle paralyzed, in many instances when patients are examined, the findings cannot be made to fit the picture of a single paralyzed muscle.

On reviewing a series of case histories of ocular muscle paralyses, it was found that in a number the data indicated a paralysis of two muscles instead of one, which caused confusion in making a diagnosis. This was borne out by an analysis of the varying angle of strabismus in the oblique positions of gaze, measured by the cover test and the fixation fields, and by the characteristics of the diplopia fields. These cases could be divided into two groups. (1) Those in which the two muscles seemingly paralyzed could not have been caught by any one single lesion. The muscles of these cases were either (a) the superior rectus of one eye together with the superior oblique of the opposite eye; or (b) the inferior rectus of one eye together with the inferior oblique of the opposite eye. (2) Those in which a single lesion could have caused the paralysis of

* The terms "paralysis" and "paresis" have been used interchangeably as it seems to labor the point to distinguish between varying degrees of weakness of a muscle for the purpose of this article.

† Delivered on October 15, 1947, at the convention of the American Academy of Ophthalmology and Otolaryngology, Chicago, Illinois.

both muscles. The explanation of the cases in this group is obvious. If, for example, both elevators or both depressors of one eye

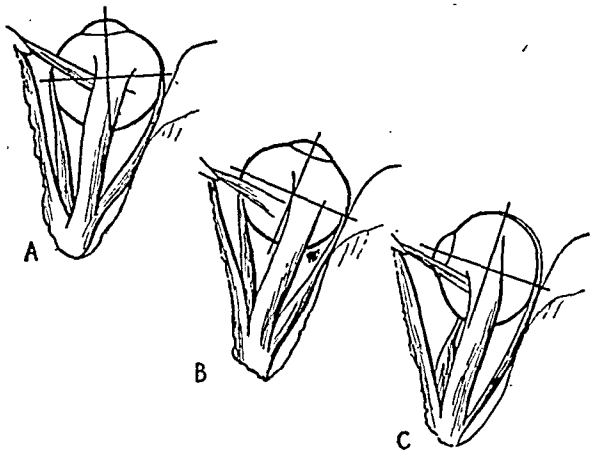

Fig. 1 (Adler). The right eye seen from above, showing the direction of pull of the superior rectus when the eye is in (A) the primary position; (B) abducted 23 degrees; (C) adducted 67 degrees.

are paralyzed, it is probable that they have been caught by a local process in the orbit such as scar formation or a tumor; or the nuclei of origin of the nerves supplying the two muscles have been involved by a lesion such as a hemorrhage in the pons.

The explanation of the cases belonging to Group 1 is not so obvious, since there is no place in the body where a single lesion could involve both of the muscles affected. It is the purpose of this paper to try to explain the cases in this group and to report some illustrative examples of cases belonging to the second group.

Group 1. The cases belonging in this group seem to have a paralysis of a superior rectus of one eye combined with a paralysis of the superior oblique of the opposite eye, or else an inferior rectus of one eye combined with an inferior oblique of the opposite eye. Since no single lesion in the body can produce such a combination of paralyzed muscles, what is their explanation?

The textbook description of paralysis of each of the ocular muscles is based on the varying action of each of the muscles in the different positions of gaze. When the eyes are in the primary position, the superior rectus, for example, will mainly effect an elevation of the globe. To this must be added a slight degree of intorsion and adduction (fig. 1A). When the globe is abducted 23 degrees so that the visual line coincides with the line of pull of the muscle, its contraction will produce nothing but elevation (fig. 1B). If the globe is adducted 67 degrees from the primary position (a degree of adduction never attained normally) contraction of the muscle produces intorsion and adduction (fig. 1C). The muscle's chief effect on the globe in one position of gaze becomes secondary or disappears altogether in another position, while a previously subsidiary effect now becomes predominant. This applies not only to the superior and inferior recti, but to the two obliques as well.

It is a simple matter to predict the strabismus and the diplopia fields which should occur in paralysis of any muscle, based on a knowledge of its action. This picture is based, however, on the effect which the paralyzed muscle has on the movements of this eye alone, and does not take into account the fact that the effect is never confined to the action of the paralyzed muscle alone but influences other muscles in the same eye and, under certain conditions, other muscles in the opposite eye, as well. This is always true when the paralyzed eye is used for fixation, following Hering's law of voluntary movements.

Hering's law states that in all voluntary movements of the eyes, the innervation sent down from the cortex is equally distributed to the muscles of both eyes concerned in that direction of gaze. When a subject voluntarily moves his eyes up and to the right, an equal innervation is sent to the right superior rectus and to the left inferior oblique. An equal inhibition is also sent to the corresponding antagonists of these muscles, according to Sherrington's law of reciprocal innervation. When a muscle is paretic, it requires more nervous energy to effect its movement than if it were normal. In patients with a paralyzed muscle, therefore, an

excessive innervation is sent not only to the paretic muscle, but to the yoke muscle in the opposite eye as well. If the right superior rectus is paretic and the patient looks up and to the right, with the right eye fixing, an excessive innervation will be sent to this muscle and to the left inferior oblique. This

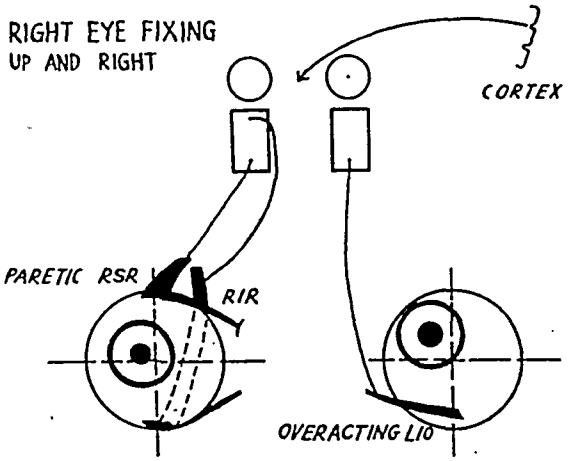

Fig. 2. (Adler). Diagram showing the secondary deviation of the left eye on looking up and to the right when the right superior rectus is paralyzed and the right eye is fixing. An excessive innervation is sent down from the cortex to both the right superior rectus and the left inferior oblique, causing overaction of the latter. Compare with Figure 3 in which the nonparalyzed eye is fixing.

latter muscle will therefore overact so that the left eye will move up too far (fig. 2). If the left eye is the fixing eye, however, the strabismus will be due entirely to the lag in elevation of the right eye. Under these conditions, the angle of strabismus will be less than when the right eye was fixing (fig. 3).

This is the principle that underlies secondary deviation, which is one of the causes of incomitance in paralytic squint. Incomitance in the angle of squint in paralysis of a muscle is due to two factors: (1) To the failure of the paralyzed muscle to move the eye in the field of its action, and (2) to the overaction of the yoke muscle when the paralyzed eye fixes.

In all cases of paralysis of sufficient severity to break up binocular vision, the eyes become dissociated and either the paralyzed or the nonparalyzed eye is used habitually for fixation. White (Tr. Am. Ophth. Soc., 31:551, 1933) believed that the paralyzed eye was usually the fixing eye in cases of congenital paralysis.

Many different factors determine which eye will be used to fix. Visual acuity is sometimes a factor, and the eye with the better acuity may be chosen. This is not always the

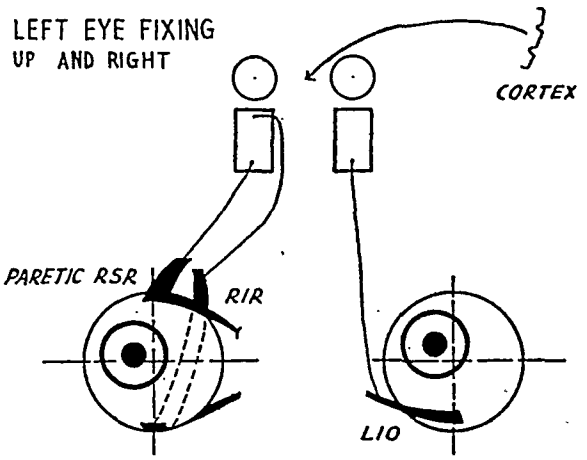

Fig. 3 (Adler). Looking up and to the right when the nonparalyzed left eye is fixing. The primary deviation is less than the secondary deviation in Figure 2.

case, however, and one may see patients in whom the paralyzed eye is used for fixation in spite of the fact that it has poorer vision than the nonparalyzed eye. Fixation with the paralyzed eye increases the strabismus due to secondary deviation. Some authors believe this is the reason why fixation is so frequently carried out by the paralyzed eye, since this increases the distance between the double images and therefore makes them less annoying to the patient.

In addition to the effect on the yoke muscle when the paralyzed eye is used for fixation, the effect on the antagonist of the paralyzed muscle must also be considered. Whenever there is a paralysis of a muscle, the antagonist in the same eye is able to move the globe in its direction of action with less effort than it does normally, since it lacks the restraining effect of the normal tonus of the now paralyzed muscle. This may seem to deny the existence of reciprocal innervation,

but does not necessarily do so. The relaxation which a muscle undergoes during contraction of its antagonist is only partial and considerable tonus is still retained. This is lost, however, when the muscle is actually paralyzed. If the right superior rectus is paralyzed, for example, the right inferior rectus can now move the eye down and to the right with less than normal effort. When

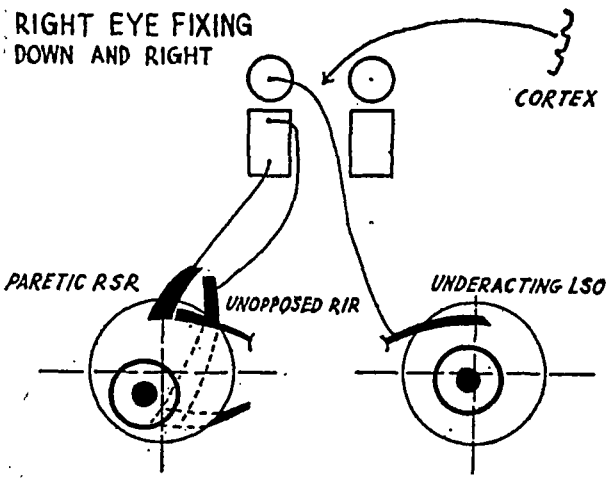

Fig. 4 (Adler). Looking down and to the right. The right superior rectus is paretic and the right eye is fixing. The right inferior rectus moves the eye down with less than the normal amount of innervation, since the opposing tonus of the right superior rectus is gone. Less innervation is sent to the left superior oblique, therefore, and the left eye fails to move down and to the right as far as it should. Compare with Figure 5.

the individual uses the right eye for fixation down and to the right, the innervation required for the right inferior rectus will be less than normal. A subnormal stimulus is sent, therefore, to the yoke muscle of the right inferior rectus; that is, the left superior oblique, and this muscle will underact with the result that the left eye will not be carried down as far as it should be (fig. 4). When the nonparalyzed left eye is used to fix in looking down and to the right, both eyes will move down almost equally well and there will be little strabismus (fig. 5). When the right eye is used to fix, therefore, the left superior oblique will appear to be paralyzed in gazing down and to the right. This has been called inhibitional palsy of the contralateral antagonist by Chavasse. This term is confusing, as well as being rather burdensome. Since it depends on the underaction of a muscle due to the principles embodied in Hering's law in the same manner that the overaction of a yoke muscle does, it would seem simpler to refer to it by the term "underaction." Unfortunately, some authors, especially Chavasse, use this term to indi-

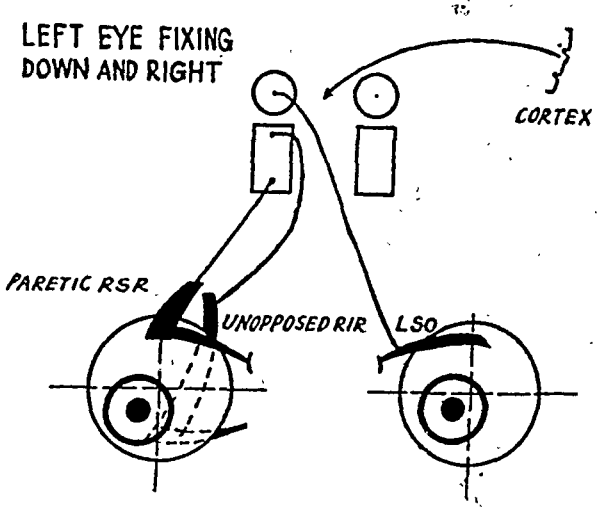

Fig. 5 (Adler). Looking down and to the right. The nonparalyzed eye is fixing and moves down normally. There is no underaction of the left superior oblique.

cate a contracture of the antagonist of a paralyzed muscle. When contracture of a muscle occurs, it is shortened and the squint produced by its shortening is comitant in all directions of gaze. Such a muscle is not underacting, and the term "underaction" of a muscle should be used only for the condition I have described above. As a matter of fact, we are quite ignorant of the changes which have taken place in muscles which are said to be contractured. This condition is seen clinically in severe paralysis of long standing, but to my knowledge no histologic examinations have been made of such muscles to determine whether they are fibrotic and shortened or hypertrophied.

Lancaster and others have emphasized the fact that the ocular muscles are at least 10 times as powerful as they need to be to effect the full rotation of the globe in the

direction of their action. It is evident on theoretic grounds that each muscle has to contract only one fourth of its length in order to move the globe its full amount in that direction; whereas, most of the other muscles of the body contract to one half their resting length. Assuming that the circumference of the adult globe is 72 mm., a

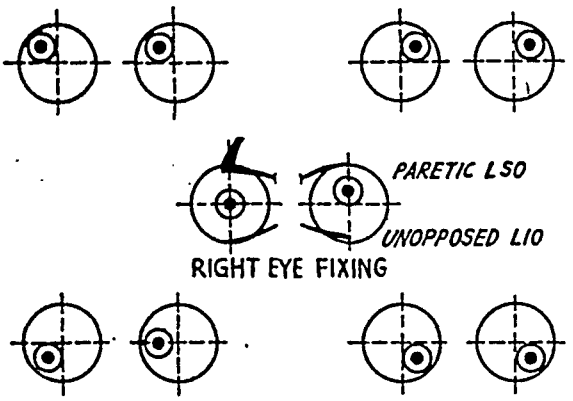

Fig. 6 (Adler). Showing the angle of strabismus in the primary and oblique positions of gaze in paralysis of the left superior oblique muscle when the nonparalyzed right eye is used for fixation.

rotation of 1 mm. equals an angular movement of 5 degrees. The external rectus need contract only 9 mm., therefore, in order to produce an abduction of the globe of 45 degrees, which is the limit of movement of the eye laterally. Since the muscle is over 40 mm. long, this necessitates a shortening of less than one fourth of the muscle's length.

It is clear that the strabismus found in the various positions of gaze will be quite different, depending upon whether the nonparalyzed or the paralyzed eye is habitually used for fixation. The typical strabismus given in textbooks for each paralyzed muscle assumes fixation by the nonparalyzed eye.

A comparison may now be made between the strabismus found when the nonparalyzed eye is used to fix with that found when the paralyzed eye is fixing. As an example, a paralysis of the left superior oblique muscle may be used. Figure 6 shows the positions assumed by each eye in the primary and the oblique directions of gaze when the nonparalyzed right eye is used for fixation. In the primary position, the left eye is too high due to the loss of tone of the superior oblique. The greatest vertical separation between the eyes occurs when the gaze is down and to the right, due to the weakness of the left superior oblique. In all other oblique positions of gaze, the eyes are in alignment.

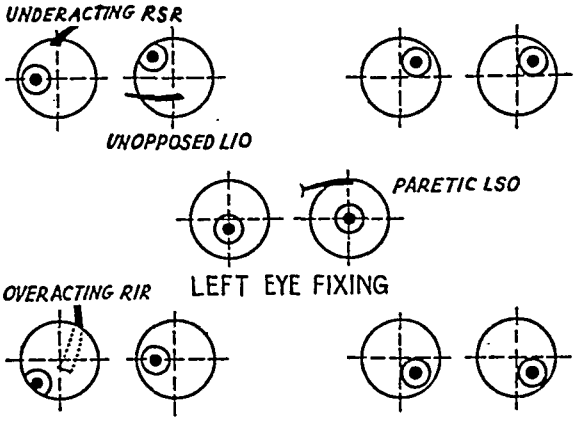

Fig. 7 (Adler). Showing the angle of strabismus in the primary and oblique positions of gaze in paralysis of the left superior oblique muscle when the paralyzed left eye is habitually used for fixation. Compare with Figure 6.

Figure 7 shows the strabismus in the various positions of gaze when the left, paralyzed eye is the fixing eye. In the primary position, the right eye will be too low and the angle of squint will be greater than when the nonparalyzed eye is fixing. The greatest separation of the visual axes will be in gaze down and to the right, and the angle of squint in this position will be greater than when the nonparalyzed eye was the fixing eye. This is due to the fact that the left eye fails to move down as far as it should and the right eye moves down too far due to overaction of the yoke muscle, the right inferior rectus. On gaze up and to the left and down and to the left, the eyes will be in alignment, but on looking up and to the right, the strabismus will increase again. The right eye fails to move up as far as it should in this direction, while the left eye is fixing. This is due to the fact that the left inferior oblique can move the left eye up and to the right with less innervation than normal, since the left

superior oblique is paralyzed. A weaker innervation, therefore, goes to the right superior rectus which underacts and this eye fails to move upward to the full extent. It will lag behind and appear to be paralyzed. If the left eye is covered, the right eye will be able to move up its full extent, showing that it is not really paretic.

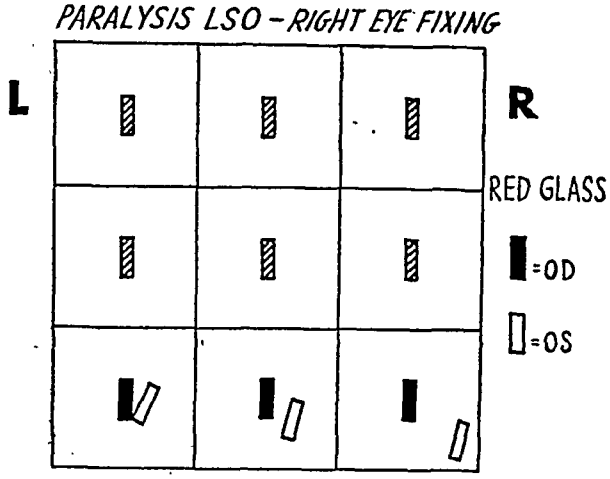

Fig. 8. (Adler). Simplified diplopia fields of paralysis of the left superior oblique as given in textbooks and found in patients when the nonparalyzed eye is used for fixation. Compare with Figure 9.

Whenever a superior oblique is paralyzed and this eye is used for fixation, one may have an underaction of the superior rectus muscle of the opposite eye. Similarly, if a superior rectus muscle is the paretic muscle, the opposite superior oblique will underact if the eye with the paretic muscle is used for fixation. The same condition will be found in paralysis of either the inferior rectus or the inferior oblique of either eye. One muscle is the paretic one, the other underacts according to Hering's law.

Corresponding to the differences in the angle of strabismus in various positions of gaze, one finds differences in the diplopia fields, depending on whether the paretic or nonparetic eye fixes. When the nonparalyzed eye is the fixing eye, the diplopia fields will generally be those given in the textbooks. When the paralyzed eye is habitually fixing, the diplopia fields will indicate two paralyzed muscles. Figure 8 shows the diplopia fields as given in textbooks when the left superior oblique is paralyzed. Figure 9 shows the diplopia fields frequently encountered, indicating both a paralysis of the left superior oblique and a paralysis of the right superior rectus. This type of diplopia field is found if the paralyzed left eye is the fixing eye. The involvement of the right

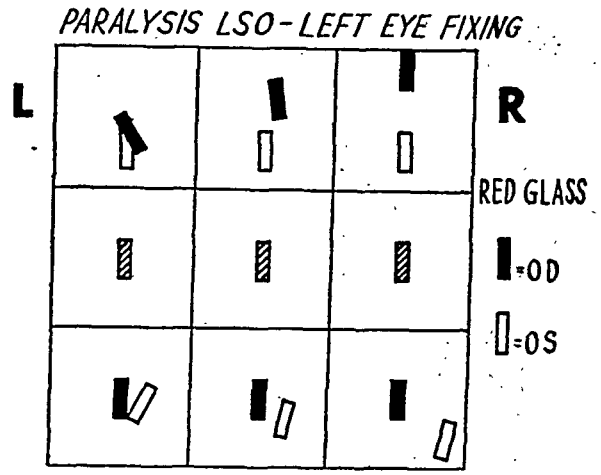

Fig. 9 (Adler). Simplified diplopia field in paralysis of the left superior oblique muscle found in patients who habitually choose to fix with the paralyzed eye. The fields indicate a paralysis of the left superior oblique and a paralysis of the right superior rectus.

superior rectus is due to underaction of this muscle and not to actual paralysis. This type of diplopia field is quite common. It should cause no confusion, if it is properly interpreted.

The varying angle of strabismus and the diplopia fields alone are not sufficient to enable one to tell which muscle is actually paralyzed and which muscle is merely underacting. I have called attention elsewhere (Arch. Ophth., 36:661, 1946) to the methods by means of which one may make a differential diagnosis in most cases between paralysis of these two muscles. Occasionally, it is not possible to decide which is the paralyzed muscle. Whenever patients are seen in whom two muscles appear to be paralyzed, and these muscles are a superior or inferior rectus of one eye, combined with a superior or inferior oblique of the opposite eye, one should recognize that one or the other muscle

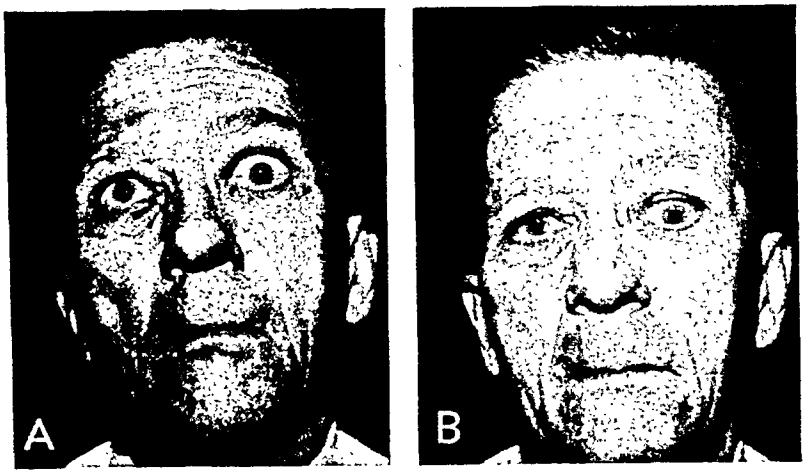

Fig. 10 (Adler). *Case 1.* Paralysis of the left superior rectus and left inferior oblique. (A) Left paralyzed eye fixing. (B) Right nonparalyzed eye fixing.

is actually the paretic muscle while the other is underacting due to habitual fixation with the paretic eye.

Group 2. The second group of cases are those in which the two muscles paralyzed are caught by a single lesion in the pons or the muscles themselves are involved in the orbit. The muscles paralyzed may be the elevators or the depressors of one eye or both superior obliques. Cases of supranuclear paralysis and paralysis due to myasthenia gravis have purposely been omitted from this discussion.

Anatomists are generally agreed that the muscles for elevation of the eye; that is, the superior rectus and the inferior oblique, have their nuclei of origin in the extreme anterior portion of the ipsilateral third-nerve nucleus. These cells all lie very close together and may easily be caught by small lesions in this region, such as a hemorrhage. Patients with a unilateral paralysis of the superior rectus and inferior oblique, either with or without ptosis, due to a small hemorrhage in this region, are frequently seen. (Kirby, D. B.: Arch. Ophth., 35: 199 (Mar.) 1946).

Case reports

Case 1. Mr. C. L., aged 65 years suddenly began to have vertical diplopia without any antecedent injury or illness. Examination showed a paralysis of the left superior rectus and left inferior oblique. Figure 10A shows the position of the eyes in the primary position when the left paralyzed eye is fixing, which is habitually the case. The right eye is elevated 25 degrees (secondary deviation) and the left upper lid is tucked due to overaction of the left levator consequent to the paresis of the left superior rectus. In Figure 10B, the nonparalyzed eye is fixing and the left eye is down 15 degrees.

Fig. 11 (Adler). *Case 1.* Angle of squint in the four oblique positions of gaze with the left paralyzed eye fixing. (A) Overaction of the right superior rectus. (B) Overaction of the right inferior oblique. (C) Underaction of the right inferior rectus. (D) Underaction of the right superior oblique.

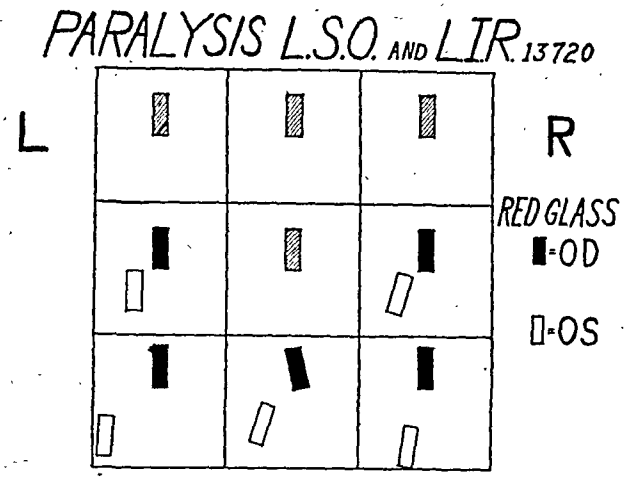

Fig. 12 (Adler). *Case 2.* Diplopia fields in paralysis of the left superior oblique and left inferior rectus. Right eye fixing.

Figure 11A shows the eyes up and to the right. The left eye is fixing, and the right eye overshoots due to overaction of the right superior rectus, the yoke muscle of the paretic left inferior oblique. In Figure 11B, eyes are up and to the left. The left eye is fixing and the right overshoots, due to overaction of the right inferior oblique, the yoke muscle of the paretic left superior rectus. In Figure 11C, the eyes are down and to the right. The left eye is fixing, and the right fails to move down as far as it should, due to underaction of the right inferior rectus, the yoke muscle of the left superior oblique. In Figure 11D, the eyes are down and to the left. The left eye is fixing and the right fails to move down as far as it should due to underaction of the right superior oblique, the yoke muscle of the left inferior rectus.

Studies of this patient showed nothing except advanced arteriosclerosis and hypertension. He has been under observation for a year. The final diagnosis is "paralysis of the left superior rectus and left inferior oblique due to a lesion, probably vascular, in the left third nucleus."

Case 2. Mr. J. A., aged 31 years, had an auto accident in June, 1946, and suffered severe contusion of the brain. There was no injury to the face. He has had vertical diplopia since then. Vision is 6/7.5 in each eye, with correction. There is no detectable strabismus except on covering so that the eyes are dissociated. The strabismus indicates a paralysis of the left inferior rectus and the left superior oblique. This is borne out by the fields of fixation on the Hess apparatus and the diplopia fields.

Figure 12 shows the diplopia fields. Figure 13 shows the fixation fields measured on the Hess charts, indicating a paresis of the left inferior rectus and superior oblique and

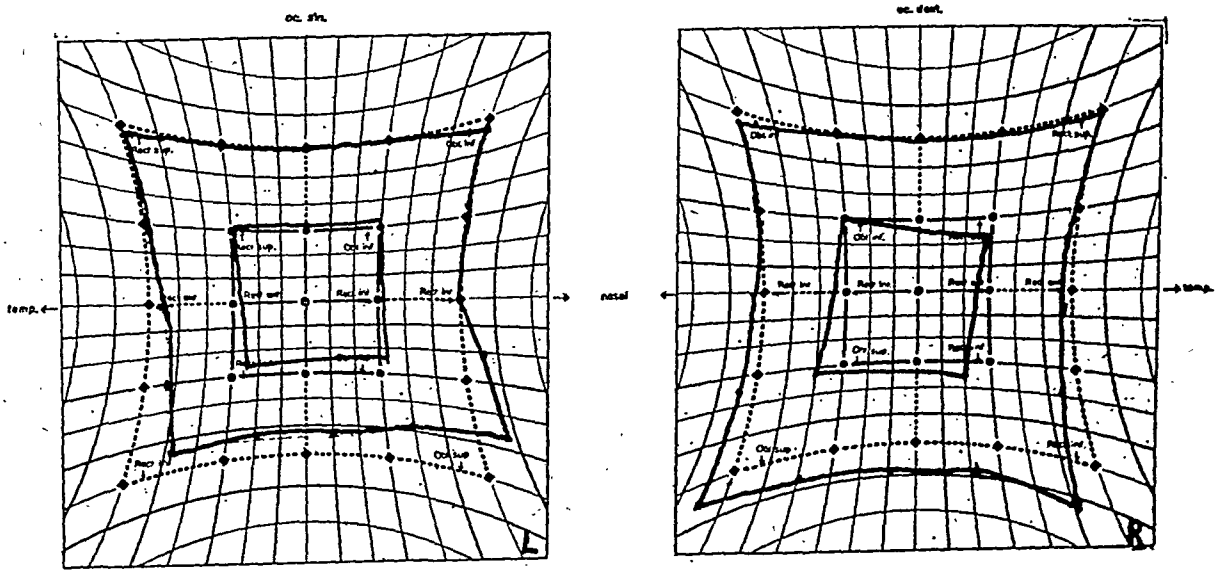

Fig. 13 (Adler). *Case 2.* The fixation fields on the Hess chart, showing a paresis of the left inferior rectus and the left superior oblique and overaction of the right superior oblique and right inferior rectus.

an overaction of the right superior oblique and inferior rectus.

A diagnosis was made of paralysis of the depressor muscles of the left eye due presumably to a hemorrhage in the pons involving the cells of the inferior rectus and superior oblique which lie close together.

Case 3. Mr. J. Van D., aged 34 years, was in an auto accident four weeks prior to examination and was struck on the right side of his head. Since then he has had diplopia when looking to either side below the horizon. He carries his head with chin depressed on chest. The eyes are straight in all positions except on looking down and to the right or left. The strabismus, fixation fields, and diplopia fields suggest a paralysis of both superior oblique muscles, greater on the right side.

Figure 14 shows the diplopia fields taken at the initial examination. All studies were negative. A diagnosis was made of hemorrhage in the pons catching the fourth nerves as they cross one another before emerging from the pons. Five months later the patient was reëxamined and found to have made a complete recovery of the left superior oblique and marked improvement in the right superior oblique. The fixation fields

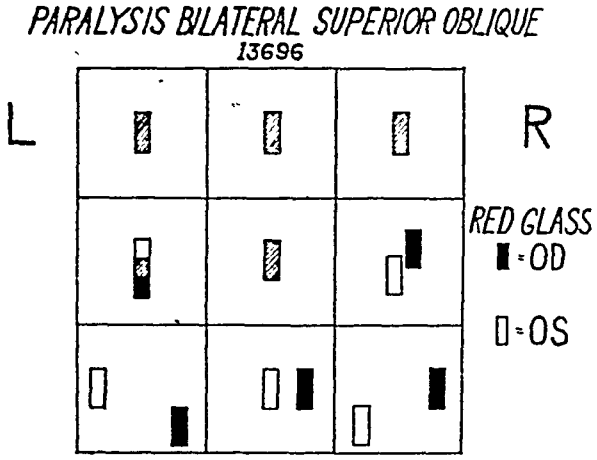

Fig. 14 (Adler). *Case 3.* Diplopia fields indicating bilateral paralysis of the superior obliques. On dextroversion, the right eye assumed fixation, and in levoversion, the left eye.

(fig. 15) failed to reveal any weakness of either superior oblique, but showed a marked overaction of the left inferior rectus. Evidently the right superior oblique had recovered to the extent that it could now move the right eye its full extent down and to the left, but the excessive innervation required to do this caused the yoke muscle, the left inferior rectus, to overact.

Case 4. Mrs. J. D., aged 56 years, had a paralysis of right superior rectus and inferior oblique due to a metastatic tumor in

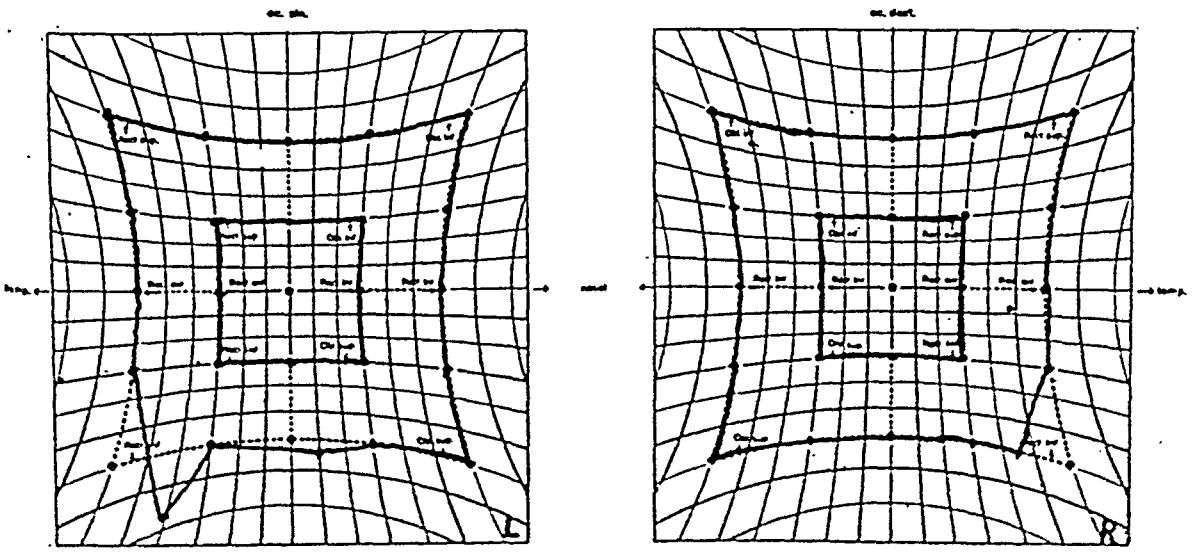

Fig. 15 (Adler). *Case 3.* Fixation fields made five months after first examination. At this time, both of the obliques had recovered, leaving no residual difficulty except overaction of the left inferior rectus.

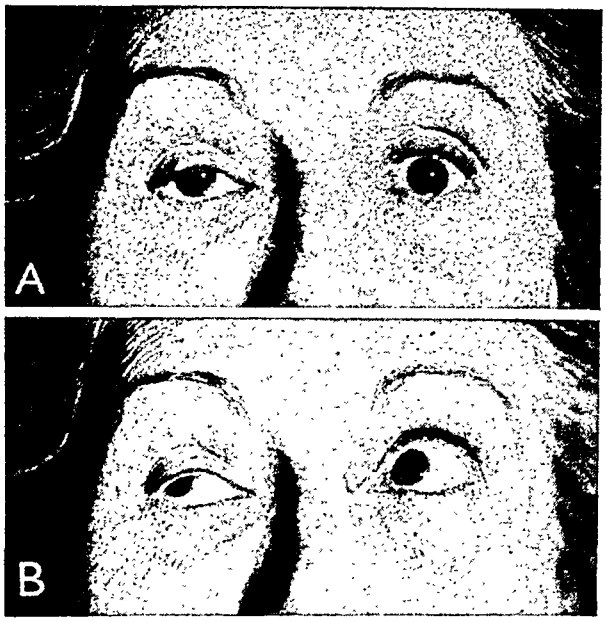

Fig. 16 (Adler). *Case 4.* Ptosis and right hypotropia due to a mass in the right orbit, preventing upward rotation of the right eye. (A) Eyes in the primary position. (B) Looking up and to the right.

the right orbit. For the past six months, this patient has complained of increasing diplopia on looking upward. Examination showed a mass in the right orbit, freely palpable, and an enlarged lymph node above the right clavicle. The right breast, which contained a tumor, was removed along with the enlarged lymph node. The diagnosis of the breast tumor was carcinoma, and the lymph node was diagnosed as a metastatic lesion from this. It was presumed that the mass in the right orbit was also a metastatic lesion which had involved the globe so that upward rotation was impaired. Figure 16 shows the appearance of the patient, and Figure 17 shows the fixation fields, indicating a paralysis of the right superior rectus and the right inferior oblique.

Summary

In a number of cases of paralysis of the vertically acting muscles, the diagnosis is made difficult because two muscles appear to be paralyzed. These cases fall into two groups. (1) Those in which no single lesion could involve both muscles. The muscles seemingly affected are either the superior rectus of one eye together with the superior oblique of the opposite eye, or the inferior rectus of one eye together with the inferior oblique of the opposite eye. In these cases, only one muscle is actually paralyzed, while the seemingly paralyzed muscle in the opposite eye is underacting on the basis of Hering's law. It is evident that the description given in textbooks of paralysis of each of the vertically acting muscles is inadequate

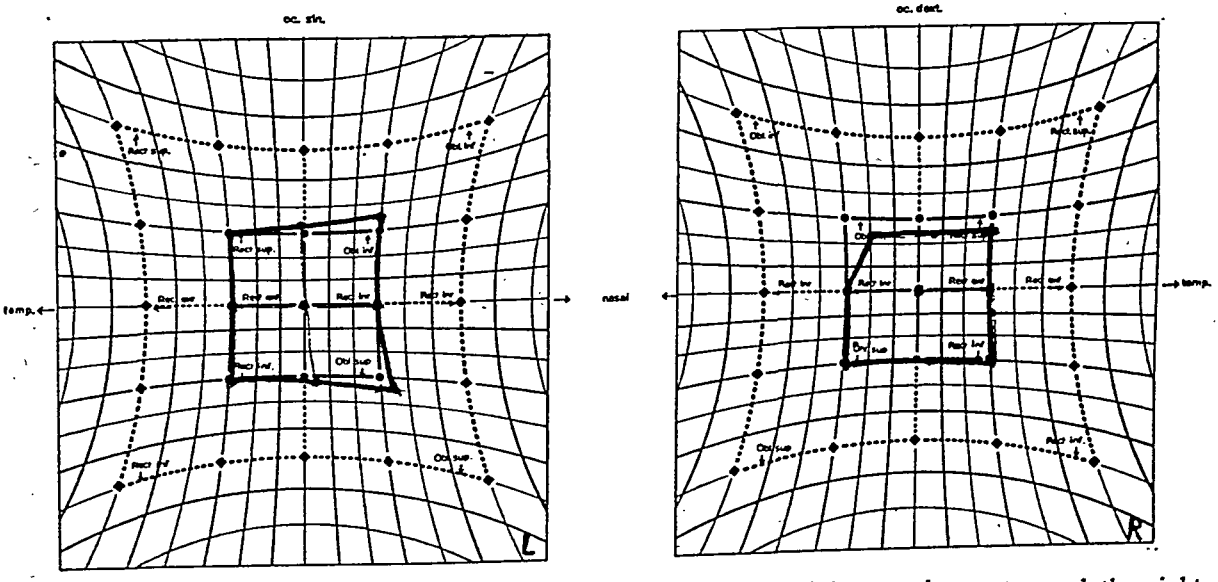

Fig. 17 (Adler). *Case 4.* Fixation fields show paralysis of the right superior rectus and the right inferior oblique and overaction of the left inferior oblique. There is also an overaction of the left superior oblique for which I have no explanation.

in that it only considers the effect the one paralyzed muscle might have on the strabismus and diplopia fields. When the paralyzed eye is habitually used to fix, the effect of a paralysis of one muscle extends to the activities of other muscles in the same and in the opposite eye and this leads to a picture which can be very confusing if the situation is not understood and kept in mind when these cases are analyzed.

In the second group of cases a single lesion involves the elevators or the depressors of one eye or both superior obliques. This is quite understandable on anatomic grounds and should lead to no confusion. The elevators and depressors of one eye can be caught in the orbit by scars and growing tumors, or the nuclei of origin of their nerves may be damaged by small lesions in the pons. The two fourth nerves may be caught as they cross each other before emerging on the posterior face of the brain stem.

THE PROBLEM OF SYMPATHETIC OPHTHALMIA*

THE MONTGOMERY LECTURE

BERNARD SAMUELS, M.D.
New York

The term sympathetic ophthalmia designates a disease which is always bilateral. It breaks out first in an eye the external tunic of which has been penetrated, called the exciting eye, and afterwards in the uninjured eye, called the sympathetizing eye. That a disease in one organ should excite an identical disease in a symmetrical organ is, in any event, a most extraordinary phenomenon in human pathology. To remove it still farther from the common order is the fact that the agent that causes it has never with certainty been identified. Hippocrates mentioned, in one brief sentence, that when an eye has been lost from injury the fellow eye often becomes blind. Strange to say this truth received but passing notice through all the centuries until William MacKenzie, in 1835, brought the importance of it to the attention of the modern world. Since then an immense body of writings has dealt with the subject.

The disease is characterized anatomically by the appearance in the pigmented and highly vascular uvea of an infiltration composed of three elements: lymphocytes, epithelioid cells, and giant cells, known as the specific infiltration of sympathetic ophthalmia (fig. 1).

ARTIFICIALLY MADE OPENINGS OF GLOBE

Before going further into the minutiae of the infiltration it would seem timely to speak of the artificially made openings of the globe and of the incarceration of uveal tissue therein, with all of which the problem of sympathetic ophthalmia is inextricably bound up.

ACCIDENTAL OPENINGS

By far the greater number of accidental openings take an anteroposterior direction and many of them are located in the center of the cornea. A small opening in the center is not complicated by a prolapse of the iris and hence is considered to be less dangerous than one in the periphery into which the iris would more readily fall.

A prolapse of the iris, large or small, in a corneal wound is particularly hazardous

* Delivered before the Irish Ophthalmological Society, at Trinity College, Dublin, Ireland, May 12, 1947.

because it lies naked on the cornea which, when the lids are apart, is the most exposed field of the globe. Unless the iris is excised the wound remains open a long time and the prolapse can only disappear by necrosis.

Singularly, an exposure of the iris as a whole after a most extensive perforating wounds of the sclera over the ciliary body are more dangerous than analogous wounds elsewhere because of the greater tendency of the uveal tract to prolapse. Particularly disastrous are ruptures at the limbus because here the root of the iris, either alone or with the ciliary processes, is most likely to become

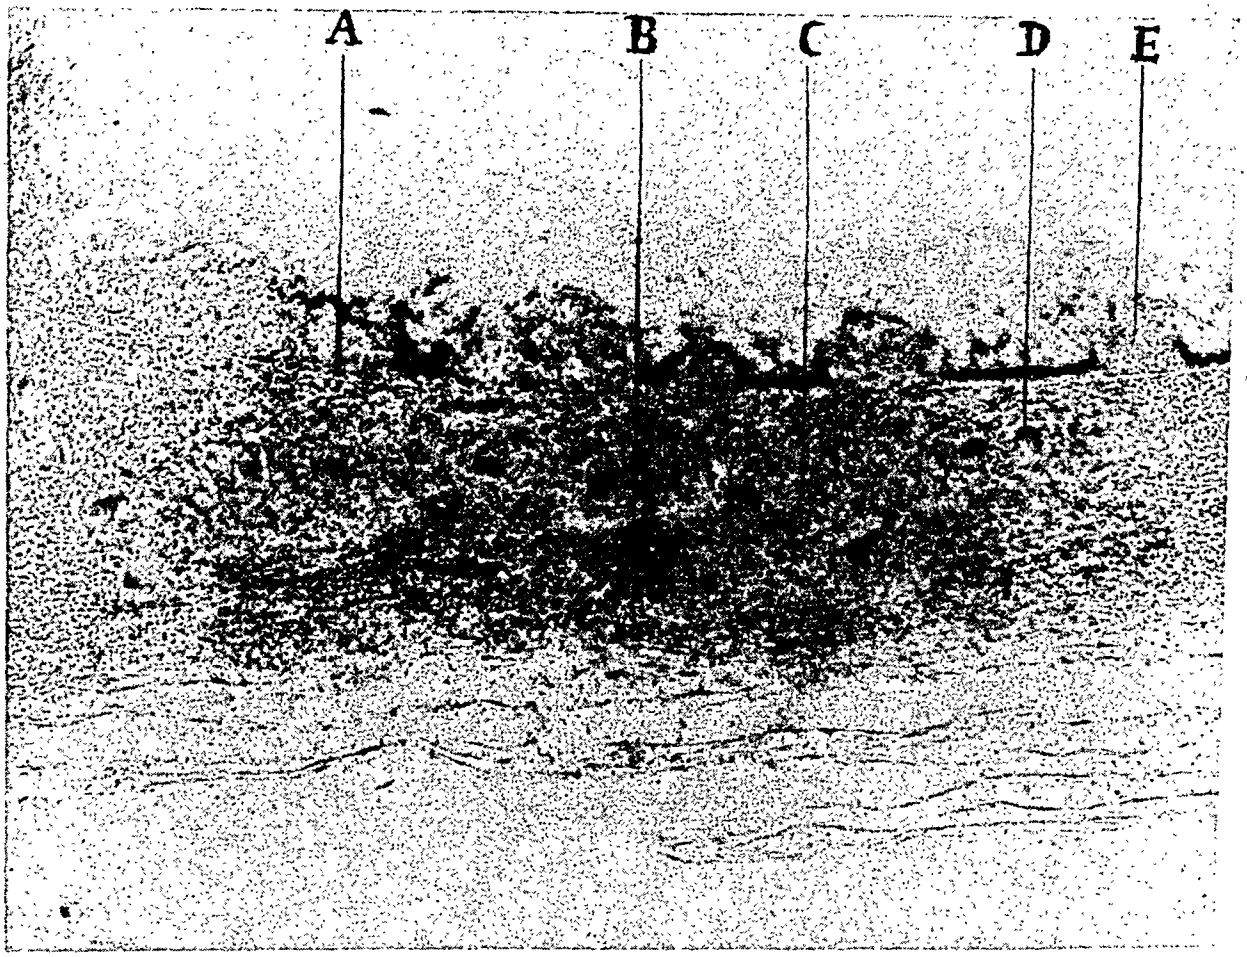

Fig. 1 (Samuels). In this specimen from the choroid, the entire pathologic anatomy of sympathetic ophthalmia is shown. (A) Lamina vitrea. (B) Lymphocytes. (C) Epithelioid cells. (D) Giant cells. (E) Galen's foci.

serpiginous ulcer is seldom followed by sympathetic ophthalmia. The iris is not constricted or strangulated as in a small opening and, as the iris and the limbus are heavily inflamed, there is soon produced a fibrinous exudate which seals off the exposed area in the first step of what will in time become a staphyloma of the cornea.

The regions of the ciliary body is appropriately called the "dangerous zone." Punctured, incised, contused, and lacerated incarcerated, whether injured or not. In general, the larger the perforation, the longer it remains open; and the more extensive the uveal prolapse, just so much greater is the hazard.

A few cases of sympathetic ophthalmia are reported as having been brought on by a contusion over the ciliary body without rupture of the sclera. Probably in some of these cases the blow produced ruptures in the conjunctiva and sclera too minute to be seen.

SURGICAL OPENINGS

Surgical openings, except those made for corneal transplantation, generally take a frontal direction parallel to the anterior surface of the iris. The surgery of today, instead of lessening the possibilities of sympathetic ophthalmia, has vastly increased them. Formerly the field of intraocular operations was restricted to the periphery of the cornea and the limbus. It now embraces every zone of the surface of the eyeball from the center of the cornea to the neighborhood of the optic nerve. While no incision is ever made directly over the ciliary body, yet diathermy here is one of the methods employed for glaucoma.

Among the earlier operative procedures that had to be abandoned is iridodesis which Critchett devised in 1858. He sought to obviate the large opening of an optical iridectomy and the loss of pupillary reaction by drawing the periphery of the iris into a small incision in the cornea above, leaving the pupillary border within the chamber. A thread was tied around the protruding iris to prevent its slipping back. No thought seems to have been given to the danger of the procedure until Graefe, in 1863, published a case of bilateral inflammation and blindness following its used, which he believed had been caused by traction on the incarcerated iris from within the globe but which must have been due to sympathetic ophthalmia.

In recent years Key's method for the repair of iridodialysis by suturing the root of the iris to the periphery of the cornea was soon abandoned as unsafe after the report of a case of sympathetic ophthalmia. Evisceration of the contents of the globe is not considered to be free of danger for it is not possible to scrape off the uveal tissue that lines the walls of the emissaria.

As regards operations for the removal of cataract, the flap incision at the periphery of the cornea is considered safest from the standpoint of sympathetic ophthalmia. Graefe's linear extraction, in which the incision lies back of the limbus where a conjunctival flap is not easily obtained, fell into disrepute after several cases of sympathetic ophthalmia were reported. An idea prevails that the intracapsular operation is less dangerous than the extracapsular. It is true that the occurrence of lens capsule and lens matter in the wound, with consequent delay in healing, is obviated by the intracapsular method but when an actual prolapse of the uvea has happened one method must be as dangerous as the other. I recently examined a globe in which, after an intracapsular operation, there was a large prolapse of the iris and ciliary processes. There was no purulent infection. The specific infiltration was extensive and in pure form. The fellow eye became violently inflamed six weeks after the operation and was blind almost from the start.

Sympathetic ophthalmia may occur after operations for glaucoma whether the opening is small, as in a trephine operation, or large, as in a modified Lagrange. All parts of a globe affected with long-standing glaucoma are more or less degenerated and inflamed so that a fistulous opening, with or without prolapse of the iris, is often not possible. The very low tension that sometimes sets in and which may be thought to be due to filtration may, in fact, represent a postoperative iridocyclitis with fine deposits on Descemet's membrane. Such a globe is at the threshold of atrophy and is as dangerous for sympathetic ophthalmia as if it had never been glaucomatous. It is borne out by experience that as long as an eye remains hard after an operation the probability of sympathetic ophthalmia is remote.

The possibility of sympathetic ophthalmia following operations for detachment of the retina is practically never considered in spite of the numerous openings that are made into the sclera and choroid. These two structures are membranous and lie in close apposition so that there is no reason for the choroid to prolapse. Rather it shrinks from the wound

by its own elasticity and, moreover, the openings are immediately closed by tissues at the end of the operation.

In point of surgical procedures contributing to sympathetic ophthalmia, cataract extration heads the list and next come operations for glaucoma. They are all near the "dangerous zone," and cataract operations

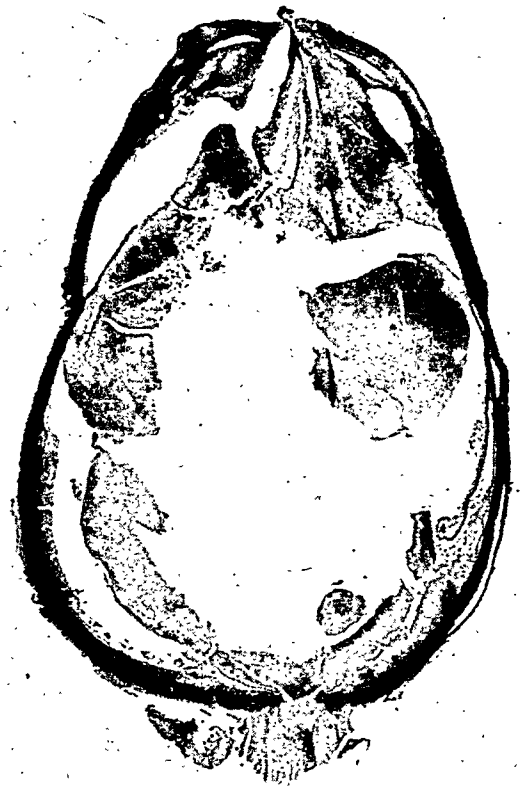

Fig. 2 (Samuels). Open panophthalmitis with purulent destruction of papilla. Sclera is intact.

require the largest of all incisions. There is no standard operation in ocular surgery that has not had marked against it a case of sympathetic ophthalmia or infection. That the occurrence of sympathetic ophthalmia has not kept pace with the ever-increasing number and complexity of operations is certainly due to good surgery and thorough antisepsis. A factor not to be overlooked in the causation of postoperative sympathetic ophthalmia is a tendency on the part of a surgeon to delay too long the enucleation of an eye that has not healed properly. In a hospital a case or two of sympathetic ophthalmia may occur and then be followed by an interval of freedom which lasts as long as the memory of the lesson taught by this experience remains fresh. That the danger of sympathetic ophthalmia was fully realized by surgeons in World War II is evident from the statistics of the Army Institute of Pathology in Washington. Until recently there had been received only 16 globes that had developed sympathetic ophthalmia following training and combat injuries.

Role played by the healing process of a perforation

There is nothing remarkable about the scar tissue that heals a perforation and in so doing distorts the globe and causes it to become soft. One cannot say that the fellow eye will become inflamed but it may. In the cases in which this occurs two separate pathologic conditions are found in the injured eye: (1) the consequences of the injury itself and, (2), without discernible cause, the specific infiltration in the uvea.

Complications in the healing process

1. *Endophthalmitis Septica.* Pyogenic bacteria may be introduced into the vitreous body by the instrument or enter later. Here they multiply and elaborate toxins which set up an exudative process from the blood vessels in the adjoining retina, papilla, and ciliary body. The pus cells, being highly motile, travel inward toward the bacteria to form an abscess of the vitreous. The iris is little affected because it is bound down to the lens capsule and, where it is exposed in the periphery, the pigment epithelium and the dilatator muscle protect the stroma from the toxins, which accounts for the aqueous and cornea remaining clear. The bacteria soon die and the pus cells become necrotic. A cyclitic membrane detaches the retina. The essential thing is that the choroid be protected from toxins by the retina and later also by the subretinal fluid. When such an

eye has caused sympathetic ophthalmia there is found in the choroid, entirely independent of the damage caused by injury or infection, the specific infiltration. Whatever the causative agent of sympathetic ophthalmia, the pus-producing bacteria do not always destroy it, if they ever do, for it is estimated that from 2 to 13 percent of all cases of sympathetic ophthalmia have originated in globes that had suffered from posttraumatic endophthalmitis septica.

2. Septic Panophthalmitis. In septic panophthalmitis, virulent bacteria in the vitreous destroy not only the retina but also the choroid. The amount of the destruction depends largely on the state of the opening (fig. 2). If it remains open—open panophthalmitis—there is less damage to the uvea because the abscess can discharge itself through the preformed opening. If the wound is closed—closed panophthalmitis—the destruction of the uvea must be great before the abscess can break through the sclera, usually at the equator, and discharge itself into the orbital tissue (fig. 3). In either case the eye shrinks to a mere stump—phthisis bulbi. Neverthless, a minute amount of uveal tissue is almost certain to be spared. The incidence of sympathetic ophthalmia after panophthalmitis I estimate to be about 3 percent.

3. *Foreign Bodies.* It is computed that particles of steel constitute 98 percent of all intraocular foreign bodies found in civilian life.* The size of such particles varies from 0.5 to 6 or 8 mm. in diameter. In most instances the point of entrance is through the cornea. Most of these foreign bodies are extracted with good results, particularly when the anterior route is used. Sympathetic ophthalmia in these cases is exceedingly rare. The penetrating wound is very small and the tissues touched by the foreign body tend to fall inward in its pathway.

Every foreign body that remains within the globe sooner or later surrounds itself with a bed of connective tissue which may be so large as to occupy half of the vitreous cavity. Eventually the bed tends to break down and discharge poisonous substances and extrude the foreign body into the cavities of the globe or outside of it. The presence of a foreign body, even while still

Fig. 3 (Samuels). Closed panophthalmitis. The sclera and orbital tissues are blended in necrosis. (C) Cornea. (O) Optic nerve.

confined in its bed, causes the eye to be more or less sensitive, and may excite irritation of the other eye, all of which may go on for years. If such an eye has been the source of sympathetic ophthalmia, it will show, aside from the consequences of the wound and of the foreign body, the specific infiltration in the uvea, as if no foreign body existed. When, concurrent with the foreign body, bacteria are introduced, it is the bacteria that cause the first inflammatory reaction and the presence of the foreign body is of no immediate consequence. Acting as a

* Gulliver, F. O.: Particles of steel within the globe of the eye. Arch. Ophth., 28:896-903, 1942.

foreign body in atrophic eyes of long standing and not of itself dangerous for sympathetic ophthalmia is a plate of bone which forms out of a connective-tissue membrane on the internal surface of the choroid or within its stroma.

Stage 1. Isolated nodules of lymphocytes appear in and around the walls of the larger veins of the choroid.

Stage 2. In the midst of the nodules of lymphocytes appear groups of large oblong cells with faintly staining nuclei and poorly

Minute anatomy of the specific infiltration of sympathetic ophthalmia

The exciting eye

In making a pathologic differentiation of sympathetic ophthalmia in the exciting eye, the posterior part of the choroid is chosen because the uvea is here the least damaged by the injury, and it is here that the infiltration is generally the more typically developed, probably because of a greater thickness of the tissue and a richer blood supply (fig. 4). The infiltration takes place in the following manner.

defined borders, known as epithelioid cells because they resemble the same cells in tuberculosis. They are believed to originate in the endothelium of the walls of the blood vessels which by this time have disappeared.

Stage 3. Later a number of epithelioid cells may merge to form a giant cell. This third element is not necessary. A typical nodule consists of lymphocytes and epithelioid cells.

In time the nodules coalesce and diffusely replace the vascular structure of the choroid, forming a layer of three or more times the normal thickness. No matter how heavy the

infiltration is, the overlying choriocapillaris remains singularly free. It may be because this layer is not composed of typical uveal tissue but is made up of a network of capillary tubes in a nonpigmented almost homogeneous stroma. In disseminated chorioretinitis, the capillary layer is always destroyed. In sympathetic ophthalmia, the pigment epithelium and the retina are not affected. Occasionally small mounds of proliferated pigmented cells develop on the internal surface of the choroid—Galen's foci—which are of no importance (fig. 1).

Externally, the suprachoroidal lamellae become infiltrated but epithelioid cells are not to be found here, at least in the first stage, because the lamellae contain no blood vessels. The infiltration travels outwardly along the uveal tissue that lines the emissaria so that typical nodules may appear on the external surface of the sclera. Indeed, the stroma of the sclera may become so invaded that the inflammation takes on the nature of a chorioscleritis. Typical nodules have been encountered at a considerable distance from the sclera among the bundles of the inferior oblique muscle (fig. 5). Not infrequently the infiltration makes its way through the emissaria that surround the nerve head and travels into the pial sheath. As a rarity nodules are seen along the walls of the retinal blood vessels in the cribriform plate. It is to be emphasized that, strictly speaking, sympathetic ophthalmia is a disease that is not confined solely to the inner eye.

In the ciliary body the nodules coalesce to form plates in the vascular layer. Here the pigment layer may be destroyed, but the nonpigmented epithelial layer is always preserved just as is the choriocapillaris. Giant cells are more often to be found in the ciliary body and when pigmented they are probably derived from the chromatophores.

In the iris, the infiltration may assume the size and shape of a tumor filling out the entire anterior chamber (fig. 6). No matter how excessive the infiltration is, it leaves the anterior limiting layer of the iris free. On the other hand, posteriorly, the pigment epithelium is broken through very early in the process and nodules of lymphocytes and epithelial cells expand along the surface of the lens. When the root of the iris is heavily infiltrated and thickened, the infiltration passes into the anterior emissaria, and files of lymphocytes, penetrating between the limbus and sclera, actually destroy many of the bundles so that the corneoscleral margin may be the most severely inflamed part of the margin. One of my specimens reveals a typical nodule in Schlemm's canal.

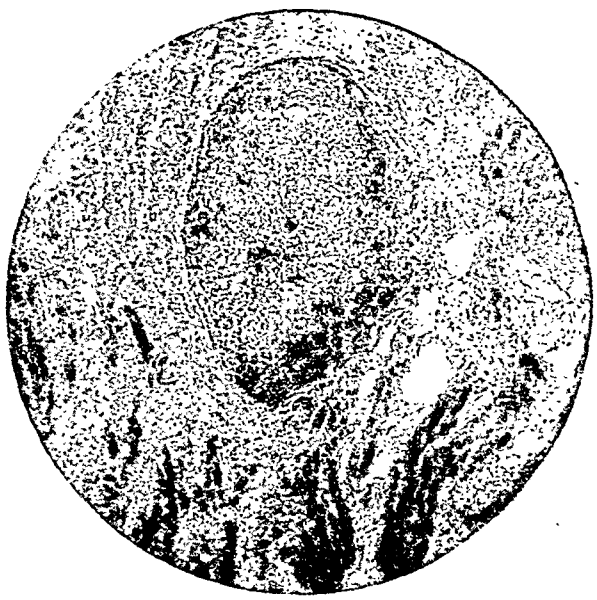

Fig. 5 (Samuels). Sharply defined sympathetic nodule among the fibers of the inferior oblique muscle.

The disease reaches its anatomic peak when the iris, the ciliary body, and the choroid are all infiltrated. The infiltration may be so exuberant as to almost fill the globe within the brief space of 5 or 6 weeks. The stages of disintegration take a long time, often years. First the giant cells disappear and then the epithelioid cells. At last the entire infiltration is replaced by a membrane of dense uncharacteristic connective tissue.

The sympathizing eye

A very short time after the infiltration forms in the injured eye it appears in the

fellow eye. Only about a dozen of the sympathizing eyes have come to histologic examination because there is no reason for enucleating one unless the patient dies or the eye causes so much pain that he prefers to have it out. In these few cases the same kind of infiltration and the same distribution in the uveal tract are found as in the injured eye. Most often it is the most anterior part of the uveal tract that suffers first. The picture is a pure one, uncomplicated by the consequence of traumatism or infection.

Occurrence in different countries

Sympathetic ophthalmia is thought to occur with about the same frequency in the Americas, Europe, and China.* However, in India, notwithstanding the many thousands of cataract extractions that are performed annually, it is said to be practically unknown. Either the people of that country possess an exceptional degree of resistance to the disease or the agent that causes it does not exist there.

* Fuchs, A.: Ueber sympathisierende und sympathische Ophthalmie. Med. Welt., 15:313 (Mar.) 1941.

Anatomic similarity and difference between sympathetic ophthalmia and tuberculosis

Points in common

Sympathetic ophthalmia and tuberculosis are composed of the same histologic elements: lymphocytes, epitheloid cells, and giant cells. The two diseases are alike when it comes to two of their chief characteristics; namely, proneness to recurrence and exacerbation. As regards the bilateral aspect, it cannot be sympathetic ophthalmia unless both eyes are involved. However, tuber-

culosis has a well-known tendency to attack both eyes simultaneously.

Points of difference

In sympathetic ophthalmia the nodules are located in the outermost layers of the choroid; in tuberculosis in the innermost layers. A giant cell in each disease contains many nuclei but the arrangement is different. In sympathetic ophthalmia the nuclei are formed by an irregular fusion of epithelioid cells. In tuberculosis the nuclei are apt to be disposed in the form of a ring—Langhan's type—being considered the product of a proliferation of the endothelium of a capillary. Caseation takes place almost from the beginning in tuberculosis; rarely in sympathetic ophthalmia, and then in the latest stage. The necrosis that is sometimes seen in sympathetic ophthalmia is not to be mistaken for caseation. Over a tuberculous nodule, the pigment epithelium of the choroid is destroyed as in miliary tuberculosis; over a sympathetic nodule, it is preserved. Tuberculosis tends to be localized in one part of the uvea. For example, when it starts in the iris or ciliary body it remains there indefinitely. Sympathetic ophthalmia spreads rapidly to all parts.

In tuberculosis of the iris, the nodules are located in the posterior layers, and the anterior limiting layer is spared. In sympathetic ophthalmia, the nodules pierce the pigment epithelium and expand against the capsule of the lens and proliferate into the circumlental space. They may develop while the pupil is widely dilated and cause the iris to be plastered to the lens in this shape, in contrast to ordinary plastic iritis in which there are no adhesions as long as the pupil is wide. In tuberculosis of the iris, the pupil reacts over a long period. In sympathetic ophthalmia, it is almost immediately fixed. In sympathetic ophthalmia, the normal color of the iris is less altered than in tuberculosis where it assumes a dull, grayish hue from the destruction of the chromatophores.

In the ciliary body, the nodules of sympathetic ophthalmia coalesce and form plates within the vascular layer and are separated from the vitreous body by the intact nonpigmented epithelial layer. In tuberculosis, the nodules destroy both epithelial layers of the ciliary body and lie free on the surface or suspended in the zonular fibers.

In sympathetic ophthalmia, the retina is practically never involved. In tuberculosis, secondary nodules in the retina are by no means rare.

In sympathetic ophthalmia, nodules in the emissaria appear almost at the same time that they do in the choroid. A careful search should always be made for early infiltration in the emissaria. In tuberculosis, involvement of the emissaria comes much later.

The most important anatomic difference between sympathetic ophthalmia and tuberculosis lies in the behavior of the lesion of each toward the adjoining tissues. Tuberculous infiltration has a tendency to invade other tissues. If it starts in the iris it will gradually fill the anterior chamber, and when it touches the cornea and sclera it produces in them an excavation of the same size and shape as the tuberculous tumor itself and in time destroys them. Such malignancy the sympathetic lesion does not possess. It remains in the uveal tract and destroys neither the retina on one side nor the sclera on the other.

Clinical signs of sympathetic ophthalmia

1. Sympathetic irritation

While the pathologic signs in sympathetic ophthalmia are almost unfailingly characteristic, such is not the case with the clinical symptoms. Thus the photophobia, the tearing, and the failing accommodation of sympathetic ophthalmia may also be seen in the second eye when there is no more than a foreign body embedded under the epithelium of the first eye. Actually, the only sure way to exclude the possibility of inflammation in the second eye, when it is irritated, is to make an examination of the media with the

slitlamp and ophthalmoscope. Even when no evidence of inflammation is found in the second eye, mere irritation is not to be taken lightly but rather as a warning of an impending outbreak of sympathetic ophthalmia. If it be mere irritation, this will disappear in a few days after the enucleation of the injured eye.

2. True sympathetic ophthalmia

The inflammation begins in the uninjured eye slowly and at first without pericorneal injection or pain. Disturbance of vision is often the first symptom, which probably manifests itself after nodules have formed in the uvea. In an early case, fine, grayish precipitations are seen on the posterior surface of the cornea. In attempting to dilate the pupil, adhesions are found, and in the vitreous, numerous fine opacities will be visible. Sometimes, at the very beginning, the media are clear enough to permit observation of an edema of the papilla, with cloudiness of the neighboring retina—a picture that is almost never seen in other forms of uveitis. Small yellowish patches in the choroid, about the size of a druse and almost as sharply defined, are very characteristic. They often disappear without leaving a sign. Anatomically these are probably isolated nodules of lymphocytes and epithelioid cells lying deep in the choroid. The infiltration into the emissaria, with scleritis, is probably the cause of the deep-seated pain that is one of the most distressing symptoms of the disease.

The state of the pupillary border, even before the loupe and lens came into general use, was considered of the greatest importance in arriving at a differential diagnosis. In the mildest form of iritis—iritis serosa—the pupil is free. The severer form —plastic iritis—is prone to cause incomplete adhesions which, as a rule, are confined to the pupillary zone. On the other hand, in genuine sympathetic iritis, sometimes called iritis maligna, the entire posterior surface of the iris is very soon agglutinated to the capsule of the lens. Occasionally grayish nodules break out at the pupillary border and expand on the lens capsule. This is a finding that is considered the most significant clinical sign of sympathetic ophthalmia in the anterior chamber. The iris may bulge forward, not from a damming back of the aqueous but from an increase of thickness as a result of the infiltration. The manifestation of iritis maligna marks the arrival of the disease at the culminating peak of its clinical severity.

Pathogenesis of sympathetic ophthalmia

1. Various theories

For over a hundred years many conjectures have been advanced as to the pathway by which the lesion in the injured eye sets up an identical lesion in its fellow. The infiltration in the sheaths of the injured eye does not travel via the chiasma since it is not found in the sheaths of the fellow eye. Transmission by way of the optic-nerve fibers cannot explain the infiltration in those cases in which it makes its first appearance as far forward as the iris of the fellow eye. The idea that it is transmitted through continuity of the ciliary nerves fell into oblivion because no connection between the two systems has been found. The old guess that the disease is carried to the other eye in the blood stream by a circuitous route through the vessels at the base of the brain approaches more nearly the present conceptions.

2. The allergic theory

In 1909, Elschnig, in Prague, published the theory that portions of the uveal pigment from the injured eye enter the blood stream and, acting as foreign matter, set up an anaphylactic reaction in the uvea of the fellow eye. Woods, in Baltimore, has carefully developed this theory and ascertained that, in its immunologic reactions, uveal pigment has the power of producing the formation of antibodies. The bleaching of the eyebrows that is occasionally seen in sympathetic

ophthalmia seems to speak for some disturbance of the pigment metabolism.

3. THE INFECTIOUS THEORY

a. The Tuberculosis Theory. In the Meller school in Vienna, in the years prior to 1940, tubercle bacilli were demonstrated in 20 percent of the eyes removed because of posttraumatic iridocyclitis. In one case of sympathetic ophthalmia which neither clinically nor histologically was entirely typical, Meller succeeded in cultivating tubercle bacilli. He concluded that sympathetic ophthalmia is of tuberculous origin and that between sympathetic ophthalmia and tuberculosis there is no essential difference, since they are both caused by the same microörganism.

b. The Virus Theory. In a microscopic study of the pathology of sympathetic ophthalmia, embracing some 120 globes and extending over many years, I have occasionally encountered an infiltration which was confined to the site of the opening. If the uvea had prolapsed then, the infiltration was both without and within the globes (fig. 7). More often the infiltration, while

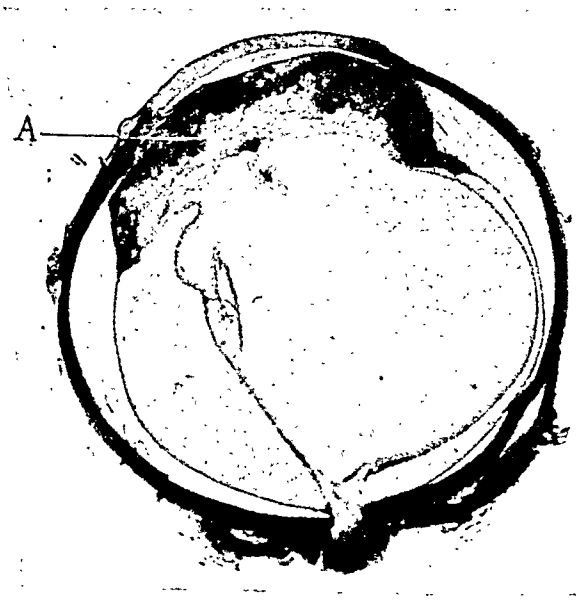

Fig. 7 (Samuels). Massive specific infiltration confined to the anterior segment of the globe at the site of the wound. (A) Cicatricial tissue caused by attempted iridectomy.

present elsewhere, was overwhelmingly heaviest at the site of the wound. Often the infiltration at the site of the wound was about equal to that in the choroid. In a few globes the infiltration here was less than

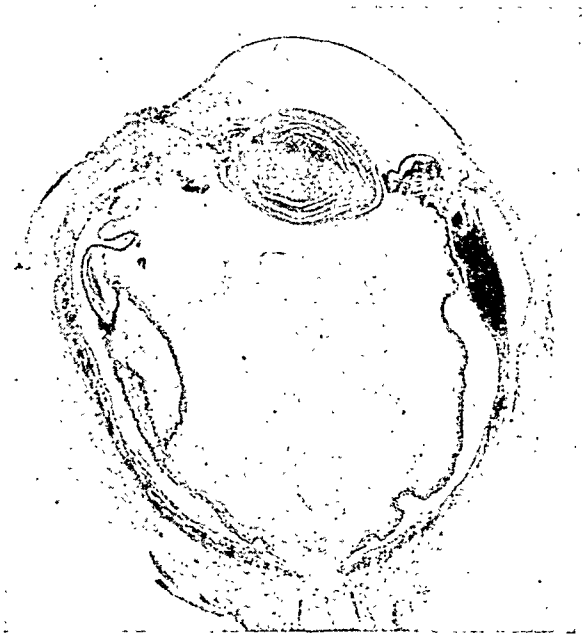

Fig. 8 (Samuels). Absence of infiltration at depressed scar of wound. Typical nodules in choroid becoming coalescent. Pial sheath of optic nerve infiltrated and also emissaria in sclera.

that elsewhere. There were still fewer globes in which it was absent at the site of the wound. The meagerness or absence of infiltration at the site of the wound could be explained by the circumstance that the uveal tissue in this location was too much damaged by the primary injury to react or else that it had been excised (fig. 8).

It is recalled that in the eye, as elsewhere in the body, an exogenous infection may occur without a primary lesion; that is, without a local accumulation of cells. It is also possible for a primary lesion to be so small as to pass unnoticed. The fact that primary lesions in the uvea at the site of the opening do occur leads me to accept the theory that sympathetic ophthalmia is a disease produced by a virus which has the perforating wound as its point of entrance. Here it lodges in the uvea and produces an

irritation which results in the specific infiltration of sympathetic ophthalmia. It spreads from this point to other parts of the uvea of the same eye and thence through the blood stream to the uvea of the other eye. That the infiltration confines itself to the uvea under all circumstances indicates a selective affinity on the part of the virus for this particular tissue.

One theory is that the virus is already in the blood and only after the uvea is traumatized does it lodge and multiply there and take on its selective affinity.

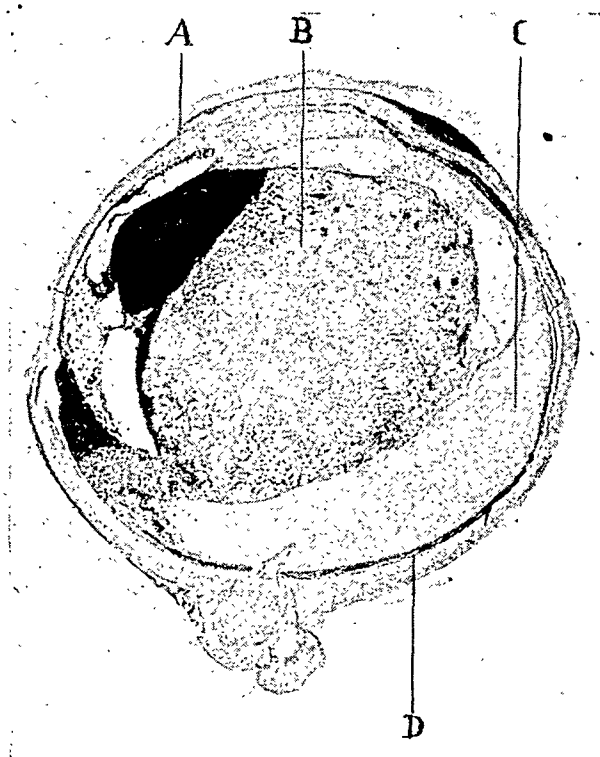

Fig. 9 (Samuels). Malignant melanoma of choroid and sympathetic ophthalmia. (A) Site of the wound. (B) Tumor with highly pigmented area next to wound. (C) Subretinal fluid. (D) Specific infiltration of sympathetic ophthalmia.

In further support of the theory of primary infection is the fact that, in the iris, the infiltration always appears to be older than in the choroid. Many times in the course of an observation, I have been able to trace the progress of the infiltration from the iris and ciliary body to the choroid and thence to the emissaria and external surface of the sclera, with as much certainty as tuberculous foci can be traced from the ciliary body to the choroid and retina.

In those cases in which sympathetic ophthalmia breaks out long after the injury, it is assumed that the virus has lain dormant in the tissues as bacteria may do in a healed alveolar abscess. Hence the infiltration in the late outbreaks has, as a rule, the appearance of being of recent origin.

A very few cases, some of them doubtful, have been reported in which a lesion similar to that of sympathetic ophthalmia is said to have broken out in one eye in connection with a malignant melanoma in the other. However, this can detract but little from the fact, so long established clinically and pathologically, that sympathetic ophthalmia is overwhelmingly associated with unnatural openings of the globe. I have recently examined a globe which exhibited both a malignant melanoma of the choroid and the specific infiltration of the choroid characteristic of sympathetic ophthalmia (fig. 9). The eye had been operated upon for absolute glaucoma and cataract. Two weeks after the operation the fellow eye became inflamed and the vision reduced. The exciting eye was immediately removed. Microscopically, it showed the specific infiltration in the choroid at a distance from the tumor. It is reasonable to suppose that the operation and not the tumor was the sole cause.

Prognosis and Treatment

I. Surgical treatment

a. Time to Enucleate

1. When the fellow eye is irritable, even if it be apparently normal, the injured eye should be removed.

2. At the discovery of deposits on the posterior surface of the cornea of the fellow eye, the injured eye should be removed.

3. In all cases in which the wound is retracted, especially if it contains uveal tissue and the eyeball is soft and tender to touch; when the vision is failing; when, in short,

there is no hope that the organ will ever again be serviceable, the time to enucleate has arrived.

Sympathetic ophthalmia has been known to set in within 48 hours after the injury, but it may not happen until years have elapsed. It is at once the gravest and the most unpredictable of all ocular diseases. The most hazardous period is during the first 2 or 3 months.

4. A globe with endophthalmitis is removed with safety at any time because the infection is confined within the fibrous tunic.

b. When Not to Enucleate

1. When the wound heals properly, the tension is good, some sight is retained, and the fellow eye shows no irritation, it is safe to wait and watch.

2. When the injured eye still has some vision after the fellow eye has become severely inflamed, the rule is to retain the injured eye, for in the end it may be the one eye that retains any sight.

3. When both eyes are violently inflamed, the enucleation of the injured eye can serve no purpose.

4. As regards panophthalmitis, Graefe reported the loss of two patients from meningitis after the enucleation of a globe with flagrant panophthalmitis. Since that time, it has been traditional in Germany and Austria never to excise such a globe until the inflammation has subsided.

Sympathetic ophthalmia has occurred during the active stage of panophthalmitis but so rarely as to justify delay. Occasionally, after the promptest removal of an injured eye the remaining one becomes inflamed. This may happen up to 20 days, which is the longest time on record. Such a retarded attack was formerly believed to have been excited by the removal of the injured eye. In these delayed cases, the virus was probably on the way but had not reached its destination at the time of the removal of the globe.

In the matter of enucleation, it is well to excise a long strip of the optic nerve and with it the surrounding tissues, not omitting to leave a long strip of the inferior oblique muscle with the globe. Radium treatment to the socket is suggested (fig. 10).

c. Complicating Secondary Glaucoma

As regards the secondary glaucoma which so frequently complicates the disease in the sympathizing eye, the surgical field is limited strictly to the clear cornea. No greater mistake can be made than to attempt to perform an iridectomy, for the iris as such no longer exists but is replaced by granulation tissue.

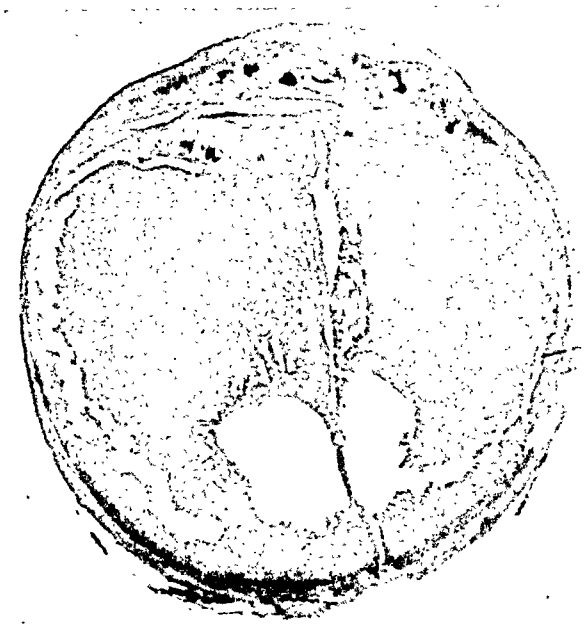

Fig. 10 (Samuels). Section shows buphthalmic eye six years after injury. Optic nerve excised within scleral canal. Heavy episcleritis. Probably much sympathetic material remained in the orbit.

Paracentesis is the sole operation permissible. The incision may be opened the following day in order to improve the general condition by the evacuation of a cloudy and toxic aqueous. This procedure may be repeated many times. The highly swollen iris with its intact anterior surface—iritis maligna—is sometimes mistaken for iris bombé which leads to an attempt to reëstablish the communication between the two

chambers by transfixion or, worse still, by iridectomy.

d. Complicating Cataract

Concerning the complicating cataract that develops in time in the sympathizing eye, the dictum is not to attempt its removal until it is certain there has been no sign of inflammation for many months, and even then the indication should be nothing less than almost total blindness. The best result is promised by opening the occluded pupil and extracting the lens matter through it. Even by this method, the pupil is apt to close over from shrinkage of the surrounding membrane.

II. Medicinal treatment

Miotics would tend to increase the central synechia, and mydriatics would be harmful on account of the tendency to glaucoma—if, indeed, these solutions can have the least effect on iritis maligna.

Starting with the salicylates and mercury in the early days, down through salvarsan and tuberculin to the sulfa preparations and penicillin, not omitting fever therapy, medicinal remedies of many kinds have been tried. A complete list would form a catalogue of the passing moods in therapeutics during many decades. From almost every remedy there has come a report of a cure, after the removal of the injured eye. No doubt a number of these cases have been reported far too soon. The sight of an eye may improve immediately after the removal of the exciting eye and then, within a month or two, there may be a return of the inflammation followed by one attack after another through years until blindness ensues. It is to be remembered that cases of spontaneous cure are on record in which the removal of the injured eye was refused.

In evaluating the efficacy of any particular medicinal treatment, it is necessary to know in what exact pathologic stage of the disease it was begun. Treatment is conceivably helpful in the first stage before too many nodules have infiltrated the choroid and invaded the sclera, but in the second and third stages, it is difficult to understand how any remedy can affect the infiltration which by this time must have replaced the normal uvea and can only end in a fibrous membrane.

57 West 57th Street (19).

Historical Miniature

Ibn Sina calls attention to the possibility of ablation of prolapsed iris but advises against it in the following words: "Sometimes there is an outpouring of material which is also directed to the other eye." His commentator, Gentilis de Fuliginio, (died 1348 in Perugia) adds: "Quia oculi sunt alligati in cruciatione nervorum." Here we have the oldest suggestion of sympathetic inflammation of the eyes and even a theory of it.

Hirschberg in *Graefe-Saemisch Handbuch*, v. 13.

A SIMPLE PTOSIS OPERATION: UTILIZATION OF THE FRONTALIS BY MEANS OF A SINGLE RHOMBOID-SHAPED SUTURE*

J. S. FRIEDENWALD, M.D., AND J. S. GUYTON, M.D.
Baltimore, Maryland

Each of the many ptosis operations in current usage can be classified into one of three general types: (1) Utilization of the paretic levator, (2) utilization of the superior rectus, or (3) utilization of the occipitofrontalis. It is generally conceded that no single type of ptosis operation will serve for the best correction of all cases of ptosis. This report describes a simple yet effective technique of utilizing the frontalis. The results of 31 such operations, performed on 23 patients, are analyzed.

Techniques for utilization of the frontalis are so legion as to obviate the necessity of a detailed description of each. Those in more common usage are Machek's attachment of the lid to the frontalis by means of two strips of dermis, Reese's attachment by means of orbicularis fibers, and Derby's attachment by means of a fascia lata sling. Kitlowski[1] has modified the fascia lata sling operation in that he places a strip of fascia lata in the shape of a rhomboid between the lid and the frontalis. The technique we have used is a modification of Kitlowski's in that we have used a permanently buried suture instead of fascia lata, have avoided dissection in the lid, and have placed the suture in such a position that a satisfactory lid fold has resulted.

TECHNIQUE OF OPERATION

Two small stab incisions are made at the upper border of the brow, one 5 mm. from its nasal termination and the other approximately 3 cm. lateral to the first. Each of these incisions goes down to periosteum. Two tiny incisions are made through the skin, 2 mm. above the upper lid margin and about 2 cm. apart, placed symmetrically so that they lie about 7 mm. from the nasal and lateral canthi respectively (fig. 1). A braided white-silk suture (size from 2-0 to No. 2) on a No. 5 three-eighths curve surgical cutting needle is inserted through the upper nasal of these four tiny incisions, through the fascial ter-

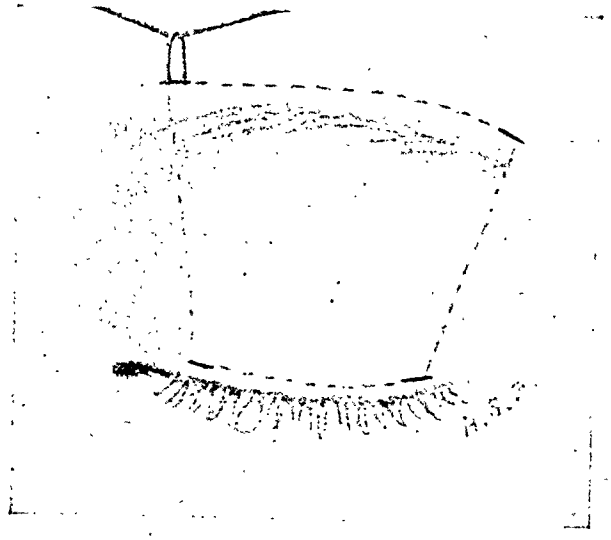

Fig. 1 (Friedenwald and Guyton). Incisions and path of suture.

mination of the frontalis above the brow (just over the periosteum of the frontal bone), and out through the upper lateral incision. From here the suture is carried down through the lid along the under surface of the orbicularis to emerge through the lower lateral incision adjacent to the lid margin; then through the dermis, 2 mm. above the lid margin, to emerge through the lower nasal incision; then along the under surface of the orbicularis to emerge through the upper nasal incision. The suture is tied with the knot in the depths of the upper nasal incision. As the suture is tied, it is pulled tight enough to elevate the upper lid 2 mm. above the desired final position (fig. 2). If there is palsy of the superior rectus, the cornea is protected for a day or

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University.

so by whatever means the surgeon is accustomed to employ with ptosis operations. A small dressing is placed over the superior nasal incision only for one day. It is seldom necessary to hospitalize the patient more than a day after operation.

The operation is best performed under general anesthesia because local anesthesia, even in the form of a nerve block deep within

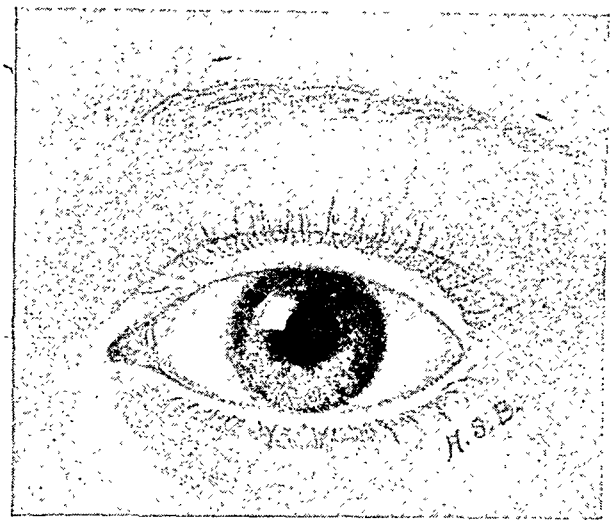

Fig. 2 (Friedenwald and Guyton). Appearance after tying suture.

the orbit, produces enough change in the resulting position of the lid to make it difficult to estimate how firmly the suture must be pulled together as it is tied.

The exact type and size of suture material may be varied considerably, depending upon what is most readily available. Smaller silk sutures, cotton sutures, braided nylon sutures, and braided tantalum sutures of various sizes have all been used with essentially equal success. The optimal size of braided tantalum for this procedure is probably 2-0. In instances where a larger braided tantalum suture was used, the path of the suture along the lid margin was subsequently visible. We have not used tantalum sutures recently because of reports of late fragmentation of tantalum wire following certain plastic procedures and of late fragmentation of tantalum mesh used in the repair of hernias.

Any size and type needle may be used so long as the needle is long enough and strong enough to be pushed through the proper paths. However, of a number of different needles we have tried, a No. 5 three-eighths curve surgical cutting needle has been the easiest to manipulate. The needle is best inserted with a strong clamp such as the Halsted.

It is most important that the suture be placed at the proper depth adjacent to the lid margin. If it is placed superficially in the fibrous layers of the chorium, it will hold firmly; or if it is placed much deeper, in the tarsus, it will hold firmly. However, it must not be placed in the loose connective tissue between skin and tarsus because it will gradually slip upward in this loose tissue with a resulting undercorrection of the ptosis.

Results of operation

Description of cases. During the past four years, 31 such operations have been performed on 23 patients; in 8 of the patients the ptosis was bilateral, while in the remaining 15 it was unilateral. In 15 cases, the ptosis was congenital; in 5 it was posttraumatic; in 2 it was a result of progressive nuclear ophthalmoplegia; and in one, it was a result of cutting the levator in a jaw-winker. Ten of the patients had had previous ptosis operations with unsatisfactory results. These previous operations included Blascovicz operations in 5 cases; a Tansley-Hunt in one; a Machek in one; a Dickey in one; a fascia lata sling (Derby) in one; and a Motais in one. In 18 instances there was complete levator paralysis, and in the remaining 13 there was doubtful or slight levator action. There was complete paralysis of the superior rectus in 13 instances, slight to moderate palsy of the superior rectus in 8, and normally functioning superior recti in the remaining 10.

Operative course. The lids tended to slip below the positions to which they were elevated for 2 or 3 weeks following operation,

but there was generally no further slip after this length of time. The actual amount of slip depended on how tight the suture was tied, there being a greater slip if the suture was tied with very tight tension than if it were tied only firmly. In general, if the suture was tied tight enough to elevate the lid margin about 1 mm. above the limbus with the eye in the primary position, the slip amounted to about 2 mm., so that the final position of the lid was excellent.

Postoperative complications were encountered in five instances.

1. In a patient with bilateral ptosis, the initial correction was excellent for each eye and continued so until four months later when the child was struck a heavy blow on one brow.

The initial operations had been performed with a 4-0 silk suture. Immediately following the blow the ptosis completely recurred, apparently indicating a break in the suture. One month following the blow the ptosis was again corrected according to the same technique and the result was again excellent and remained that way.

In three instances there were late infections around the sutures.

2. In the first of these, operations had been performed on both eyes and the initial results were excellent. Six weeks later, a chronic infection became manifest around the suture in the left lid. This infection cleared after administration of systemic penicillin without the necessity of removing the suture, but the left lid thereupon drooped 3 mm. lower than the right. Five months later another operation of the same type was performed on the left lid without complication and with an excellent result.

3. In the second of these cases, a chronic infection became manifest around the suture two months after operation. The suture was removed and the infection rapidly disappeared. The lid remained elevated in the same position it was before the infection appeared and the result remained excellent even though the suture was removed. The infection in this instance was chronic in nature, and apparently enough fibrosis had occurred along the suture tract before the suture was removed to obviate the necessity of the suture remaining in place to hold the lid in proper position.

4. In the third case the result was excellent until five months after operation, when an abscess occurred around the suture. This suture was removed and the infection quickly cleared but the ptosis partially recurred. There was still, however, a final total correction of 4.5 mm. in the position of the lid, and a good lid fold was retained.

5. The fifth complication consisted of an exposure keratitis. In this case, operations were performed on both lids of the patient with bilateral congenital ptosis and bilateral superior rectus palsy. At the time of operation, the lids were elevated too high, approximately 3.5 mm. above the upper limbus in each eye. The lower lids were pulled up over the corneas by means of sutures fastened to the forehead with adhesive for a period of one day. These protection sutures were then removed and, within two days, exposure keratitis began to develop in each eye. The patient was anesthetized, and the upper lids were grasped about 3 mm. above the lid margins with two Allis clamps and pulled downward forcibly until sufficient slip had occurred in the sutures to position the lid margins just at the upper limbus. The lids were then sutured together temporarily with two mattress sutures for each eye. These sutures were removed four days later, at which time the exposure keratitis had healed with slight residual scarring. No further keratitis developed and the final correction of the ptosis was satisfactory.

Exclusive of these five cases, in which complications occurred, and of one additional case in which the result was not recorded, the cosmetic results in the remaining 17 cases were graded as excellent in 12, good in 4, and 2 mm. undercorrected in one.

Comment

We believe that utilization of the frontalis is the type of operation best chosen for ptosis characterized by complete or almost complete paralysis of the levator and with palsy of the superior rectus, or in the presence of normally functioning superior recti if the patient has binocular vision.

The technique we have described for this operation is a simple one. It may be performed regardless of previous ptosis operations and may be repeated or followed by another type of ptosis operation should such prove necessary. We do not believe that this operation should be used in preference to a procedure which utilizes the levator, such as the Blascovicz operation, if there is appreciable function in the levator. However, in some instances a Blascovicz operation does not give a good cosmetic result even though the patient apparently does not have complete paralysis of the levator. In five such instances, utilization of the frontalis has given excellent results in four and a satisfactory result in the remaining one.

The one major point about which we are uncertain is whether this operation will prove permanently effective. It is possible that there may be some recurrence of ptosis, due either to very gradual "slip" or cutting in of the suture or to actual breakage of the suture years after the operation is performed. However, if such proves to be the case, the operation can easily be repeated or a different operation can be performed.

One of the most important aspects of this operation is the resulting lid fold. If the suture is placed parallel to the lid margin, actually in the dermis rather than in the loose subcutaneous tissue, a normal appearing lid fold usually results. We have not seen such lid folds result from other techniques of anchoring the lid to the frontalis; in fact, these lid folds are generally better than those obtained with operations utilizing the levator.

Summary

A simple, yet effective, technique of correcting ptosis by utilizing the frontalis consists of placing a single, permanently buried suture in the shape of a rhomboid connecting the dermis of the lid just above the lid margin to the fascial termination of the frontalis. The initial correction at the time of operation must be an overcorrection of about 2 mm. because the lid slips back downward about this distance within three weeks after operation.

This operation has been performed on 31 eyes of 23 patients. Postoperative complications have consisted of a broken suture following trauma to the brow in one instance, late infections around the sutures in three instances, and exposure keratitis immediately following operation in one instance. None of these complications proved serious, and the cosmetic results have been satisfactory both with regard to the final position of the lids and the resulting lid folds.

VISUAL-FIELD INTERPRETATIONS IN CHIASMAL LESIONS*

DANIEL KRAVITZ, M.D.
Brooklyn, New York

The greatest difficulty in visual-field interpretations is from lesions in the chiasmal region. In this area lies the optic chiasma which is made up of visual fibers from the optic nerves that enter into it anteriorly. After a rearrangement of the fibers, they leave the chiasma posteriorly as the optic tracts. It is only in this region, therefore, that it is possible to get field changes limited to one eye or to both, and varying from blindness to temporal or nasal defects and to combinations of these.

This compact area contains many structures, pathologic conditions of which may cause field defects. Above the chiasma is the diencephalon, and below are the pituitary gland and the base of the skull. Surrounding the chiasma is the circle of Willis with its many anastomosing vessels, the main cerebral arteries, the venous sinuses, some of the intracranial nerves, and the meningeal membranes with their arachnoidal granulations.

PATHWAY OF FIBERS IN OPTIC CHIASMA†

The optic chiasma is an oblong structure which measures about 13 mm. transversely, 8 mm. anteroposteriorly, and 3 to 5 mm. in thickness. According to Schaeffer[1] and other investigators, it rarely lies in the chiasmal groove which is in front of the tuberculum sellae. In 91 percent of the 125 skulls studied by Schaeffer, the chiasma lay above the diaphragma sellae so that its posterior part was partially on the dorsum sellae behind. In 4 percent, the major part of the chiasma lay upon the dorsum sellae; and in the remainder, the chiasma was in the sulcus chiasmatis.

Within the chiasma, the fibers from the optic nerves are arranged in a fairly regular pattern. Those from the inferior nasal halves of the retinas cross in the anterior part of the chiasma until almost to the other side; while the fibers from the superior nasal halves of the retinas stay on the same side of the chiasma until almost to the optic tracts and then cross in the posterior part of the chiasma. After crossing, the fibers leave the chiasma, posteriorly as the optic tracts, and form the inferior and superior nasal halves of the tracts. The fibers from the lower temporal halves of the retinas stay near the outer borders of the chiasma, while the fibers from the superior temporal halves arch toward the middle. The temporal fibers do not cross but proceed posteriorly to form the lower and upper temporal halves of the optic tracts. The macula fibers also divide into crossed and uncrossed fibers, the crossing taking place near the posterior border of the chiasma.

PITUITARY-GLAND FORMATION‡

In typical pituitary tumors, the pressure is first on the anterior border of the chiasma causing loss of the upper temporal fields. Later there is loss of the lower temporal fields. The arched fibers from the upper temporal quadrants are next involved, and lastly, those near the lateral borders, causing loss of the lower and upper nasal fields, respectively. A pituitary tumor may grow under the chiasma and press upon an optic nerve, resulting in monocular blindness before involving the other eye; or, it may grow backward and press upon an optic tract, resulting in homonymous hemianopsia. The

‡ See illustration: Grinker, R.R.: Neurology, Springfield, Illinois, Charles C Thomas, 1937, p. 40.

suprasellar tumors usually press from above downward, often upon the posterior part of the chiasma so that the macula fibers may be involved. Third-ventricle tumors usually involve the posterior part of the chiasma and the macula fibers. As a rule, atypical field defects are due to tumors other than pituitary tumors.

Of primary interest in this area is the pituitary gland. Roughly, the gland is made up of two parts—the anterior and posterior lobes. The posterior lobe starts as an outpouching from the diencephalon and grows downward, retaining its connection with the brain by means of a stalk, the infundibulum. The anterior lobe starts as an outpouching from the posterior wall of the pharynx and grows upward and around the posterior lobe to invest it. As the base of the skull develops, the anterior lobe loses its connection with the posterior pharynx. Vestigeal remains of the buccal part of the pituitary gland may be found in the posterior wall of the nasopharynx, lining an opening sometimes present from the pituitary fossa to the base of the skull—the craniopharyngeal canal; or they may appear as a small island of primitive tissue within the sella turcica. Either of these may commence to grow and form the so-called Rathke's pouch tumor, craniopharyngeoma, or suprasellar cyst.

Anatomy of the diencephalon[§]

The gland lies within a fossa, the sella turcica, the roof of which is formed by dura called the diaphragma of the sella. This is pierced by the pituitary stalk. The optic chiasma lies above the sella turcica with the pituitary stalk in proximity to its posterior border. Just anterior to the sella turcica is the tuberculum sellae which is sometimes the seat of a meningioma giving rise to the so-called pituitary syndrome of the adult.

Lateral to the chiasma are the internal carotid arteries which here divide to form the middle and anterior cerebral arteries. These give off anterior and posterior communicating branches which join with communicating branches from the posterior cerebrals to form the circle of Willis. Aneurysms and sclerotic changes in these vessels may press upon the chiasma and cause field changes. Anterior to the chiasma are the olfactory grooves on the base of the frontal lobes of the brain. These are sometimes sites for tumors which may be difficult to differentiate from chiasmal lesions.

As previously stated, the stalk of the pituitary gland arises from the diencephalon, which here is the floor of the third ventricle. Tumors in this area may give symptoms and field changes difficult to distinguish from pituitary adenomas or from suprasellar cysts.

Anatomic differences[‖]

Sella turcica

Atypical field defects from pituitary tumors may be due to anatomic differences in the pituitary fossae. In some cases, the anterior or posterior walls may be faulty, and the tumor will naturally grow in the direction of least resistance. The direction of growth may also be influenced by the relation of the thickness of the anterior and posterior walls and also by the diaphragma sellae. The latter may be thick and strong; or it may be very thin or even missing. The opening for the hypophysial duct may be very large so that a tumor can go through without rupturing the diaphragma. In these cases, the tumor may not cause enlargement of the sella but will present as a suprasellar growth. It is also interesting to note the relation of the sphenoidal sinuses to the pitu-

§ See illustration: Grinker, R. R.: Neurology. Springfield, Illinois, Charles C Thomas, 1937, p. 40.

‖ See illustration: Schaeffer, J. P.: Anatomical Record, 28:245 (July) 1924.

itary fossa. The intervening bone may be so thin or deficient that a retrobulbar neuritis from sinus infection can readily be explained. Very occasionally a bitemporal field defect may be found in this condition. Rarely, the pituitary tumor may rupture and grow into the sinus.

Blood vessels at base of brain[¶]

In addition, anatomic variations of the blood vessels may help to modify the field changes. The anterior cerebral arteries are most commonly at fault in this respect. These usually cross over the optic nerves, but at times may cross the optic chiasma, and rarely may be found as far back as the optic tracts. Less often, the posterior communicating arteries which connect the internal carotids with the posterior cerebrals may pass over the optic tracts. In all of these locations, a tumor from below may press the chiasma against the vessels so that they may act as pressure cords with consequent destruction of visual fibers. In addition to direct pressure, a certain amount of ischemia due to interference with the local blood supply may further modify the fields.

With the field defects, there are frequently clinical signs and symptoms which are of help in localizing the lesions.

The mammillary bodies and the tuber cinereum surround the base of the stalk. These structures are part of the hypothalamus which controls the vegetative nervous system. The posterior portion seems to regulate the sympathetic system, while the anterior part regulates the parasympathetic system. Injury to these parts causes diabetes insipidus, Frölich's syndrome (adiposogenital dystrophy), disturbances in sugar and fat metabolism, disturbances in temperature regulation (particularly around the third ventricle), disturbances of emotions, and disturbances of sleep, so that there may be drowsiness, loss of sleep or sleep inversion.

[¶] See illustration: Jamieson, E. B.: Illustrations of Regional Anatomy: Section 1. Baltimore, Wm. Wood & Co., 1934, p. 43.

Tumors of chiasmal region

Pituitary adenomas

Pituitary adenomas are the most frequent tumors in the chiasmal region. To date, there has been no recorded tumor of the posterior part of the pituitary gland. The anterior portion consists of two types of cells: (1) Cells which contain granules that take either the acid stain—acidophiles, or the basic stain—basophiles. (2) Cells with large nuclei and clear-staining plasma—the chromophobes.

Tumors of the acidophile cells cause symptoms which vary according to the age of the patient. In the young, whose bones are still in the stage of growth, the outstanding features are gigantism and early development of the secondary sex characteristics. In the adult, there is acromegaly, characterized by overhanging supraorbital margins, broadening of the nose, and progressive enlargement of the hands and feet.

According to Cushing,[2] tumors of the basophile cells results in hirsutism and elevation of blood pressure, symptoms usually associated with tumors of the adrenal glands.

Abnormal growth of the chromophobe cells results in pressure atrophy of the chromophile cells. The symptoms are, therefore, due to loss of function of the latter. In children, there is infantilism; while in adults, there are increases in the body fat and loss of libido or menses.

Features common to the above tumors are enlargement or destruction of the sella turcica, field defects which progress to blindness, and primary optic atrophy. Typically, there is first a loss of the upper temporal field, then the lower temporal, lower nasal, and, last, the upper nasal field. The tumor may occasionally cause blindness in one eye before involving the fields of the other eye, or there may even be homonymous hemianopia because of involvement of the optic

tracts. Infrequently, the tumor may break through the diaphragma of the sella and cause symptoms resulting from irritation or destruction of the diencephalic region of the brain.

Craniopharyngioma

The next most common type of tumor is the craniopharyngioma. As these tumors are derived from embryonal rests, they usually occur in the young. In fact, next to cerebellar tumors, they are the most frequent tumors of childhood. The field changes are varied but more or less typical of tumors in the chiasmal region. Because of pressure on the posterior part of the chiasma, central or caecocentral scotomas are frequent. There may be primary or secondary optic atrophy or even choked discs. Frequently symptoms of involvement of the diencephalon are present. In addition, they cause destruction of the chromophile cells and give symptoms characteristic of chromophobe tumors. The sella turcica may or may not be enlarged. X-ray examination of the skull usually shows the presence of calcified plaques in the chiasmal region.

Meningioma of tuberculum sellae*

Meningiomas of the tuberculum sellae are fairly frequent. They are benign and can be removed in toto if not too large, so that an early diagnosis is important. They arise from the meninges,[3] probably from the arachnoidal granulations in the venous sinuses. They are called the chiasmal syndrome of the adult. Recently, Schlezinger[4] reported such a tumor in a girl, aged 16 years. This is considerably below the average age. These tumors usually present anteriorly to the chiasma and press directly on the optic nerves, causing atypical temporal field defects. Because of the vulnerability of the macula fibers, central and paracentral scotomas are frequent. Primary optic atrophy is constant and progressive. The sella turcica is not enlarged, because the tumor is well outside of the sella turcica.

Less common tumors

Among the less common tumors in this region are tumors of the sphenoidal ridge. These cause a progressively increasing exophthalmos, paralyses of the external ocular muscles, and atrophy of the optic nerve. X-ray examination shows increased density of the sphenoid ridge. All the findings are on the side of the lesion. The condition is sometimes known as the syndrome of the cavernous sinus.

Aneurysms of the circle of Willis have been fully described by Walsh.[5] They are characterized by unusual field changes, frequently with central or paracentral scotomas, pains in the back of the eyes, and ocular-motor paralyses, most commonly involving the third nerve. A previous episode of subdural bleeding makes the diagnosis definite.

Third-ventricle tumors are uncommon but should be thought of in patients giving symptoms and field changes suggestive of lesions around the chiasma. There are usually disturbances of the vegetative nervous system, especially the persistence of an unexplained fever. Central and paracentral scotomas are frequent.

Arachnoiditis[6] in the chiasmal region may give symptoms typical of tumor. In fact the cysts often found are a form of tumor. There is usually a history of rapidly developing blindness. The discs have the peculiar appearance of a mixed primary and secondary atrophy. A preceding history of head trauma, sinus infection, or lues is of etiologic importance. If tumors are suspected, early surgery, before irreparable blindness supervenes, is important.

Meningioma of the olfactory groove is really a frontal lobe tumor. A Foster-Kennedy syndrome, optic atrophy on the same

---

side with a choked disc in the other eye, is an important sign if found. More frequently, it is absent, and occasionally it may be present in other conditions. Anosmia, loss of smell, on the side of the lesion is present.

Other tumors, such as chordomas, are rare and are usually diagnosed at operation.

Report of cases

Case 1

C. M., a woman aged 29 years, was admitted to the Brooklyn Hospital with a history of intermittent headaches of 10 years' duration. For the past six months, her vision had become progressively more blurred and her sense of smell had been lost. She also had a constant buzzing in the left ear.

X-ray examination showed an area of lessened density of the frontal bone which was almost centrally placed a little above the orbits. The sella turcica was not well defined but it was enlarged. The floor was depressed, and the posterior clinoid processes were eroded. In view of these findings, it was thought that a tumor of the sella turcica, or of the area around it, and a tumor of the frontal bone were present. The growth in the frontal bone was thought to be metastatic.

Ocular examination. There were no ocular palsies and no nystagmus. The pupils reacted to light and accommodation. There was about 5 or 6 diopters of swelling of both discs, with a few hemorrhages around the left disc but none around the right. Vision in the left eye was so poor that a 10-mm. test object was the smallest that could be used. This showed a complete loss of the nasal field with retention of a small island in the temporal field. The visual field of the right eye could be plotted with a 2-mm. test object and showed a marked concentric contraction with a loss of the nasal field. There was no evidence of secondary atrophy of either disc.

Diagnosis. As a result of this examination, it was thought that the condition was tumor of the left side of the brain, near the chiasm. For the degree of intracranial pressure and the headaches complained of by the patient, she was markedly euphoric and jocular. There was a distinct forward bulge in the middle of the forehead.

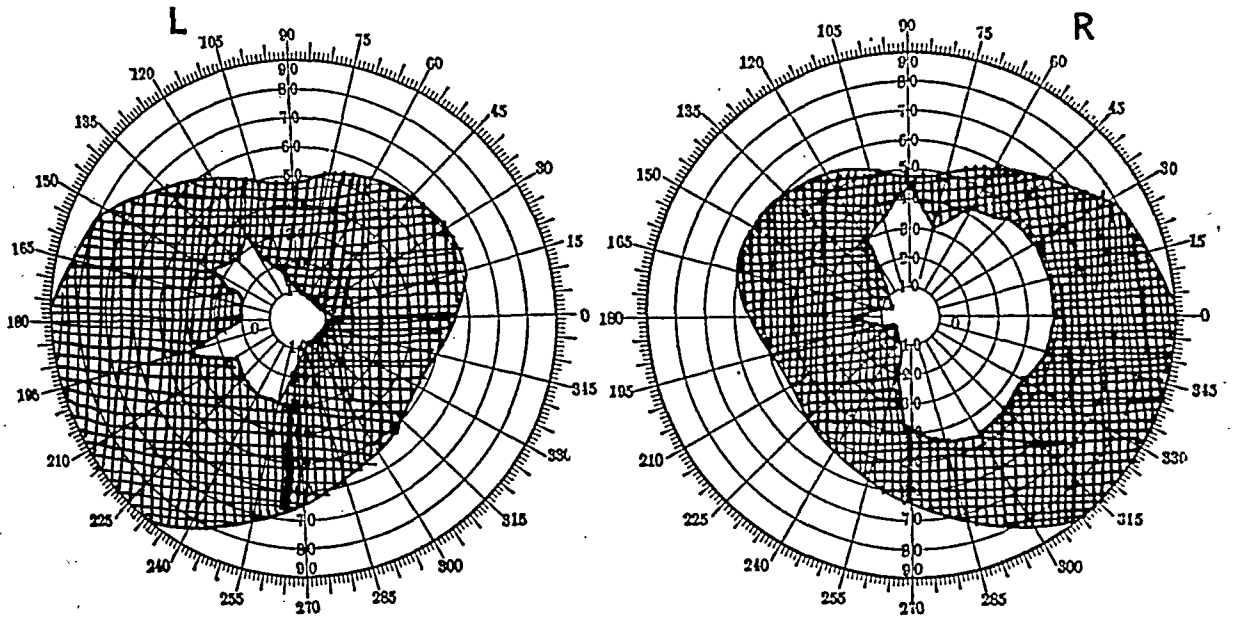

Fig. 1 (Kravitz). *Case 1.* Left: field for 10/250 mm. white; right: field for 2/250 mm. white.

The neurologist found no signs of localizing value and was of the opinion that the condition was a tumor of the frontal lobe.

A bone flap in the right frontal region was turned down and a meningioma, the size of a small orange, occupying the frontal aspect of both anterior cranial fossae, was removed.

The loss of both nasal fields was probably caused by a flattening of the chiasm against both internal carotid arteries.

Case 2

C. A., a man aged 27 years, gave a history of loss of libido for about 12 years. He was treated with glandular preparations. After a while, he complained of visual disturbances, and glasses were prescribed. For some time he continued to receive glandular therapy and, every now and then, he would have a severe headache. Vision deteriorated so slowly that he was not conscious of its loss until it was well advanced. Recently his headaches became severe and persistent and were accompanied by projectile vomiting.

Physical examination showed the patient to be short and slight of build, with no hair on the face. He had small delicate hands and feet with the voice of a preadolescent boy. He had complete loss of sexual power.

Ocular examination. Vision was 20/70 in each eye, not improved with correction. Both discs showed advanced primary atrophy. The visual fields showed practically complete bitemporal hemianopia.

A right transfrontal osteoplastic craniotomy was performed and a cyst, extending anteriorly to the chiasm, was removed. When it was opened, a large amount of yellow fluid containing fatty deposits was evacuated. Immediately below the chiasm and pressing upward into its structure was a large globular irregular mass of cholesterol. It extended into the tissue of the chiasm. Part of the wall of the cyst and as much of the cholesterol as possible were removed without severing the chiasm.

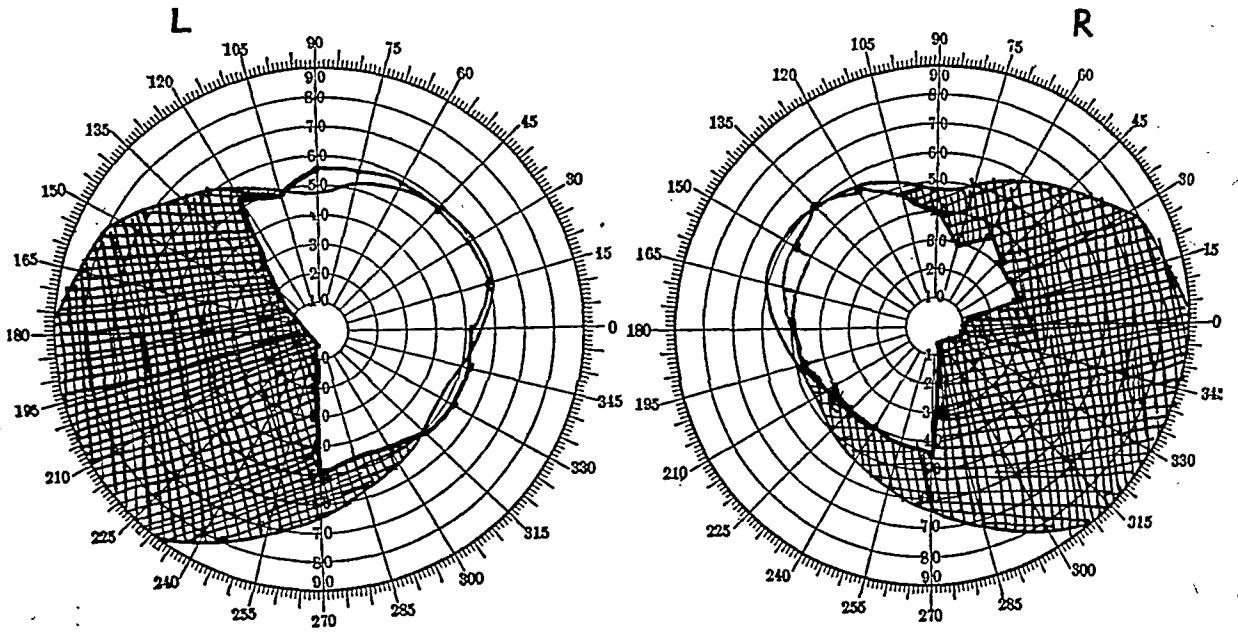

Fig. 2 (Kravitz). *Case 2.* Left and right: fields for 2/330 mm. white.

Case 3

L. T., a woman, aged 50 years, gave a history that 13 years before, she had noticed a tingling of her hands and feet. One year

later, and until about four years before admission, she began to grow larger in all dimensions. During this period, she gained about 100 pounds and her hands and feet grew so large that she had to wear men's sizes. About two years ago she began to have pains in her legs, and about six months later, she developed polyuria and polydipsia. At this time she received X-ray treatments to the pituitary gland. This was followed by a loss of vision in the left eye. Her periods started at the age of 13 years and were normal until her menopause at the age of 44 years.

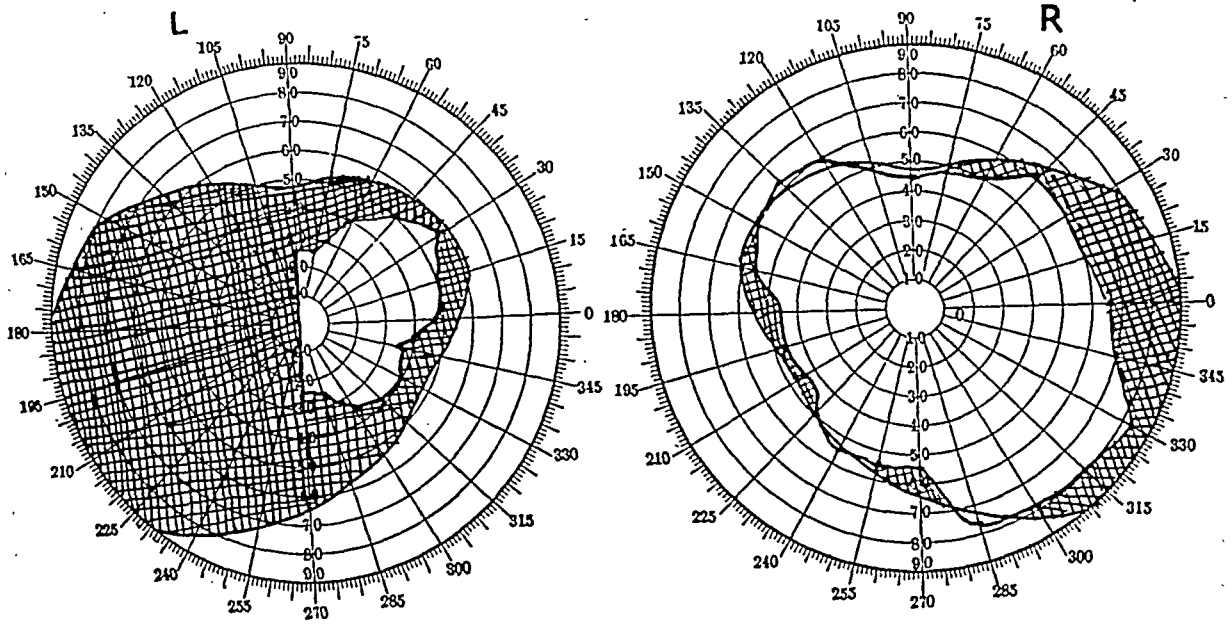

Fig. 3 (Kravitz). *Case 3.* Left: field for 40/250 mm. white; right: field for 2/250 mm. white.

Physical examination revealed a typical acromegalic type.

Ocular examination. Vision was: R.E., 13/13; L.E., perception of fingers at 12 inches. The left pupil was slightly larger than the right but both reacted to light and accommodation. The margins of the right disc were blurred, although no measurable edema was present. The disc was pale. With a 2-mm. test object, the right eye showed a moderate loss of the temporal field, most marked above. With a 40-mm. test object, there was a complete absence of the temporal field in the left eye and a concentric contraction of the nasal field. Through a transfrontal approach, an acidophilic adenoma was removed. A knuckle of this had broken through the diaphragma sellae and was pressing upon the diencephalon.

CASE 4

W. C., a Negress, aged 32 years, gave a history of failing vision for one year. About six months before, her menses stopped and she began to have occasional frontal headaches usually with vomiting. She had a continual thirst and an excessive craving for "sweets." The neurologic examination was entirely negative.

Ocular examination. Vision was: R.E., limited to perception of hand movements on the nasal side; L.E., perception of fingers at two feet. The visual fields were unreliable but suggested a right homonymous hemianopia. A month later, she developed optic atrophy in both eyes. At operation, a large suprasellar cyst was exposed and about 30 cc. of xanthrochromic fluid was evacuated. The following day, the patient was able to count fingers with either eye at five feet. It was

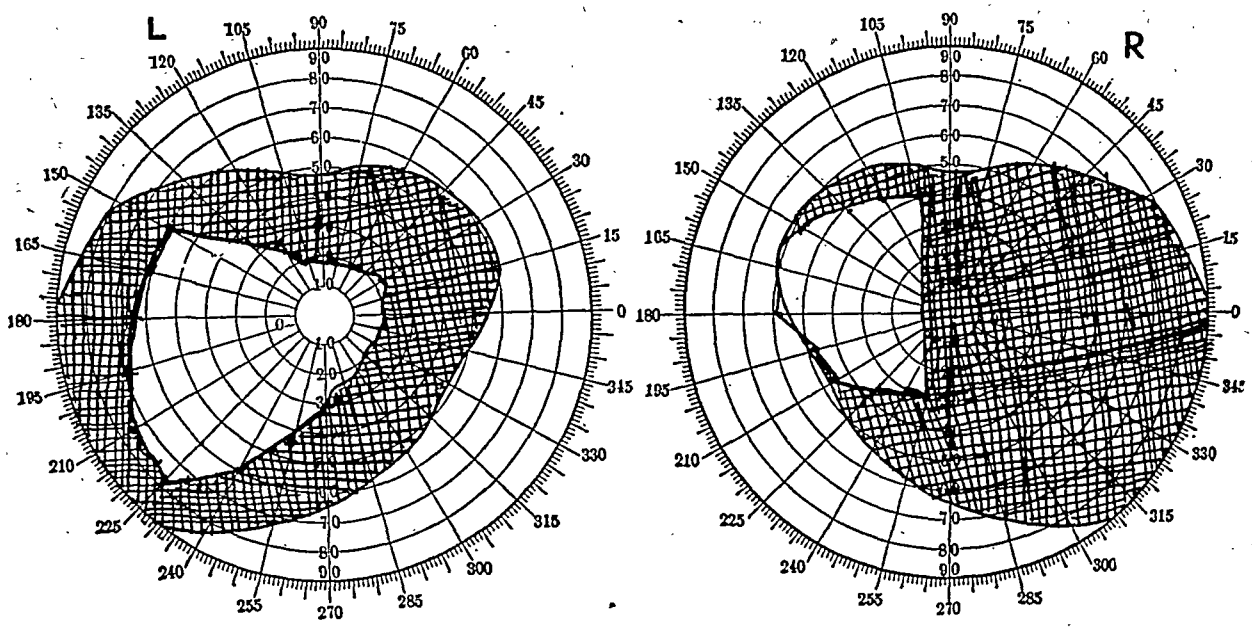

Fig. 4 (Kravitz). *Case 4.* Visual acuity in the left eye is limited to finger movements at two feet; in the right eye, hand movements.

felt that a good deal of the previous loss of vision was probably hysterical in origin.

CASE 5

J. G., a Negro, aged 34 years, gave a history that about nine years before, he began to grow in size and his features changed. About five years before, vision in the right eye began to fail and the hair on his face and pubis become more scant and his sexual power impaired. Gradually he became more lethargic so that he was unable to work. In a period of nine years, he had grown about 5 or 6 inches.

Physical examination showed a very tall, thin Negro who appeared ill and toxic. His features were typically acromegalic and his mentality was dull. X-ray studies of the

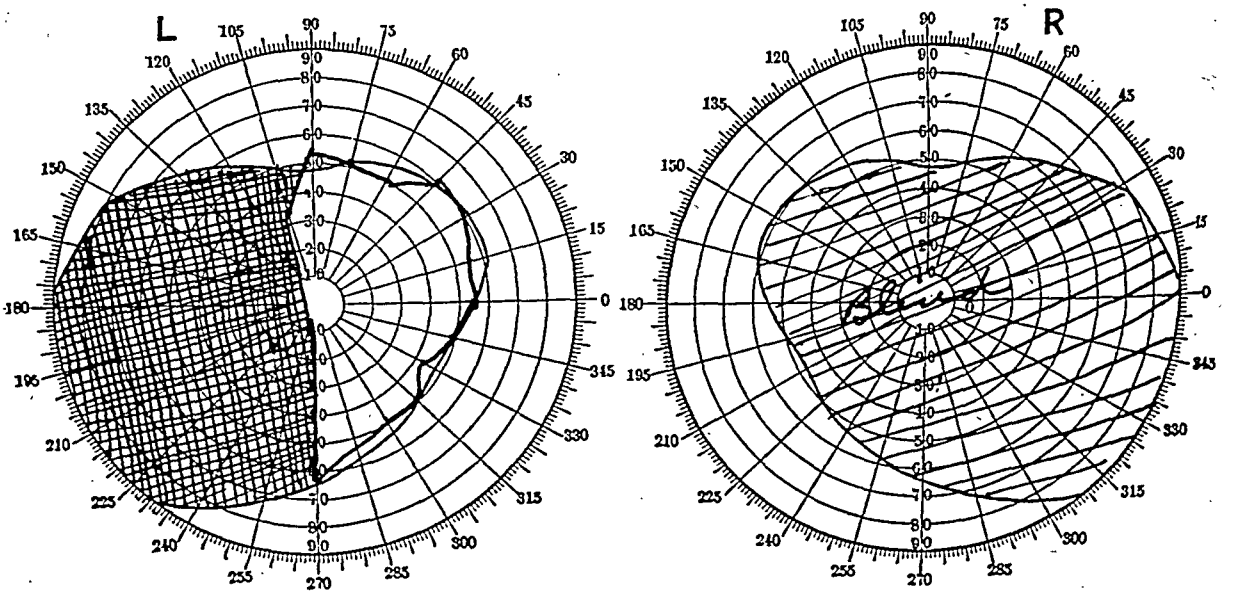

Fig. 5 (Kravitz). *Case 5.* Left: field for 2/330 mm. white. The right eye is blind.

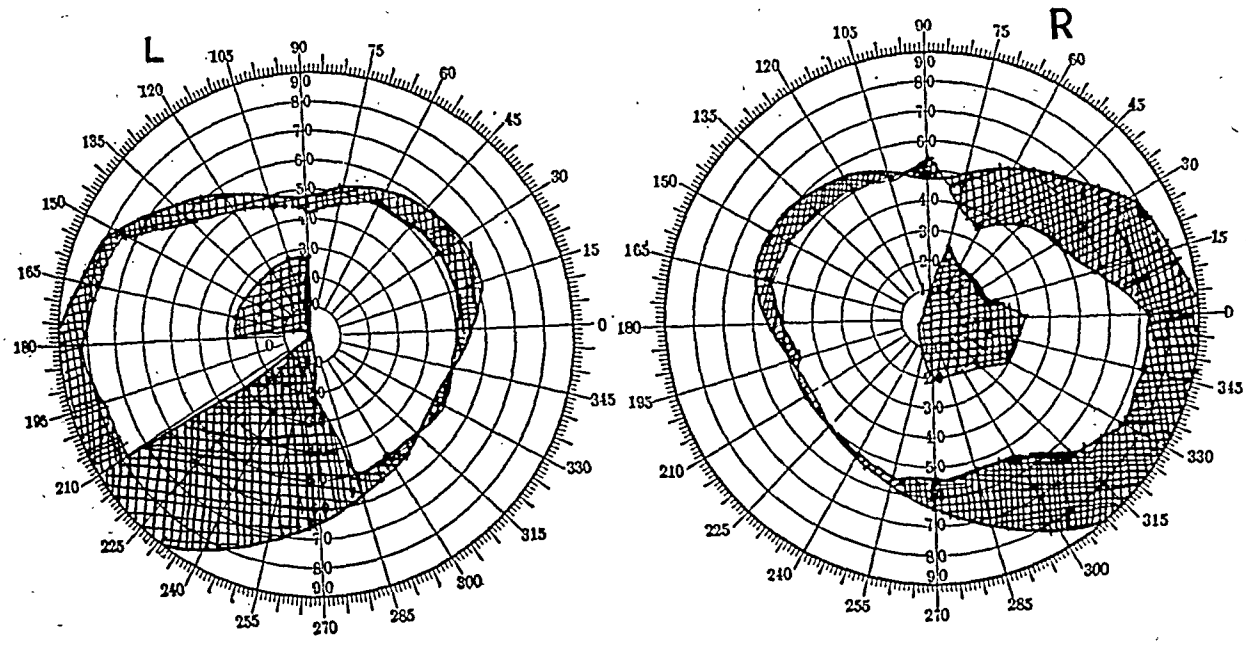

Fig. 6 (Kravitz). *Case 6.* Left: field for 5/250 mm. white. Visual acuity in the right eye is limited to hand movements.

skull showed an immense sella turcica with anterior and posterior clinoid processes eroded.

Ocular examination. There was advanced optic atrophy of the right disc with imperfect light perception. The left disc was of good color and there was a complete loss of the temporal field, with sparing of the macula. Vision was not taken because of very poor coöperation. At operation, a large cystic degenerated tumor of the pituitary gland was removed.

CASE 6

A. D., a woman, aged 29 years, gave a history of failing vision for four months and

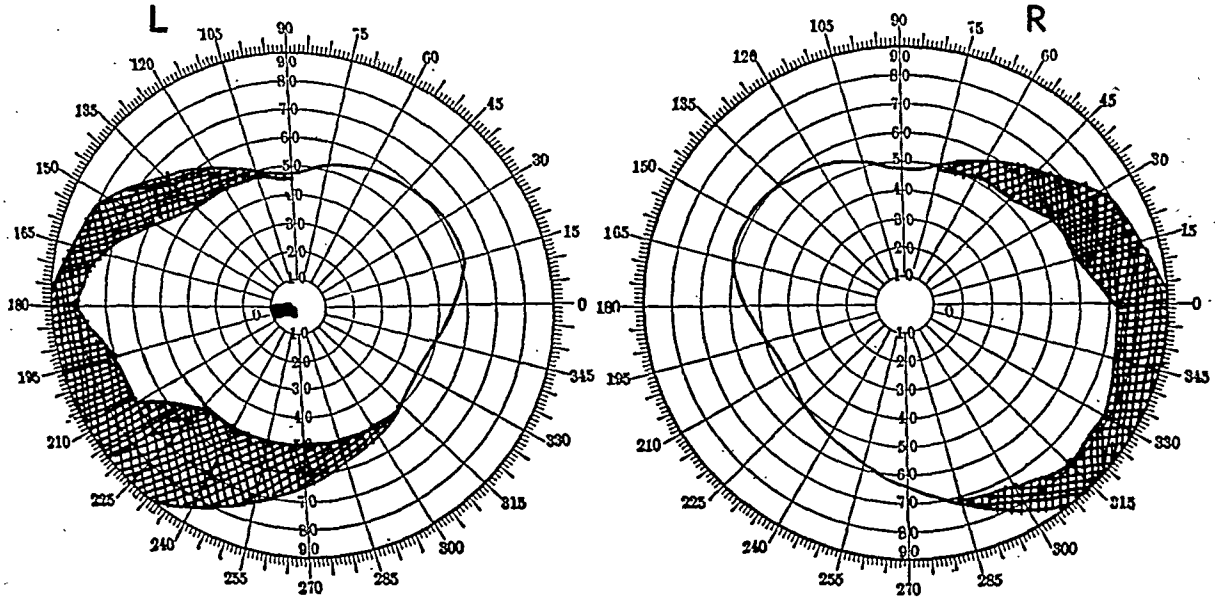

Fig. 7 (Kravitz). *Case 7.* Left and right: fields for 1/250 mm. white.

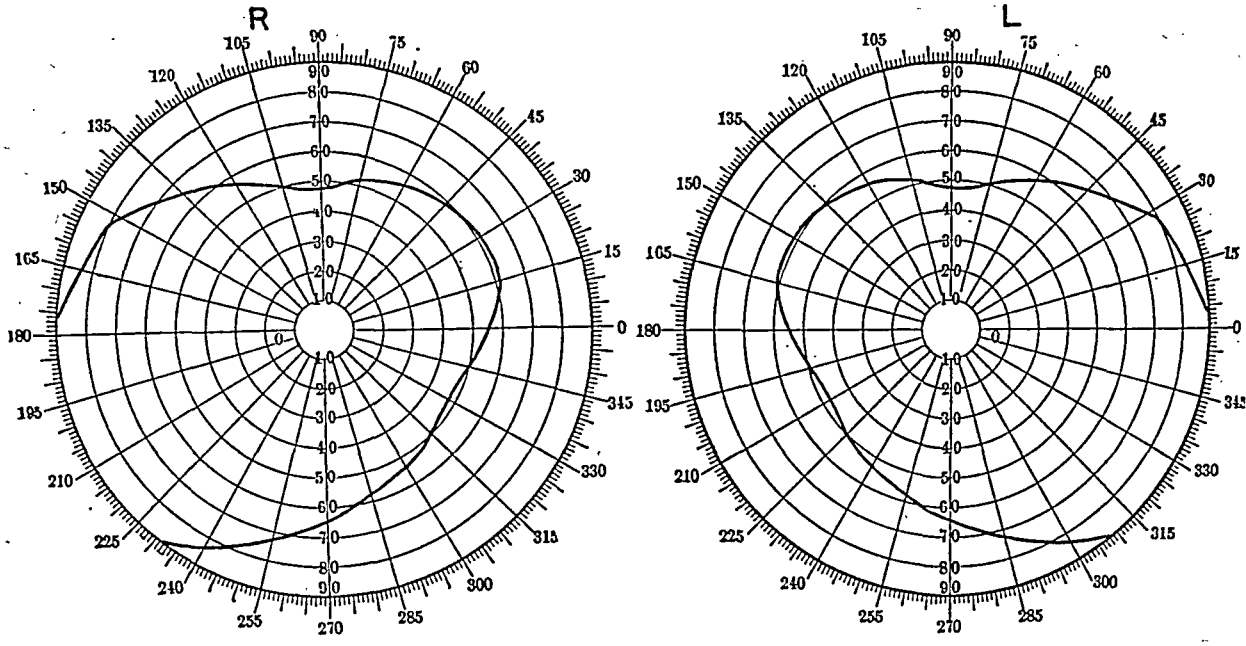

Fig. 8 (Kravitz). *Case 7.* Right and left: fields for 2/1000 mm. white.

severe periodic headaches for the past five months. The headaches came about once a month and lasted from 1 to 2 days, usually with vomiting. Her menstrual periods stopped completely about seven years before, but she had not lost or gained any weight since then. X-ray examination revealed a distended sella turcica with encroachment on the sphenoid sinuses.

Ocular examination. Vision was: O.U., 5/200, and there was moderate primary atrophy. Field examination revealed a temporal central defect in the right eye with a contraction of the temporal field. The left eye also had a loss of temporal central field with a central defect on the lower temporal area. The fields were evidence of pressure on the posterior chiasma with in-

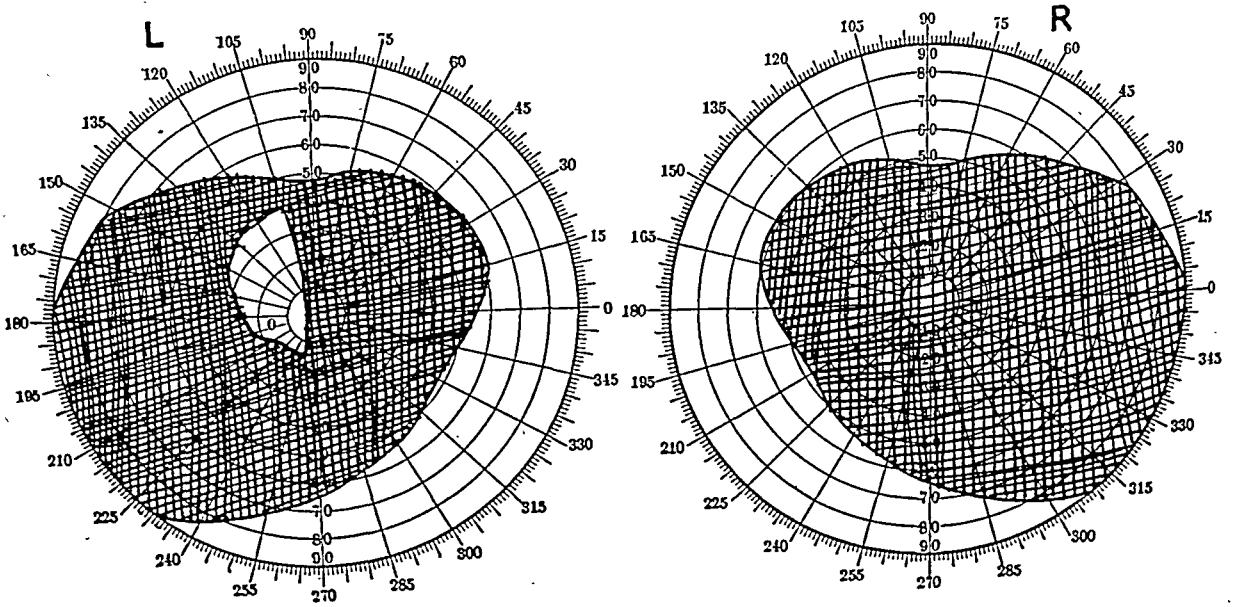

Fig. 9 (Kravitz). *Case 8.* Vision in the left eye is limited to hand movements. In the right eye, there is no light perception.

volvement of the crossed macula fibers. Operation revealed a suprasellar cyst which had encroached on the chiasm posteriorly and superiorly. A postoperative diagnosis of tumor of the pituitary gland with cystic degeneration was made.

CASE 7

M. W., a young woman, aged 17 years, gave a history that, about two years before, she had lost considerable weight. A year ago, she developed a persistent fever with headaches, nausea, and vomiting and soon thereafter she began to gain a good deal of weight and her menses became scanty and irregular. She also became dull and apathetic with symptoms of diabetes-insipidus.

Ocular examination. Vision was 20/20 in each eye and the disc borders were somewhat blurred, with slight pallor of the temporal portions. Field examination showed an enlargement of the blind spots with some loss of temporal fields, particularly of the right lower temporal. Examination two months later, showed a caecocentral scotoma of the left eye.

A diagnosis of a supra sella cyst was made.

Operation revealed an infiltrating lesion of the third ventricle with involvement of the visual fibers near the posterior border of the chiasm.

CASE 8

M. W., a woman, aged 29 years, came to the Post-Graduate Hospital because of menstrual disturbances for the past six years and failing vision for the past four years.

Previous to the onset of symptoms her menses came regularly every 28 days and lasted for four days. Now they came every two weeks and lasted one day. The visual disturbances began with blurring in one eye and then in the other, and vision had deteriorated steadily since the onset.

Neurologic examination revealed nothing abnormal, but ophthalmic examination showed pallor of both discs and left homonymous hemianopsia. Operation was performed for tumor of the pituitary gland but none was found, and the patient was discharged after recovery from the operation.

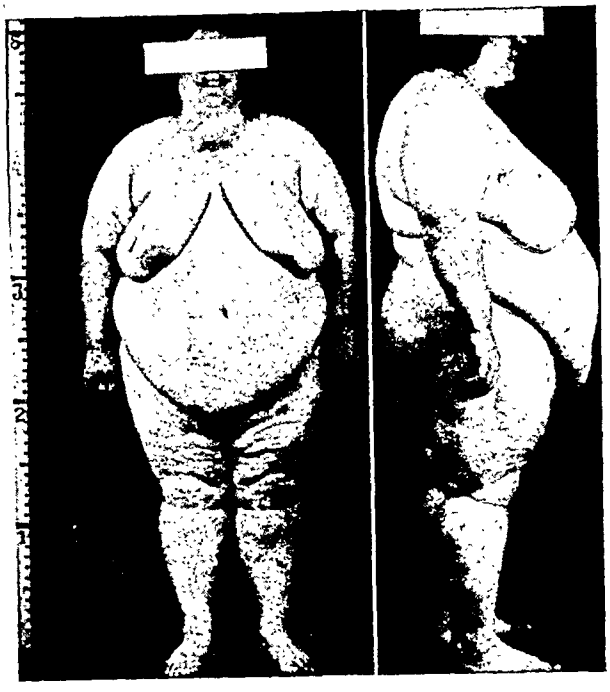

Fig. 10 (Kravitz). *Case 8.* An operation was performed on this patient for tumor of the pituitary gland, but none was found. After this she gained rapidly in weight. Several years later a second operation revealed extensive chiasmic arachnoiditis.

Unfortunately, all the original records were lost, so that more detailed information is not available.

She was readmitted with the history that, after operation, vision had failed more rapidly and she had gained considerably in weight, about 63 pounds (28.6 kg.). She had not had her menses since the operation. For the past five months she had had polyuria and polydipsia.

An encephalogram revealed a normal ventricular system and normal sella turcica, and she was again discharged for further care in the outpatient department. She was placed under mixed glandular therapy and at intervals X-ray studies of the skull were

taken. These always revealed no pathologic change.

The patient was readmitted to the Hospital three years later because her symptoms had become worse. Examination of the eyes showed a mixed type of primary and secondary atrophy of the optic nerve. The right eye was blind, and only an island of vision was retained in the temporal field of the left eye. A ventriculogram revealed dilatation of the left ventricle with cortical atrophy. The right ventricle was normal.

Operation revealed extensive chiasmic arachnoiditis, with a large cyst which had lifted the chiasm upward. The cyst was emptied and the adhesions were ruptured, but the patient's condition was not improved. When she was last seen, there was progressively increasing drowsiness and great impairment of memory.

The first operation was performed before the entity of chronic arachnoiditis was well known. If the adhesions had been separated then, the subsequent course of the patient's condition might well have been different.

Conclusion

Most of the cases herein reported, presented physical symptoms and showed loss of vision in one or both eyes before operation. If the ophthalmologist, who often sees these cases first, is to be of help, he must familiarize himself with the brain so that he will be better able to interpret the field changes as well as the patient's symptoms. To wait for typical field changes will frequently result in tragedy.

RELATIONSHIPS BETWEEN LATERAL HETEROPHORIA, PRISM VERGENCE, AND THE NEAR POINT OF CONVERGENCE*

RICHARD G. SCOBEE, M.D.†
Saint Louis, Missouri
AND
EARL L. GREEN, PH.D.‡
Columbus, Ohio

Numerous physiologic functions of the binocular neuromuscular mechanism have been measured for years with various kinds of testing equipment. Relatively few studies have been made to determine to what extent these various testing devices measure the same or different characteristics. This study was designed to investigate the relationships between lateral heterophoria, prism vergence, and the near point of convergence, as well as the relationship of these variables to age, sex, and refractive error.

Other partially similar studies have been made previously. Haessler[2] considered the relationship of heterophoria at 20 feet to refractive error and to the convergence angle. His sample consisted of 1,000 cases and was preselected to the extent that the following subjects were eliminated: (a) those with more than 0.5 prism diopters of hyperphoria; (b) those with more than 4.0 diopters of ametropia; and (c) those who had not worn correcting lenses for their ametropia for at least several months.

Haessler employed the Maddox-rod test for heterophoria and justified his use of it on the basis of a study by Weymouth,[7] who, with data from 12 subjects, concluded that the screen and parallax test, von Graefe's prism diplopia test, and the Maddox-rod test were essentially equivalent at a testing distance of 20 feet. Weymouth's interpretation has since been confirmed.[5] Haessler measured prism divergence at 20 feet but calculated convergence as the convergence angle using the PcB (the near point of convergence calculated from the convergence base line). After studying the distribution of heterophoria for each category of prism divergence—that is: 1, 2, 3, 4, 5, and so forth, prism diopters—as well as for each category of the convergence angle, he concluded that there was no correlation between heterophoria and vergence as expressed in the usual clinical measurements.

Abraham[1] studied heterophoria and vergence both at 20 feet and at 13 inches in 4,000 cases. He was primarily interested in the possibility of predicting the symptoms of a patient from the measurement of heterophoria or of vergence. He found that the prism divergence at 13 inches might serve this purpose and his work has been confirmed.[4]

SAMPLE AND TESTING METHODS

SOURCE OF SUBJECTS

Records were collected for this study upon 184 male and 217 female subjects. They were either emmetropic or had been rendered so by correcting glasses prior to the study. Roughly half of the subjects had no ocular complaints whatever and were either employees or patients from other clinics. The remainder were patients from the private practice of one of us (R. G. S.), although the chief complaint of many of them was not one of asthenopia, but rather "a red eye" or "something in the eye." An attempt to get as nearly a true random sample as possible was made and it is felt that this was for the most part successful.

* This study was made under a contract with the Office of Naval Research as Project N6onr-202, Task Order I.

† From the Department of Ophthalmology, Washington University School of Medicine, and the Oscar Johnson Institute.
‡ From the Department of Zoology, Ohio State University.

Data

For each subject, a record was made of:

1. Sex.
2. Age in years to last birthday.
3. Refractive error of the right eye, recorded as the spherical equivalent.
4. Refractive error of the left eye, recorded as the spherical equivalent.
5. Near point of convergence in millimeters.
6. Lateral heterophoria in prism diopters at a testing distance of 20 feet.
7. Prism convergence break point at 20 feet.
8. Prism convergence re-fuse point at 20 feet.
9. Prism divergence break point at 20 feet.
10. Prism divergence re-fuse point at 20 feet.
11. Lateral heterophoria in prism diopters at a testing distance of 13 inches.
12. Prism convergence break point at 13 inches.
13. Prism divergence break point at 13 inches.
14. Prism divergence re-fuse point at 13 inches.

Testing methods

All subjects used were refracted by one of us (R. G. S.). Those under 40 years of age had two examinations—one under homatropine cycloplegia and a second, postcycloplegic check. Subjects over 40 years of age received a manifest refraction. If correcting lenses were needed and desired, these were prescribed and a period of one month was allowed to elapse during which time the subject became adjusted to his correction.

The methods used in measuring the near point of convergence, prism vergence, and heterophoria have already been described in detail previously.[5] Only a brief description of each should be necessary.

The near point of convergence was determined in the usual manner with a millimeter rule, the target being a May-type ophthalmoscope with the head removed and the globe illuminated.

All heterophoria measurements were made with a white Maddox rod placed before the right eye. The rod was attached to a phorometer (American Optical Co.); the movement of its image was produced by means of a Risley rotary prism which was calibrated in units of one prism diopter and had a maximum strength of 30 prism diopters.

Tests of prism vergence were made using the Risley rotary prism on the phorometer, the prism being placed before the right eye. The order of testing was as follows: (a) prism convergence, break and re-fuse point at 20 feet; (b) prism convergence, break and re-fuse point at 13 inches; (c) prism divergence, break and re-fuse point at 20 feet; and (d) prism divergence, break and re-fuse point at 13 inches. All tests for heterophoria were completed before any tests of prism vergence were made. A muscle light rather than a printed target was used in the testing of prism vergence, since the correlation coefficient for measurements made using the different type targets is very close to 1.0.[4]

The spherical equivalent for the correcting lens for each eye was calculated by taking one half of the value of the cylinder and adding it algebraically to that of the sphere.

Age, sex, and refractive error

The chief objective of this study was to examine the relationship between heterophoria, prism vergence, and the near point of convergence, but this cannot be accomplished until the mutual dependence of these functions upon age, sex, and refractive error is known. If, for example, both the prism convergence break point at 20 feet and the lateral heterophoria at 20 feet were found to depend upon age, we should be interested in the correlation between these characteristics only after the effect of varying ages has been removed.

Age vs. heterophoria, near point of convergence, and prism vergence. In the sample of 184 males, with an average age of 33.5 years and an average of 0.8 prism diopters of esophoria at 20 feet, there is not a very marked change in the heterophoria with age. Still, the correlation ($r = +0.17$) is significant in the statistical sense, and implies that the subjects tend to change from slightly exophoric when younger to slightly esophoric when older. This correlation is definitely not enough to permit a satisfactory prediction of a subject's heterophoria from a knowledge of his age alone, since only 3 percent of the variance in heterophoria could be accounted for by so doing.

Among the 217 females, whose average age was 33.8 years and whose average heterophoria at 20 feet was 1.3 prism diopters of esophoria, the relationship appears to be the opposite of that among males. The correlation ($r = -0.20$) implies that younger females tend to be more esophoric and older females less esophoric. Again, the relationship is not sufficient for predicting heterophoria from age alone since only 4 percent of the variance in heterophoria would be accounted for by so doing.

The disagreement between males and females, positive correlation between age and heterophoria in males, negative in females, is difficult to explain. An inspection of the two-way frequency distributions in Figure 1 shows that a few males in the lower age groups were extremely exophoric; whereas, a few females of the same ages were extremely esophoric. No reason for this difference is known at present.

The near point of convergence was 49.0 mm. in males and 45.3 mm. in females, and these averages appear not to change significantly with age ($r = +0.13$ for males, $r = +0.06$ for females).

At a testing distance of 20 feet the prism convergence break point, averaging 18.7 diopters in males and 19.5 diopters in females, tends to decrease with increasing age; this tendency is statistically significant only in males ($r = -0.16$ for males, $r = -0.10$ for females). The prism divergence break point appears not to change significantly in either sex with increasing age ($r = -0.06$ for males, $r = +0.08$ for females).

The amount of manifest heterophoria at a testing distance of 13 inches, which averaged 4.0 prism diopters of exophoria for males and 2.3 for females, tends to increase toward more exophoria with increasing age, although this tendency is statistically significant only in females ($r = -0.12$ for males and $r = -0.19$ for females, where the correlation coefficients have negative signs because exophoria is represented on the negative side of orthophoria). In neither case is the correlation sufficiently intense to predict the amount of heterophoria from a knowledge of the age alone.

At a testing distance of 13 inches, the relationship of the break point of prism convergence to age (or to any other variable) is difficult to assess because of the nature of the frequency distribution of the prism convergence break point. For reasons which are not particularly pertinent at this point, we did not wish to introduce a Risley rotary prism before the subject's left eye when one was already before the right eye; because of this, the maximum convergence recorded was 30 prism diopters and this amount of prism convergence or more occurred in 132 of the 184 males and 164 of the 217 females. An examination of the two-way frequency distribution of the prism convergence break point and age (fig. 2) shows no obvious relationship to either sex.

Changes in age appear not to affect the prism divergence break point at a testing distance of 13 inches ($r = +0.14$ for males, $r = +0.13$ for females).

In general, the relationships of age to heterophoria and prism vergence, which are summarized in Table 1, are relatively slight if present at all. Nevertheless, it seems desirable to adjust for the possible mutual dependence upon age when examining the

relationship between heterophoria and prism vergences.

Sex vs. heterophoria, near point of convergence, and prism vergence. The males and females in this study, in addition to being comparable in age, also appear to be comparable with respect to the near point of convergence (averages: males, 49.0 mm.; females, 45.3 mm.), lateral heterophoria at 20 feet, prism convergence break at 20 feet, and prism divergence break at 13 inches. For prism divergence break at 20 feet, the difference of 0.82 prism diopters (=7.70 −6.88) is significant, having a standard error of ±0.30. Similarly the sexes are different in lateral heterophoria at 13 inches by 1.68 ± 0.54 prism diopters. Because of these differences, we have treated the sexes sepa-

neither the males nor the females is there any systematic association of the amount of refractive error with the amount of heterophoria, the near point of convergence, or with prism vergence at 20 feet or 13 inches.

HETEROPHORIA, PRISM VERGENCE, AND THE NEAR POINT OF CONVERGENCE

Heterophoria and prism vergence. The observed correlation coefficients between lateral heterophoria and the prism convergence break point at a distance of 20 feet

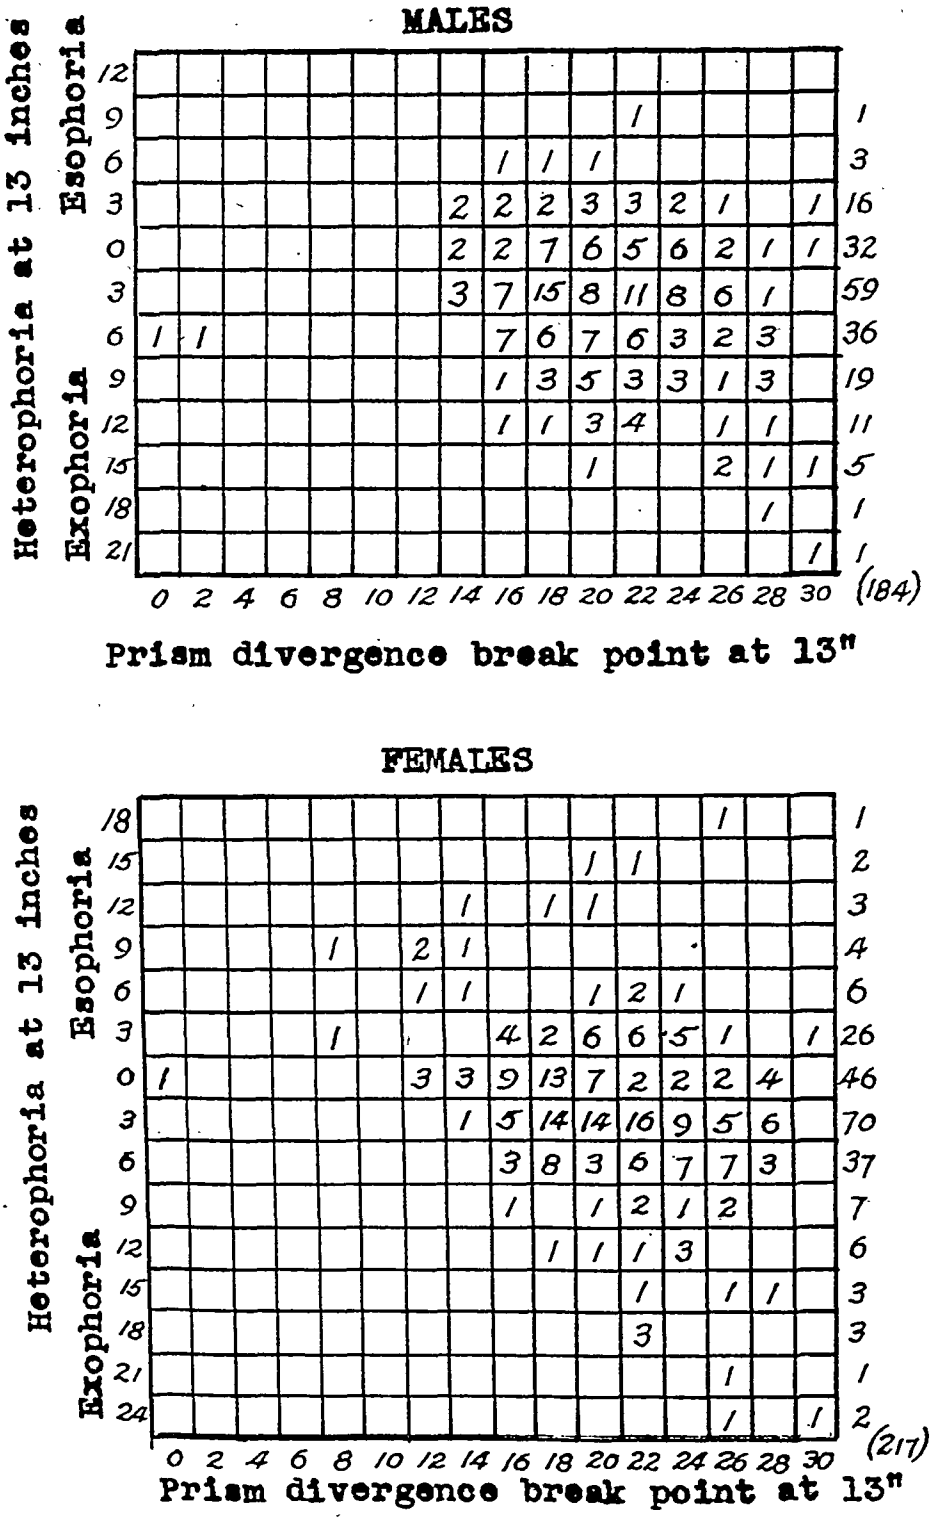

Fig. 3 (Scobee and Green). Relationship of heterophoria at 13 inches to prism divergence break point at 13 inches.

were +0.16 for males and +0.09 for females. When these coefficients are adjusted by removing the common effect of age, the partial correlation coefficients are +0.19 for males and +0.07 for females. The adjustments for age are in opposite directions because the relationships between heterophoria and age are different in the two sexes. The

partial coefficient is statistically significant for males but not for females. The adjusted coefficients for the relationship between heterophoria and the prism divergence break point at 20 feet are about on the border line of significance ($r_a = -0.13$ for males, $r_a = -0.17$ for females), suggesting that greater

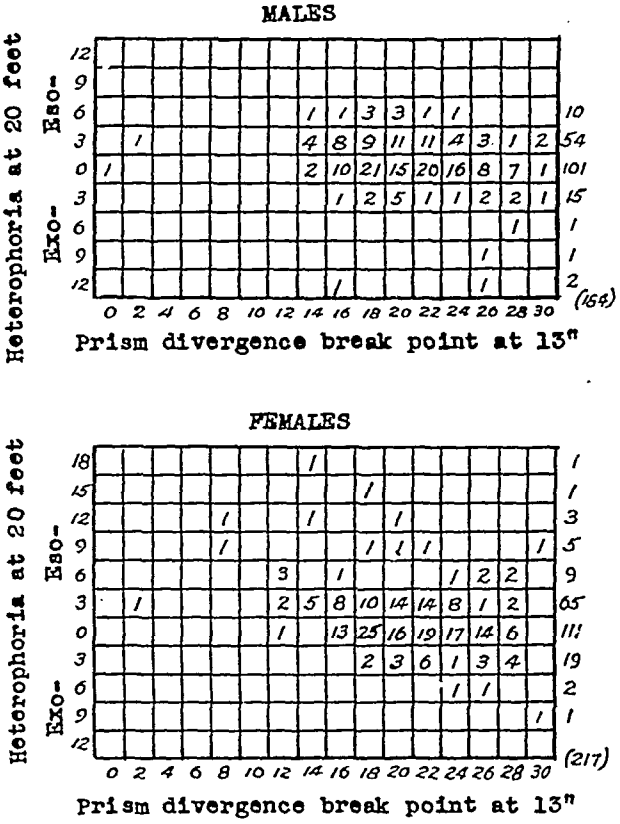

Fig. 4 (Scobee and Green). Relationship of heterophoria at 20 feet to prism divergence break point at 13 inches.

amounts of esophoria accompany lower amounts of prism divergence.

These correlations between lateral heterophoria and prism vergences at 20 feet are so weak as to prevent a satisfactory substitution of a heterophoria measurement for a prism vergence measurement. It appears that the two measurements, although correlated, are largely measures of different ocular functions.

On the other hand, the prism convergence break point does not correlate significantly with the point of prism divergence break at 20 feet ($r = +0.09$ for males, $r = +0.01$ for females).

At a testing distance of 13 inches, the amount of manifest lateral heterophoria is significantly correlated with the prism divergence break point even after removing the common effect of age on each function ($r = -0.18$ for males, and $r = -0.31$ for females). These coefficients imply that greater amounts of exophoria tend to accompany greater amounts of prism divergence and that greater amounts of esophoria tend to accompany lower amounts of prism divergence *at 13 inches*. This is shown in Figure 3.

A comparison of prism divergence at 13 inches with heterophoria at 20 feet shows that these two functions are related. The coefficients of correlation adjusted for age were -0.23 for males and -0.31 for females. The implication here is that greater amounts of exophoria at 20 feet tend to accompany greater amounts of prism divergence at 13 inches and that greater amounts of esophoria at 20 feet tend to accompany smaller amounts of prism divergence at 13 inches (fig. 4). This is another way of saying that if a patient is known to have a large amount of exophoria at 20 feet, one would expect a large amount of prism divergence at 13 inches; similarly, if a large amount of prism divergence at 13 inches is found, one expects to find a fairly marked exophoria at 20 feet.

Patients with much esophoria at 20 feet, on the other hand, usually have only small amounts of prism divergence at 13 inches; hence, a patient with poor prism divergence at 13 inches would, on the average, be expected to show fairly marked esophoria at 20 feet.

Patients with much esophoria at 20 feet, on the other hand, usually have only small amounts of prism divergence at 13 inches; hence, a patient with poor prism divergence at 13 inches would, on the average, be expected to show fairly marked esophoria at 20 feet.

The relationship is not strong enough to allow one measurement to be substituted

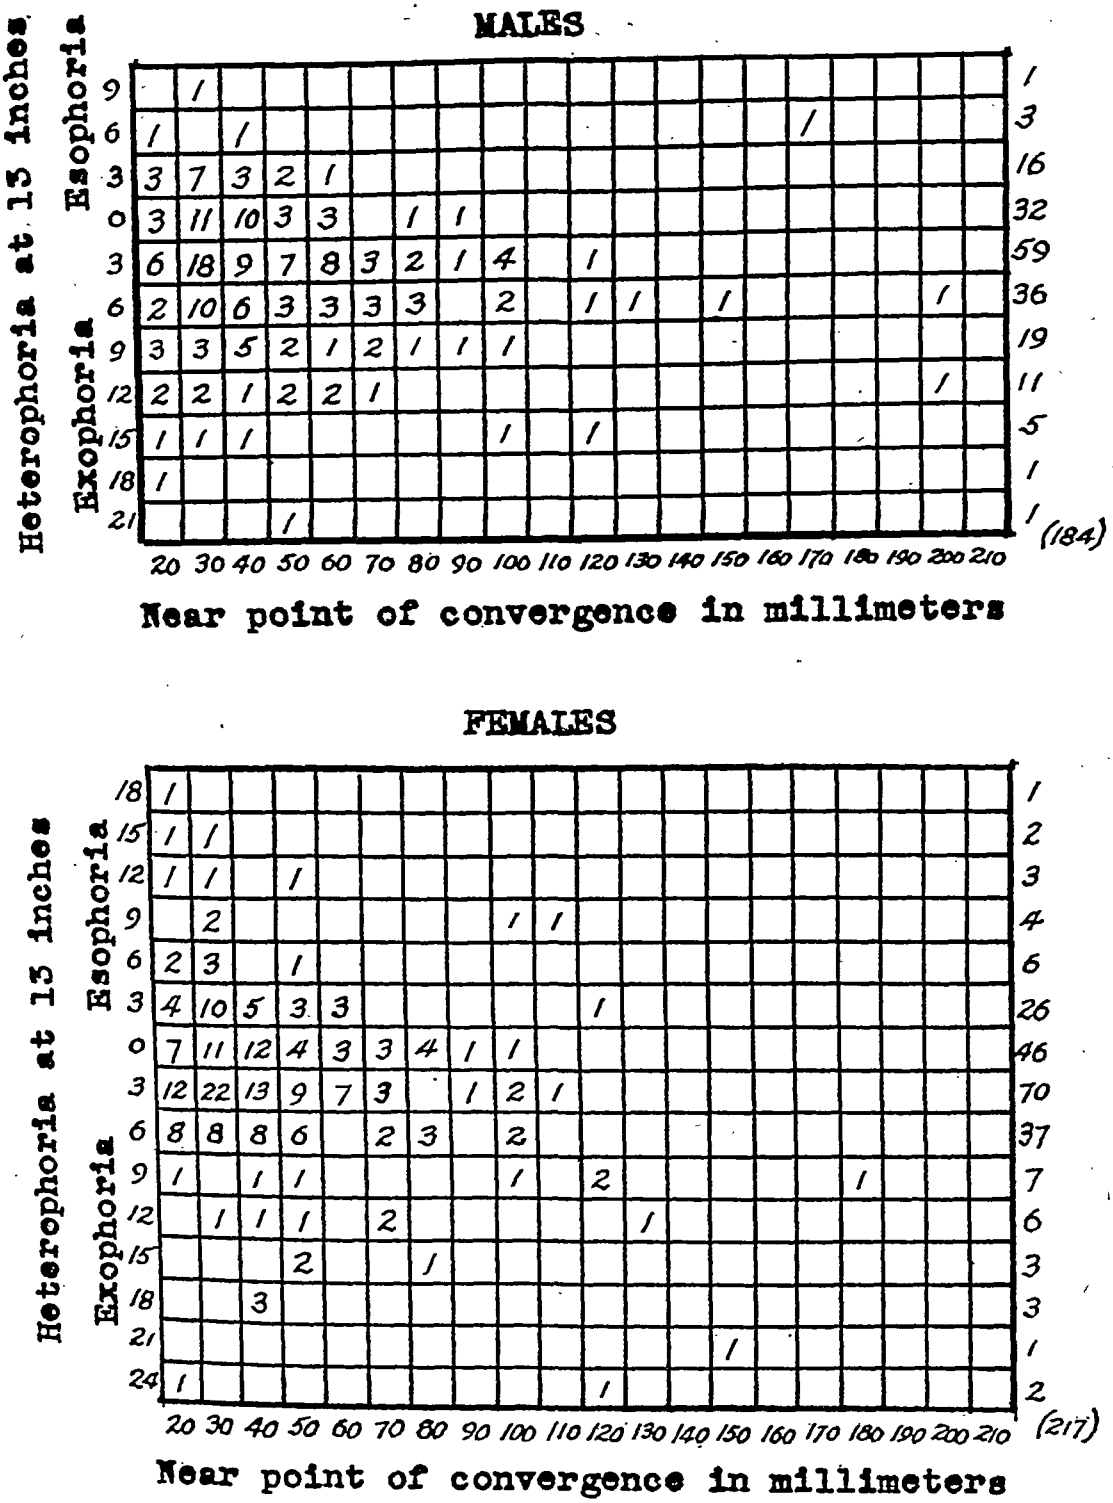

Fig. 5 (Scobee and Green). Relationship of near point of convergence to lateral heterophoria at 13 inches.

for the other, but is strong enough to enable the examiner who knows one measurement to make a guess at the other and not be too far wrong. It has been observed clinically that even large amounts of esophoria in patients with good prism divergence at 13 inches seem to be associated with no symptoms whatever; on the other hand, the patient with much esophoria and poor prism divergence at 13 inches will in all probability have many symptoms which will not be corrected by refraction alone. On clinical

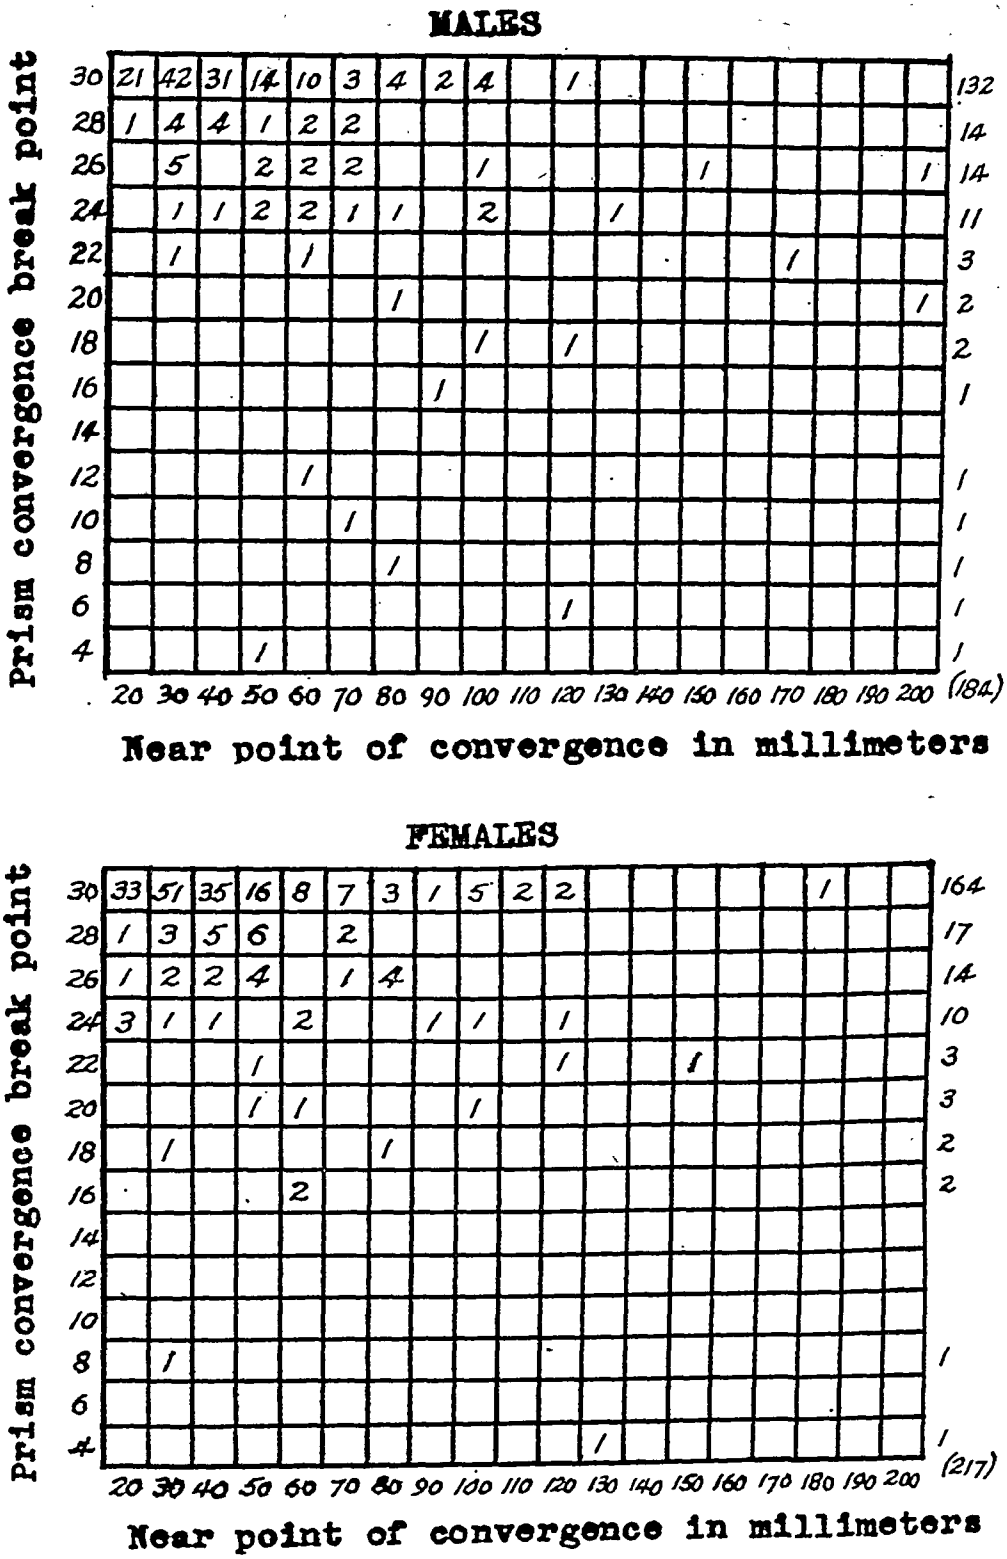

Fig. 6 (Scobee and Green). Relationship of near point of convergence with convergence break point at 13 inches.

grounds, it would seem that a knowledge of the prism divergence at 13 inches enables one to evaluate properly any esophoria which may be present.

Heterophoria and the near point of convergence. The near point of convergence is not correlated with the amount of manifest lateral heterophoria when the testing dis-

tance is 20 feet ($r = 0.00$ for males, $r = -0.08$ for females) but it is correlated with heterophoria tested at 13 inches with the effect of age removed ($r_a = -0.14$ for males, $r_a = -0.24$ for females). The relationship is such that greater amounts of exophoria tend to accompany greater measurements for the near point of convergence (fig. 5).

While it appears that a measurement of heterophoria at 13 inches and a measurement of the near point of convergence are to a slight extent measurements of the same ocular function, the similarity is not sufficient to justify an assertion that the two measurements are equivalent. It is quite obvious that the two measurements are measurements of largely different functions.

Prism vergences and the near point of convergence. As might be anticipated, the near point of convergence is correlated with the prism convergence break point (at least at the 20-foot testing distance and possibly also at the 13-inch distance, as shown in Figure 6), but it is not correlated with the prism divergence break point either at 20 feet or at 13 inches (table 1).

Discussion

The statement has been made that the data in this study show no significant relationship between age and heterophoria, prism vergence, and the near point of convergence. It is well known that some ocular functions, such as accommodation, change more or less systematically with age. It has been suspected that heterophoria also changes with age in the direction of exophoria. To discover whether or not such a change does occur, it would be desirable to study a group of subjects over a protracted period of time such as 20 or more years. No study of this sort has been made. For the time being, therefore, it is necessary to base a judgment about the effect of age on heterophoria on a sample of men and women of all ages. In our present sample, there is not sufficient relationship between age and heterophoria or vergence or the near point of convergence to enable one to predict the amount of change in the muscle balance of a patient from a knowledge of his age alone. Obviously a sample of this sort does not permit conclusions about changes in muscle balance in given individuals with changing age. Such a sample does allow the conclusion that there are no systematic changes with age affecting the population as a whole. If there are significant changes in muscle balance related to age, then these changes must be in different directions from individual to individual. This means, for example, that if the entire population had one prism diopter of esophoria at 20 feet at the age of 20, then at the age of 65, some might have 8 prism diopters of esophoria while others might have 7 prism diopters of exophoria; in other words, the change, if it occurs, is highly variable from one individual to the next. Certainly the *entire* population does not shift in the direction of exophoria with advancing years, as many have been led to suspect on the basis of observations on a few cases.

The near point of convergence is only slightly related to lateral heterophoria at 13 inches and to the prism convergence break point at 20 feet. The relationship is just barely of statistical significance and certainly is not strong enough to permit any clinical application.

There is a definite but not strong relationship between lateral heterophoria at 20 feet and the prism divergence break point at 13 inches. The relationship from the statistical standpoint is a weak although definite one. The addition of clinical observations, however, permits a clinical application of this relationship but only with certain limits. As was pointed out in the body of the paper, a knowledge of the prism divergence at 13 inches is a valuable adjunct to the proper evaluation of any esophoria present at either 20 feet or at 13 inches. Esophoria in the presence of good prism

divergence at 13 inches is not believed to be clinically important. Esophoria in a patient with poor prism divergence at 13 inches is often associated with severe symptoms which are not relieved, on the average, by correction of the refractive error, or even by orthoptics. It has been our clinical experience that patients with less than 12 diopters of prism divergence at 13 inches may be considered as having poor prism divergence and will usually have many asthenopic symptoms which are difficult or impossible to relieve by any known method of therapy at this time.

The question of the selection of an adequate battery of tests of muscle balance is and always has been a problem of particular interest to the armed forces. Tests which are highly correlated with each other are supposed to be measuring the same function and so may be substituted one for another. This means, for example, that if lateral heterophoria at 20 feet and prism convergence at 20 feet had a correlation coefficient of 1.0 or very close to it, both tests would, in all probability, be measuring the same function; that a knowledge of the results of one test would enable us to predict the results of the other; and that only one of the two tests need be included in any battery of tests for muscle balance.

On the other hand, tests that are not correlated at all are supposed to be measuring entirely different functions. If the correlation coefficient between two tests is 0.00, then we may reason that the tests are testing entirely different things and must be included in any battery of tests for muscle balance. This is the statistical approach to the comparison of various tests.

The primary difficulty in selecting a battery of tests for muscle balance is the fact that with the notable exception of the cover test, they are all almost entirely subjective. This means that they are all subject to different degrees of individual variation. A starting point would, therefore, be the comparison of various tests of heterophoria with the cover test and this has been done.[5] It is admittedly difficult to train inexperienced examiners in the proper performance and interpretation of the cover test. The armed forces have, therefore, selected the Maddox-rod test for heterophoria and it compares favorably with the cover test, at least at the 20-foot testing distance. At the 13-inch testing distance, either the Maddox-wing or the Thorington test are preferable from the standpoint of correlation with the cover test. So far, the armed forces have been content to omit any test of heterophoria at near and so the choice of a near test for heterophoria presents no problem at the present time.

The near point of convergence has been included in the battery of tests of muscle balance by the armed forces for a long time, although they appear to be about ready to drop it and apparently with good reason. It has a definite, although very slight, relationship to prism convergence at 20 feet and to lateral heterophoria at 13 inches. There are two convergence centers in the brain, one voluntary and the other involuntary. If involuntary convergence is lacking, voluntary convergence can be taught to the large majority of subjects in a very short time.[4] The near point of convergence is therefore a "trick" of crossing the eyes which can be learned in a short time; after it has been learned, the near point of convergence measurement is greatly improved although it seems obvious that there has been no improvement in the same individual's ability to perform close work over long periods of time. There are other and more reliable tests available which yield much of the desired information and hence the near point of convergence test can probably be eliminated from the test battery for muscle balance without impairing the efficacy of the battery significantly.

Like the near point of convergence, prism convergence can also be learned and is therefore so variable that there seems to be no

point in including it in the test battery at either 20 feet or 13 inches. It is not included at the present time.

Prism divergence, on the other hand, cannot be learned. No adequate demonstration of any divergence center has ever been made and prism divergence at the 13-inch distance to include prism divergence at 13 inches in any battery of tests of muscle balance. There seems to be no good reason to include prism divergence at 20 feet in such a battery.

Any decision about heterophoria tests at 13 inches is a difficult one in the light of our present knowledge. Certainly every ophthal-

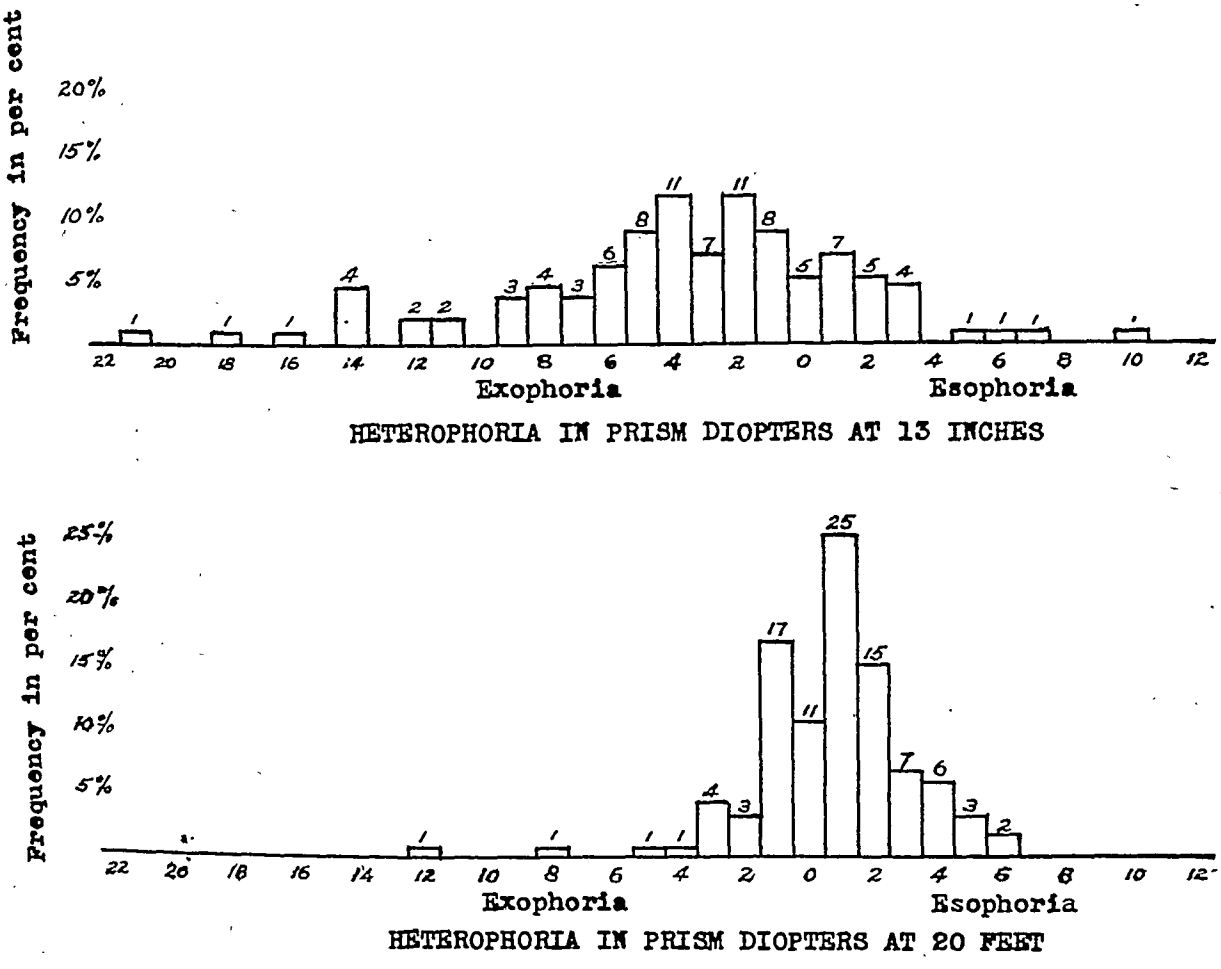

Fig. 7 (Scobee and Green). Distribution of lateral heterophoria for males 18 to 35 years of age inclusive.

appears to be a fairly reliable index of the ability of an individual to relax and give up convergence at the reading distance.[1, 5] It bears a definite, although slight relationship to heterophoria at both 20 feet and at 13 inches. Although the statistical evidence for its inclusion in any battery of tests for muscle balance is not impressive, the clinical evidence favoring its inclusion is much stronger. It would therefore seem advisable

mologist who tests muscle balance at all makes some determination of heterophoria at both 20 feet and at 13 inches. The mere fact of usage for a century or more is no evidence for inclusion in a test battery. Long usage would only indicate the weight of clinical experience seeming to favor the test. Imus[3] said that ". . . there is a small but definite relationship between the measures of near lateral phoria obtained by the

clinical method and the compensatory innervations measured at the same distance." This is substantially in agreement with our findings. Until more and better factual evidence is at hand, we are inclined to believe that a test of near heterophoria should be included in any battery of tests for muscle balance on the basis of clinical experience alone.

Selection of tests and test limits

The question arises as to what ocular functions shall be tested and what limits shall be established for "normal" ocular measurements. While such a question is of far more interest to the armed forces, since they desire to test large groups of individuals

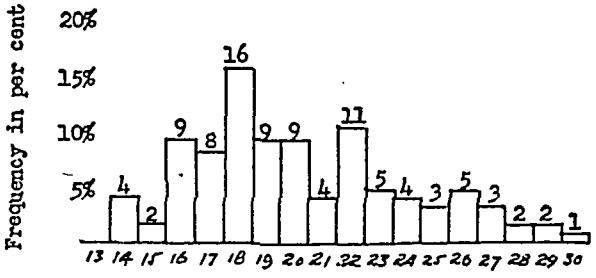

Fig. 8 (Scobee and Green). Distribution of prism divergence break point for males 18 to 35 years of age inclusive.

in certain age groups to be trained for specific tasks in time of war, than to the practicing ophthalmologist, nevertheless the question is of academic interest to all.

With the multitude of relatively unskilled examiners who must be called upon in time of war to test thousands of candidates, the armed forces are vitally interested in (a) the simplest examination which will yield reasonably reliable and significant results, and (b) a set of limits for the various tests employed which will adequately divide the "normals" from those who are likely to be unable to complete their training. Answers to these problems may be determined (1) by policy, or (2) by evidence.

Evidence would consist of data showing the various degrees of attainment in the performance of the task relative to the various readings for the test. Evidence of this sort is usually not available and can be obtained only by special studies. It is, therefore, frequently necessary to resort to a policy decision. When such a decision is made, it is desirable to know the proportion of individuals that will be classified as acceptable or not acceptable for various sets of limits.

For lateral heterophoria both at 20 feet and at 13 inches, Figure 7 shows the frequency distribution of an unselected sample of males in the age range of from 18 to 35 years inclusive. From this distribution it may be estimated that the acceptance limits of 4 prism diopters of exophoria to 4 prism diopters of esophoria at 20 feet will include about 92 percent of the population. If the limit for esophoria at 20 feet is increased to 5 prism diopters, then 95 percent of the population would be included.

With respect to lateral heterophoria at 13 inches, it may be seen that limits of 10 prism diopters of exophoria and 4 prism diopters of esophoria will include 85 percent of the population. In order to include 95 percent of the population, the limit on exophoria would have to be increased to 18 prism diopters, a figure which, by all clinical evidence, is known to be far too large for the comfortable binocular performance of sustained close work. On the basis of clinical evidence, 10 prism diopters of exophoria at 13 inches is a far more acceptable limit to be considered "normal."

Figure 8 shows the distribution for prism divergence at 13 inches of an unselected sample of males in the age range of from 18 to 35 years inclusive. From this distribution, it may be estimated that acceptance limits of not more than 27 prism diopters of divergence and not less than 14 prism diopters would include 95 percent of the population.

DISCOLORATION OF THE EYELIDS FROM PROLONGED USE OF OINTMENTS CONTAINING MERCURY*

MAYNARD WHEELER, M.D.
New York

Just a year ago, a 39-year-old woman came to my office with an unusual and rather striking discoloration of her eyelids. She had come for a routine examination but when questioned, she admitted that the discoloration was a source of considerable embarrassment to her; it had come on gradually over the last 10 years.

My first impression was that she had been using eye-shadow on her lower lids. There was a dirty gray color of the skin of both lower lids and of the lower 15 mm. of the upper lids; this latter was not apparent until she closed her eyes. The slitlamp showed a homogeneous gray cast to the skin; the pigmentation extended onto the lid margins as granules more brownish than gray. The bulbar conjunctivas, corneas, and lenses were normal. The color was very similar to that produced in argyrosis but the distribution was unusual, and there was no history of any silver preparations being used. Careful questioning finally brought out that because of granulated lids she had started rubbing yellow mercuric oxide on her lids every night and had continued it for about 23 years.

* Read at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947. From the Institute of Ophthalmology of the Presbyterian Hospital, New York.

REPORTS IN LITERATURE

A search of the literature gave nothing about such discoloration of the eyes from yellow oxide. In 1922, however, Goeckermann[1] described a woman whose eyelids, nasolabial folds, and chin were a brownish gray or slate color. It was attributed to a face cream containing bismuth and mercury. His second patient showing similar but less marked pigmentation, had used a cream containing only mild mercurous chloride. He pointed out that mercury in contact with alkaline secretions yields a blackish pigment of mercury oxide. This reaction was reversible by a dilute acid. Both of his patients improved on using a 2-percent acetic acid and did still better on a 1-percent aqueous solution of potassium cyanide, but both chemicals irritated the skin. Since mercury was freely used in creams, he concluded that the skins of his two patients were peculiar. He was able to demonstrate that the secretions of one were alkaline. The same author reported 13 more cases in 1925.[2] All were typical. A biopsy showed pigment granules in all layers of the skin and subcutis. He was not able to demonstrate mercury chemically but the granules were removed entirely by a compound solution of iodine.

The only other dermatologic report found was by Hollander and Baer, in 1929.[3] They

described a woman whose entire face was a dirty grayish black. She had used a face cream daily for 15 years. Mercury was demonstrated in the skin by an electromicroqualitative method. They rubbed the skin briskly with tincture of iodine to form soluble mercuric iodide, then alcohol to dissolve the new compound. Her skin improved but she did not complete the treatment.

I was unable to get a biopsy in my case, but the history was so definite that there seemed to be no doubt as to the relationship between the discoloration and the yellow oxide. As the treatments just described were considered too drastic for the eyelids, no treatment was attempted. The mercury was stopped and plain vaseline was suggested in its place. Six months later there was definite fading and the patient volunteered that people no longer commented about her lids. Eleven months after the mercury was discontinued, the patient is happy about her condition but the gray color, while fainter, is still fairly definite.

In the November, 1946, number of the *British Journal of Ophthalmology*, Abramowicz[4] gave the first report that I have been able to find of a case very similar to the one that I have described. The patient was a woman, aged 57 years, who had used white precipitate ointment of 6.66 percent nearly every night from the age of 16 years, that is, for 41 years, for blepharitis. The skin of her eyelids was bluish gray. Dark pigment granules were found in the bulbar conjunctiva, especially near the cornea, with preferential distribution around the perivascular lymph vessels. In the periphery of the cornea, in the region of Descemet's membrane, a discoloration varying from greenish gray to a bluish gray was seen. A yellowish-brown, lusterless opacity occupied the pupillary area of the lens.

I will return to the discussion of this case after describing very briefly four patients I have seen subsequently. This report by Abramowicz confirmed my belief that mercury had been responsible for the discoloration and increased my interest in the condition. I feel certain that without my first case, I would have missed the later ones, because the pigmentation, while definite, was subtle.

Reports of similar cases

My second patient was a druggist, aged about 55 years, who complained that his eyes were always irritated and tearing and that the lids were purple. He had used 1-percent yellow oxide for at least 10 years. There was a faint gray, slightly greasy appearance of his lids, most marked at the upper borders of the upper tarsi.

The third case was a woman, aged about 30 years. She had had many styes and had massaged her lids nightly with 2-percent yellow oxide for four years. There was faint but definite discoloration of her lower lids.

The fourth case was a woman, aged 40 years. She had used various ointments since she had trachoma 22 years previously. She was certain that yellow oxide had been one of them, but for the last four years she had been using 3-percent ammoniated mercury. There was a slight gray cast to the skin of the lower lids and the upper lid margins looked faintly blue.

None of these three persons had complained of the discoloration, nor were they actually aware of it. Yet, in each instance, it was definite enough for me to suspect mercury and to elicit the histories that have been given. While not a definite cosmetic blemish, the color was certainly unpleasant and might eventually have become embarrassingly conspicuous.

I am indebted to Dr. DeVoe for the fifth and last patient, a 67-year-old man. He is the only one who consulted an oculist because of the pigmentation of his lids. They had become red and inflamed so he had massaged them almost every night for 20 years with yellow oxide. The typical dirty gray

color involved both lower lids and the lower one centimeter of the upper lids.

Discussion

These five cases, although varying in degree of pigmentation, showed essentially the same picture. Only in the first and most marked instance was the pigmentation of the lid margins definite. None showed any pigmentation of the conjunctiva that could be attributed to mercury. There were no changes in the corneas or lenses. The much more extensive involvement in the case of Abramowicz should be easily explained because a much stronger percentage of mercury was used for a considerably longer period.

Many of the members of this society will remember the excellent report given by Atkinson[5] five years ago, in which he described for the first time a brownish reflex of the anterior lens capsule in people who had worked for long periods with mercury. This was thought to be produced by mercury vapor. That Abramowicz found the same change in the lens, from external application, is of particular interest. In four of Atkinson's cases with chronic mercurialism, the skin of the face presented a gray appearance.

Use of mercuric ointments

Yellow mercuric oxide first appeared in the English ophthalmic literature in 1866, when Pagenstecher[6] described its use for phlyctenular conjunctivitis and corneitis. It had been listed in the German pharmacopeia for 10 years previously and had gained "many ardent supporters" in that country. Since that first article, there has been scarcely any mention of it in periodicals, yet its use spread rapidly as shown by a review of textbooks. It soon became the most widely used ophthalmic ointment and has held this lead up to the present even though it is prescribed much less frequently by ophthalmologists today.[7] This decline in popularity with oculists is undoubtedly due to an appreciation of its relative ineffectiveness and the influx of new ointments such as the sulfonamides and penicillin.

Although no figures are available on the total annual consumption of yellow mercuric oxide in this country, the best evidence indicates that the amount is immense, possibly in the neighborhood of 100,000 ounces. This is largely due to the efforts of the druggists of the country, who prescribe and dispense the drug with great freedom for a wide variety of eye complaints.

Ammoniated mercury ointment apparently antedated yellow oxide in ophthalmic use. The earliest reference that I have been able to find was in the French *Annales d'oculistique*[8] for 1856, when it was called white precipitate. It has enjoyed continued popularity since that time but has never approached yellow oxide in the amount used. This is hard to understand because, for a long time, it has been generally known that the ammoniated mercury is equally or more effective therapeutically and much less irritating. In fact the great and lasting popularity of yellow oxide is a mystery that I have been unable to solve.

The wide use of mercury in ophthalmic ointments over the last 80 or 90 years has been discussed to emphasize how remarkable it is that this picture of discoloration of the eyelids has not been described before. I am convinced that we have all been seeing mild forms of it for many years. Evidence of this is the fact that, once I was aware of it, I found four more instances in 10 months.

Two other points present themselves for speculation. One is the question of individual susceptibility. This undoubtedly is a factor but it will be established with difficulty because of the very gradual onset and the lack of figures on the actual use of the drug. The other question is that of prescribing other mercury preparations, such as oxycyanide of mercury as eye drops. This experience has made me cautious about ordering them for indefinite use.

Conclusion

Five cases have been presented which show a characteristic dirty gray discoloration of the skin of the eyelids. These cases have one point in common; namely, daily use of an ophthalmic ointment containing mercury (yellow oxide or ammoniated) over a prolonged period, four years being the shortest. There appears to be a direct etiologic relationship between the mercury and the pigmentation. While no treatment is suggested, the color fades slowly on discontinuing the ointment.

Historical Miniature

Hemianopsia. Although the Hippokratic writers neither knew nor measured the extent of the visual field as the later Greeks did, the phenomenon of half vision associated with cerebral disease did not escape their notice. In the *Second Book on Diseases,* it is noted that, in a patient with a disease of the head associated with somnolence and frequent urination, the headache ceased after 20 days. "And when he looked at something the vision escaped him and he was aware of seeing only one half of persons."

THE USE OF BUCCAL MUCOSA IN THE RESTORATION OF THE ORBITAL SOCKET*

JAMES N. GREEAR, JR., M.D.
Washington, D.C.

INTRODUCTION

Restoration of the orbital socket to permit the wearing of a prosthesis is a necessary and important procedure in ophthalmic surgery. Although it is true that complete obliteration of the socket is relatively rare, partial obliteration is frequent, and only slight degrees of contraction may prevent the socket from accommodating a prosthesis. The lower cul-de-sac appears to be far more vulnerable to injury than the base of the socket or the upper cul-de-sac; therefore, it is most often deformities of this part that must be repaired. This unequal distribution of the effects of injury is emphasized by Maxwell,[1] whose ingenious operation was devised primarily to restore the lower cul-de-sac.

The recent war contributed to the problem. Many soldiers with contracted sockets could be counted among the 1,200 who were totally blinded and the thousands who lost one eye from battle wounds or training accidents. In addition to these, there was a fairly large group of inductees with only one eye, a number of whom had deformities which had prevented them from wearing a prosthesis.

The majority of these patients with contracted sockets received definitive treatment at the eye centers established throughout the United States by the Office of The Surgeon General. One of the largest of these was at Valley Forge General Hospital where I was stationed during a considerable period of the war. Here my associates and I had an unusual opportunity to apply the reconstructive procedures advocated for alleviation of contracted sockets. Even the totally blind soldiers were insistent that partially or completely obliterated sockets be restored in order that they might wear artificial eyes. They were not only willing but anxious to undergo any operative procedures that would result in giving them a normal outward appearance, even though their sight was gone. The technique which we found most satisfactory included the employment of grafts of buccal mucosa.

EARLY ATTEMPTS AT RESTORATION OF SOCKET

Earlier attempts at restoration of the orbital socket were by means of pedicle skin grafts or free skin grafts, and the surgeons who first advocated these methods made use of the full thickness of the skin. We are indebted to Reverdin,[2] Ollier,[3] Thiersch,[4] and Wolfe,[5] all more or less contemporaries, for demonstrating that pedunculated skin flaps are not essential to the vitality of the graft. Wolfe[6] conclusively demonstrated that ". . . the cause of non-success in transplantation was the areolar tissue underneath, and that, if we could transplant a skin flap free of that subjacent tissue, we should secure its adhesion and incorporation." Full thickness skin grafts were employed by Weeks,[7] Morax,[8] and others. Verhoeff[9] recommended the use of a Thiersch graft employed in a manner similar to that later advocated by Wheeler,[10] who utilized epidermic grafts. Wheeler objected to the use of the name Thiersch in connection with the epidermic graft, for the graft which Thiersch employed was dermo-epidermic. Wheeler, however, was not the first to use the epidermic graft; he had been preceded by Esser[11] who had employed it in the form of an "epithelial inlay" as a means of enlarging the orbital socket. Wheeler laid emphasis on the point that the ideal graft for

*Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947; and the New England Ophthalmological Society, Boston, Massachusetts, December, 1947.

relining the socket was epidermis only, free from layers of true skin. While this technique was eminently successful in Wheeler's hands, one is impressed by the large number who failed to attain the desired results using the operative measures he advocated. In consequence, there are few ophthalmic surgeons who observe the technique outlined by Wheeler either in dissection of the socket or in cutting the graft.

Heterogeneous transplantations

In 1872, J. R. Wolfe of Glasgow first transplanted conjunctiva from the rabbit to the human eye for the successful cure of symblepharon. This operation was soon adopted by surgeons of various countries. In a subsequent report in 1883, Wolfe[6] stated that Noyes of New York had been the first American surgeon to apply this operation to reconstruct the sac so that the patient might wear an artificial eye, when the natural cavity had become contracted. Cohn of Breslau, however, had previously made use of the procedure to achieve a similiar result.

In connection with the Wolfe operation, the following statement appeared in the *British Medical Journal* of August 20, 1888: "In showing the patient, Doctor Wolfe commented on the fact that it was nearly 15 years since he introduced this operation, and in spite of the fact that the rabbit's conjunctiva gave perfect results, efforts to transplant mucous membrane from the human subject, from the mouth and even the vagina, were being made."

Early use of mucous membrane

Van Millingen[12] must be given credit for the first operative procedure which included transplanting a strip of mucous membrane from the inner surface of the lower lip to the margin and under surface of the upper lid for the cure of trichiasis. He first described his operation in an article, in 1880, reporting the result he had obtained during the preceding three years. After several experiments, including grafting with mucous membrane from the mouth of the rabbit to replace conjunctiva, he gave preference to mucous membrane from the patient's lip. Hugo Wolff[13] of Berlin reported, in 1905, that in his operation for symblepharon he was using mucous membrane from the patient's mouth for grafting in order to form a lasting conjunctival fold.

Denig[14] began to experiment with grafts of mucous membrane from the mouth in cases of trachomatous pannus, in 1910. The favorable results obtained induced him to use it as a curative measure following chemical burns of the cornea and limbus, and he later applied it to other corneal conditions. His report was based on the results of such grafts in 150 patients.

Influence of World War I

The influence of World War I is reflected in the publications on ophthalmic surgery during the following decade. Because of the great increase in deforming injuries to the orbital structures, interest in reconstructive surgery was stimulated, just as it has been during the recent war. In 1918, in discussing Henderson's[15] paper on suture operations for contracted socket, Story referred to the procedure that he himself employed. In the case of moderately contracted sockets, where operation was possible, he transplanted mucous membrane instead of skin, and found it to be fairly successful. The next year Greene, in his discussion of Cruise's[16] paper on an operation for contracted sockets, expressed the logical conclusion that since there was mucous membrane lining in the socket it was well to follow it up with more mucous membrane. He had obtained good results by taking a large flap of mucous membrane from the inside of the mouth to replace the lost conjunctiva and inserted a glass ball to maintain contact between the graft and the underlying tissues.

Further reports in literature

In 1920, Majewski[17] called attention to the

fact that either buccal or vaginal mucosa could be utilized in the repair of contracted sockets. In an article on the subject, written about the same time, Benoit[18] mentioned that Gallemarts used vaginal mucous membrane, while Ssapiejko preferred mucous membrane taken from the lips. He also called attention to the unsatisfactory results of heteroplastic grafts.

Karelus,[19] in 1924, distinguished three classes of surgical procedures for reconstruction of the orbit after total obliteration. The first of these included the different methods of covering the prepared orbit with mucous membrane. He stated that heteroplastic grafts, the rabbit's conjunctiva, for example, must be abandoned, and trial be made of transplanting human mucous membrane from the buccal or the vaginal mucosa. To the best of his knowledge Stellwag (1889) had been the first to describe this procedure.

Gillies and Kilner,[20] in discussing the treatment of symblepharon, in 1929, reported one case in which the cornea had not been damaged. Mucous membrane from the inner surface of the lower lip was employed, and the graft was applied in a manner precisely similar to the Thiersch grafts in earlier cases. They were of the opinion that this form of grafting had many advantages to recommend it, and that it would, in selected cases, entirely supersede the Thiersch graft. In a later discussion Kilner[21] stated that the difficulty in these cases was to insure proper pressure dressing of the grafts.

Clay and Baird[22] (1936) recommended mucous membrane from the prepuce and labia minora as an ideal substitute for conjunctival tissue. They found that not only was there enough tissue available for complete restoration of the socket, but also it had none of the objectionable features of ordinary skin grafts. They pointed out that skin grafts "are most unsatisfactory to the patient in that they are uncomfortable and unsightly, desquamation is always present, and there is most frequently a disagreeable odor."

Hughes[23] offered two objections to the use of mucous membrane from other parts of the body as a substitute for conjunctiva; the first being that the secretion was thick and copious, and the second, that it was difficult to obtain a sufficiently large area of mucous membrane.

Spaeth,[24] in discussing the use of mucous membrane in ophthalmic surgery, made the following statement: "There is but one defect for which these grafts may be used; namely, for the correction of a conjunctival defect, and that in the presence of an intact and healthy eyeball." He pointed out that one need allow for little if any shrinkage in the mucous membrane graft.

Whalman[25] advocated a wider usefulness for these grafts, stating, "Whenever it becomes necessary to supplement or supplant conjunctival tissue for any reason whatever, nothing serves better than a graft of mucous membrane from the mouth. . . . Skin exfoliates, becomes rough and irritating—mucous membrane remains smooth and soft."

DeVoe[26] described the technique he had developed to restore the lower cul-de-sac by means of buccal mucosa. He stated that sockets lined with these mucous membranes had been found to be most satisfactory; furthermore, they were free from objectionable odor and discharge. He considered it impossible to procure enough mucous membrane to line a socket completely, but recognized that a socket lined partially with mucous membrane and partially with skin was extremely annoying to the patient, because the discharge was profuse and ill smelling.

Marcks and Zugsmith[27] recommended the inside of the lower lip as an ideal donor area for mucous membrane for restoration of the lower cul-de-sac. They could see no contraindication to combining skin and mucous membrane.

Stallard,[28] on the other hand, concurred with the widely held opinion that combinations of mucosal and epidermal grafts in the same socket are unsatisfactory. He regarded mucosa from cheeks or lower lip as the best material for orbital grafts, but he stated that when areas larger than 1.5 cm. had to be covered epidermis was the only possible material.

Fox[29] stated that the ideal lining for a socket was mucous membrane and that the buccal membrane could be used if large grafts were needed. Mackenzie[30] also agreed that the ideal graft for lining the orbit was mucous membrane. According to him, the choice of donor sites varied depending on the sex of the patient. In the male he listed donor sites in the following order of preference: (1) Mucous membrane of the mouth; (2) mucous membrane of the prepuce; (3) Rectal mucosa; and (4) nasal mucosa.

He considered the order of preference for donor sites in the female to be: (1) Vaginal mucous membrane; (2) oral mucous membrane; (3) rectal mucosa; and (4) nasal mucosa.

Surgical treatment of contracted socket

Since sufficient mucous membrane, even for essentially complete restoration of a socket, is available from the mouth alone, to take mucous membrane from areas so much less accessible would seem to me to be unnecessary and might even subject the patient to possible untoward sequelae.

Like most ophthalmic surgeons, I had limited the use of grafts of mucous membrane to the cure of symblepharon, but had not explored its possibilities in more extensive procedures. Confronted by the great number of patients with contracted sockets at Valley Forge, I became aware that a dependable method of reducing this deformity was imperative. The disappointing consequences of skin transplants for partial restoration of the socket prompted me to utilize buccal mucosa, which most nearly resembles the lost conjunctiva, and which had been used with success by ophthalmic surgeons during World War I. The procedure found to be most effective in the surgical treatment of contracted socket was carried out in the following manner.

Preoperative procedure

Preliminary to operation it is necessary to eliminate all pus-producing areas in the region of the socket, allowing sufficient time to insure an operative field free from infection and well healed. It is equally important that the mouth from which the graft is taken be healthy; such conditions as pyorrhea affect the vitality of the transplanted tissue.

Operative procedure

The operation can be carried out under either local or general anesthesia. If there is a considerable loss of conjunctiva, intratracheal anesthesia is desirable. With the patient anesthetized, the entire face is prepared with soap and water, followed by tincture of zephiran. A packing of gauze, squeezed out of an aqueous (1:5,000) solution of zephiran, is placed in the mouth, where it remains while the dissection of the socket is carried out.

The technique as described by Wheeler[10] is closely adhered to in preparing the bed to receive the graft. The plane of dissection must be kept superficial so that the reconstructed lid will contain nothing but lid tissue. The dissection should be carried to a point beyond the orbital margin below and temporally. Nasally it should extend to the anterior crest of the lacrimal groove and to the orbital margin above it. The caruncle should always be preserved unless it already has been destroyed. Both temporally and nasally the dissection should extend beyond the limits of the palpebral fissure. If the levator is present every effort should be made not to injure it in dissecting the upper cul-de-sac. The dissection above should extend behind the orbital margin and need not

be carried all the way to the roof of the orbit, since it is not necessary that the upper cul-de-sac be deep. Bleeding points should be controlled by pressure if possible.

All cicatricial and granulation tissue must be excised in preparing the bed for the graft, for, as Wheeler[10] pointed out, contraction of the tissue beneath the graft results in reduction of the size of the socket. It is also imperative to remove any skin and scar tissue remaining from earlier attempts to reline the socket. External canthotomy should be performed if it will facilitate the dissection; but this is seldom necessary when only one cul-de-sac is to be restored.

After the bed for the graft is prepared, the upper and lower lips are retracted by means of towel clamps, and the malar buccal mucosa is put on the stretch. The submucosa is first infiltrated with 1-percent novocaine, if local anesthesia is used, and with physiologic solution of sodium chloride, if general anesthesia is used. Next, the extent of the graft is outlined with a sharp scalpel taking care to avoid inclusion of the opening of Stenson's duct. Caution must be exercised in dissecting the graft free, so that it will not be traumatized. After it is taken up, all submucous tissue is excised from its under surface with scissors. The wound in the buccal mucosa is closed with mattress sutures of heavy silk.

The graft is sutured into its new bed with interrupted fine silk. Three or four double-armed, 4-0 silk sutures are threaded through plates of rubber tubing and then through the graft in the depths of the new fornix. Below and temporally, these sutures are passed through the periosteum of the orbital margin in a manner similar to that described by Weeks.[7] In the upper cul-de-sac the sutures should be passed through the periosteum and brought out just beneath the brow. They are finally brought out onto the skin of the cheek or brow and tied over rubber plates. This gives assurance that the graft is anchored in the fornices and cannot retract. The socket is packed with one-quarter inch vaseline gauze, instead of employing the stent which has been in general use.

Postoperative procedure

We found that uniform pressure can be far more effectively obtained by packing than by the stent. Firm packing of the socket causes the graft to spread out more evenly and establishes more uniform contact between the raw surfaces. A pressure dressing is applied and left in position for a period of from 5 to 7 days. At that time the packing is removed, but the socket is repacked firmly, and a pressure dressing reapplied. The dressing is changed every three days until at the end of two weeks the graft is well healed, and if other surgical procedures are necessary, they may be undertaken. The wound in the mouth heals rapidly, and leaves no deformity.

When there is complete obliteration of the socket, the restoration has usually been carried out in two stages, one cul-de-sac being relined with buccal mucosa at each stage. A single graft of buccal mucosa cannot be obtained that is large enough to reline a socket completely; grafts from both cheeks are required. There should be no objection, however, to taking a graft from each side at one operation. The primary advantage of such a procedure would be the elimination of prolonged hospitalization.

When the socket is restored and healing has taken place, an acrylic conformer should be placed in the socket to maintain its shape.

Case reports

I shall present several illustrative cases in which I have performed buccal mucosal transplants for the correction of contracted sockets. Some of these patients were soldiers on my service at Valley Forge, others have been operated on since my return to civilian practice. All have been followed for periods of weeks, some for months, after operation. In no instance has there been a significant degree of contracture of the socket.

Case 1. A youth, 18 years of age, had been

born with no apparent eye in the left socket. At the age of four years, two unsuccessful attempts had been made to enlarge the socket by means of skin grafts in order that he might wear a prosthesis. When we first saw him, the left upper lid appeared shorter than the right. No eye could be seen in the left socket and there was very limited motility at the base. The upper cul-de-sac showed rather marked contraction toward the outer canthus where it was lined with skin. The only conjunctiva present was that lining the upper and lower tarsal surfaces. The external canthus was round with continuation of the graft from the floor of the socket onto the skin over the outer orbital margin. There was marked eversion of the lower lid.

In August, 1946, the skin graft in the base of the left socket was excised and dissection was carried to the lower orbital margin throughout its extent and to a point beyond the midline of the temporal orbital margin. A mucous membrane graft was taken from the inner surface of the left cheek and sutured into position in the denuded area. The socket was packed with vaseline gauze and a pressure dressing was applied. The mucosal wound was closed with mattress sutures of heavy silk. All sutures were removed at the end of 16 days. The graft was healthy and in good condition.

A month from the time of the original operation a second stage of reconstruction of the socket was carried out. The remainder of the skin from the base of the socket was excised and the dissection was carried well into the upper fornix. It was also carried temporally to a point beyond the upper temporal orbital margin. A mucosal graft was taken from the inside of the right cheek and sutured into position in the usual manner and the socket was packed with vaseline gauze and a pressure dressing was applied. Five weeks later an external canthoplasty was performed. A month following this, the patient could be fitted with a permanent prosthesis, which he has worn since that time with no difficulty.

Case 2. A 19-year-old soldier was admitted to Valley Forge General Hospital in February, 1944, with a diagnosis of contracture of the left socket. The left eye had been enucleated following an infection when he was six years of age, and because of a contracture of the socket he had been unable to wear a prosthesis. A few weeks following the enucleation, an unsuccessful attempt had been made to enlarge the left socket by a skin graft. In September, 1943, another attempt to restore the socket failed.

On examination of the left socket, externally, the lids appeared normal. Lining the inside of the lower lid, and extending almost to the margin, was an epithelial graft with some hair growing from it. There were adhesions between the base of the socket and the upper margin of the tarsus in the temporal half of the upper fornix. Nasal to this was an opening which was lined with skin extending toward the upper fornix for about 1 cm. The floor of the shallow socket and the tarsus of the upper lid on the nasal side were adherent.

At operation, performed in April, 1944, an incision was made on the inside of the lower lid throughout its entire length just anterior to the skin graft. Dissection was carried down to the inferior orbital margin throughout its extent. All scar tissue was removed along with the skin which lined the lower lid and the floor of the socket. A mucous membrane graft was taken from the buccal mucous membrane on the inside of the right cheek, and sutured in position with fine interrupted silk, so as to reline the newly formed lower cul-de-sac. Three mattress sutures were passed through the periosteum of the orbital margin, coming out on the skin of the cheek below this point. The socket was packed with vaseline gauze and a firm pressure dressing was applied.

In June, 1944, dissection of the upper cul-de-sac and the remainder of the floor of the socket was carried out, all skin and connective tissue having been excised. A mucous membrane graft was taken from the left

cheek and sutured in position, as in the lower fornix. The usual packings and pressure dressings were applied.

Three weeks later an acrylic conformer was substituted for the vaseline gauze. At the end of six weeks, an acrylic prosthesis was fitted to the socket, and the patient was returned to duty.

Case 3. The right eye of a soldier, 29 years of age, had been severely injured in action in Sicily in July, 1943. An enucleation was performed on the day of the injury. He had been unable to wear a prosthesis because of damage to the lower lid.

Examination revealed the left eye to be normal. The middle one third of the right lower lid was missing. There was a fibrous band extending from the lower orbital margin toward the base of the socket. The lower cul-de-sac appeared normal toward either canthus.

Following reconstruction of the right lower lid, the lower fornix was so constricted that a prosthesis could not be worn. The lower cul-de-sac was dissected to a point beyond the inferior orbital margin through its central two thirds. A buccal mucosal graft was taken from the right cheek and sutured into position as previously described. The socket was packed with vaseline gauze, and a pressure dressing was applied.

Six weeks following this operation the patient was given a permanent prosthesis.

Case 4. A soldier, 19 years of age, was admitted to Valley Forge General Hospital in June, 1944, with a diagnosis of contraction of the right orbital socket. When he was nine years of age, the right eye had been injured by scissors and enucleation was performed two weeks later. He had never been able to wear a prosthesis.

Examination revealed anophthalmus of the right eye, with contraction of the socket and a tendency for eversion of the lower lid. There were scars at the base of the socket, particularly toward the nasal side, where adhesions connected the caruncle with the conjunctiva, extending to both upper and lower fornices. As a result of these adhesions the upper tarsus had been thrown into folds. The base of the socket and the cul-de-sac toward the temporal side appeared to be adequate both above and below. All scar tissue in the socket was removed and the dissection was carried into both the upper and lower fornices of the caruncle. A buccal mucosal graft was taken from the left cheek and sutured into the denuded area in the usual manner. The socket was then packed with vaseline gauze, and a pressure dressing was applied.

This patient was later fitted with a permanent prosthesis and returned to duty.

Case 5. A soldier, 38 years of age, was admitted to Valley Forge General Hospital with a diagnosis of contracted left socket. The eye had been removed following an operation for cataract in infancy.

Examination revealed the socket to be small, the lower fornix very shallow with a band of scar tissue extending from the fornix to the lower lid margin. A web of scar tissue extending 1 cm. temporally from the inner canthus adhered to the palpebral conjunctiva, both upper and lower lids, and the conjunctiva of the base of the socket. No implant could be palpated in the socket.

In July, 1944, all the scar tissue and adhesions in the left socket were severed and excised, including the nasal one third of the floor of the socket and the lower cul-de-sac. A mucous membrane graft from the inside of the left cheek was placed over this denuded area, being sutured in position in the usual manner. The socket was then packed with vaseline gauze and pressure dressing applied.

This patient was later fitted with a prosthesis and discharged to duty.

Conclusion

It is now 70 years since buccal mucosa was first employed to replace conjunctiva. That so few ophthalmic surgeons have taken advantage of this relatively simple procedure

is surprising, in view of the excellent results obtained. I am sure that no one who has utilized both skin and buccal mucosa as substitutes for conjunctiva would insist that skin makes a more desirable lining for the orbital socket. The only objection raised by those who used buccal mucosa is that there is not a sufficient amount available for complete restoration of the socket. The mucosal lining of both cheeks and the lower lip furnish enough mucosa to reline an entire socket. There are many features that make buccal mucosa desirable as a substitute for conjunctiva. It is easily accessible, clean, and free from odor and its removal leaves no residual deformity at the donor site. It remains moist and smooth in its new location. There is little tendency for the graft to shrink, if preliminary dissection has been properly carried out. To be sure, the secretion is somewhat thicker than that from the conjunctiva, but it is not copious and produces a minimum of annoyance to the patient.

It is a well-known fact that skin remains skin regardless of its location, and buccal mucosa also retains its characteristics in its new location in the orbital socket. Nonetheless, there is no tissue which more closely resembles conjunctiva; the differences between the two are trifling and the fact remains that buccal mucosa is a far better substitute for conjunctiva than skin.

1740 M Street, N.W. (6).

ANGIOSARCOMA OF THE ORBIT*

PAUL V. CARELLI, M.D., AND JOSEPH P. CANGELOSI, M.D.
Chicago, Illinois

Angiosarcoma of the orbit is a very rare tumor. The term "angiosarcoma" was first employed by Kolaczek[1] to designate all tumors originating from blood and lymph vessels. This loosely applied term has led to various interpretations by individual investigators of histologic findings. According to Karsner[2] the term is applied to a sarcoma provided with numerous, wide, vascular spaces. Mallory[3] feels that the term is permissible only when the rate of growth is so rapid that cell differentiation does not take place and an exact diagnosis is impossible. McFarland[4] restricts the term to malignant tumors characterized by initial and continuous new formation of blood vessels associated with an excessive number of cells resembling those of sarcoma. Many pathologists use the terms "angioendothelioma" and "angiosarcoma" interchangeably; others employ "angiosarcoma" for neoplasms in which the blood vessel as a whole is the neoplastic unit and reserve "endothelioma" for tumors which are the result of neoplastic proliferation of the endothelium alone. Ewing[5] has described the histogenesis of angiosarcomas, although MacCallum[6] does not believe that there is sufficient descriptive explanation to warrant the use of a special name. Since the establishment of a general *Registry of Bone Sarcomas* by Codman,[7, 8] in 1920, one of the most significant papers in regard to pathology and histogenesis is that published by Kolodny[9] which describes the microscopic features of angiosarcoma and discusses its confusion with angioendothelioma and angioma. Recently Schmidt[10] has described the pathologic connecting link between hemangioma and angiosarcoma. There is, however, still a great lack of material regarding the etiology and histogenesis of this disease. It is evident from a study of the literature that there is much controversy about the histologic pathology of angiosarcoma. As Kolodny remarks, such discrepancy of views and opinions is only natural when one realizes that the tumor is exceedingly rare.

In citing Birch-Hirschfeld as an authority on diseases of the orbit, Meisenbach[11] discusses the clinical and anatomic findings of hemangioma of the orbit, but makes no mention of angiosarcoma.

A thorough review of available literature reveals that, in 1909, Parker[12] presented a case of angiosarcoma of the orbit in a little girl, aged 18 months. However, he did not describe the histopathology of this case.

* From the Ophthalmological Department, Loyola University, School of Medicine, St. Anne's Hospital, and St. Elizabeth's Hospital, Chicago.

The same year Goldberg[13] presented a case which proved to be angiosarcoma of the orbit. The growth appeared in the orbit several months after an enucleation had been performed. There had been no microscopic examination of the enucleated eye, and the diagnosis was made when a small pedunculated growth, which had the appearance of a hematoma springing from the conjunctiva of the socket, was removed at the second operation.

Report of case

This patient, a white girl, aged 11 years, was first seen on September 15, 1945. Her

Fig. 1 (Carelli and Cangelosi). Appearance of the right eye preoperatively.

mother stated that her daughter was perfectly well until the last of July, 1945, when a slight swelling occurred over the right upper eyelid. There was a gradual increase in the swelling, but nothing peculiar about the eyeball was noted.

About two weeks after the onset, the patient was struck over the eye by a friend's elbow. About one week after this accident, the eyelid showed a black and blue discoloration. There was no pain and no disturbance of vision.

The patient's past history was negative except for the usual childhood diseases. The family history was negative.

Ocular examination on September 15, 1945, showed vision to be: R.E., 1.2—3 and J1 at 10 inches; L.E., 1.2 and J1 at 10 inches.

There was a swelling the size of an almond just below the right supraorbital rim involving the upper eyelid. The swelling had a doughylike feel with ecchymosis of the upper lid. Bruit and thrill were absent. There was a slight ptosis of the upper lid. The right globe, which appeared to be lower than the left, showed a limitation of movement when looking upward. Corneal findings were negative. The pupil was round and reacted to light and accommodation. The iris was a greenish blue. Fundus examination showed no unusual findings. Examination of the left eye was essentially negative.

Physical examination. The tissues in the nose were pale, a mucoid secretion was present, and the inferior turbinates were boggy. These findings suggested an allergic rhinitis. Examination of the oral cavity revealed enlarged, injected tonsils. The teeth were in good condition.

The remaining physical examination was negative.

Laboratory examination revealed the erythrocyte count to be 5,280,000; leukocytes, 14,050; hemoglobin, 102 percent; basophils, 2 percent; eosinophils, 3 percent; segmented, 75 percent; lymphocytes, 16 percent; monocytes, 4 percent. The blood Wassermann was negative.

X-ray examination of the skull was negative for bone injury or pathology. The sella turcica was of normal size and configuration. The optic foramen was normal. The sinuses showed "increased density in both frontals, ethmoid, and sphenoids due to hyperplastic changes probably associated with infection." The chest was negative.

Diagnosis was a hemorrhagic cyst of the right orbit.

Course. The patient was admitted to the hospital on October 28, 1945, and was operated the following day under general anesthesia.

An incision was made over the site of

the tumor which, on exposure appeared to be enclosed within a capsule. The mass was dissected out but was much larger than it appeared on the surface. The capsule ruptured during the dissection. The mass seemed to extend below the supraorbital rim and behind the eyeball. All visible tumor was removed. Upon palpation the superior rim of the orbit felt perfectly smooth. The wound was closed with interrupted dermal sutures.

Postoperatively, the child was given 10,000 units of penicillin intramuscularly every two hours and continuous ice compresses were placed over the right eye. The dermal sutures were removed on the sixth postoperative day, and the patient was discharged on November 10, 1945 after an uneventful recovery. Visual acuity upon discharge was the same as that obtained preoperatively.

Pathologic report. The hospital pathologic report was: "Specimen consists of pieces of soft, white tissue and soft gray hemorrhagic tissue. Microscopic examination shows a highly cellular malignant tumor; type, glioblastoma."

In view of this pathologic report, a slide of the specimen was sent to the Army Medical Museum for information concerning the diagnosis and advice as to whether irradiation or exenteration of the orbit should be performed.

The following report was received from Col. J. E. Ash: "The tumor, while highly anaplastic, presents in some areas a distinct cavernous vascular pattern and in other portions capillary structures can be made out. Diagnosis: Hemangiosarcoma. Believe irradiation is indicated."

Following this report irradiation therapy was started on December 14, 1945. The girl received 200R. of X-ray irradiation every day for nine days, using 140 kilovolts, 25 ma., with a filter of 1 mm. of aluminum at a distance of 50 cm. from the eye. The irradiation was particularly directed at the superior surface of the eyeball, a lead shield being used for the protection of the globe. There was a slight erythema reaction.

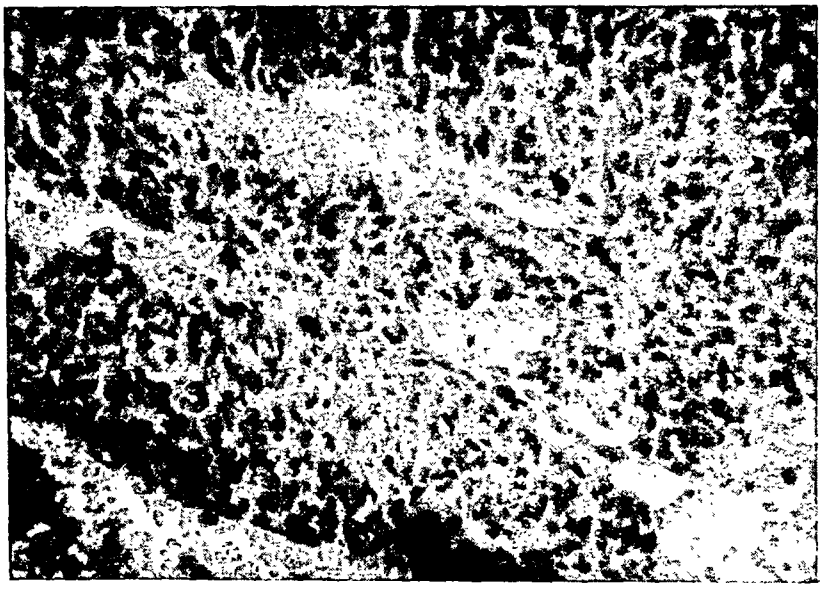

Fig. 2 (Carelli and Cangelosi). A photomicrograph reveals sheets of tumor cells that are composed of irregularly shaped nuclear cells which have vesicular nuclei. There is a moderate amount of light pink-staining collagen laid down around the cells. Many atypical mitotic figures are present throughout the cells. There are many dilated blood vessels throughout the tumor section, and in many places there is extravasation of blood cells between the tumor cells.

Follow-up. The follow-up examination on January 10, 1946, revealed a ptosis of the right upper lid with a healed curvilinear scar just below the orbital rim. Palpation was negative for any tumor masses.

Vision was: R.E., 1.2—4 and J1 at 13 inches; L.E., 1.2—2 and J1 at 13 inches. The ocular movements were within normal lim-

Fig. 3 (Carelli and Cangelosi). Appearance of the right eye 30 months postoperatively.

its; findings in the cornea and pupil were negative; the iris was greenish blue; and lens and fundus findings were essentially negative.

The girl was feeling perfectly well and was attending school regularly.

Comment

As the literature points out, angiosarcoma of the orbit is exceedingly rare; even the men with the most experience have seen only a few cases. The resulting confusion in histopathologic interpretations has been discussed and exemplified in this case.

Exophthalmus is the most frequently observed sign of the presence of any orbital tumor. Absence of pain, very slow growth, preserved motility of the eye, and elastic consistency and compressibility of the tumor are important signs in the diagnosis of orbital angiomas, but any malignant characteristics of the tumor become evident only upon microscopic examination.

This case is interesting not only because it presents a rare type of tumor, but also because the eyeball itself did not show any involvement, aside from the interference with motility. It is also noteworthy that the X-ray findings were negative.

This girl was operated 30 months ago, and there have been no visible signs of metastasis.

A DISCUSSION OF DEFORMITIES OF THE SHAPE OF THE LENS

WITH A REPORT OF A CASE OF POSTERIOR LENTICONUS

WILLIAM BROWN DOHERTY, M.D.
New York

Both the rarity of lenticular deformities and the controversy concerning the factors causing these anomalies make the subject of deformities of the shape of the lens an interesting one.

These aberrations from normal lens shape can be differentiated from congenital or developmental cataracts, since an actual abnormal curvature in the shape of the lens is present. The defects are usually unilateral, but the case herein reported (lenticonus posterior) was bilateral. These lenticular deformities do not seem to be hereditary, as in cases of ectopia lentis where the factor of heredity has been definitely established.

CLASSIFICATION OF DEFORMITIES

For the purpose of this discussion, the subject has been divided into the following classifications.

True deformities. In this category are: (1) Lentiglobus, (2) lenticonus anterior, and (3) lenticonus posterior. Although infrequent in occurrence, posterior lenticonus is not so exceedingly rare as lentiglobus and lenticonus anterior.

False abortive forms. This classification includes: (1) Lenticonus internum or lenticonus perinuclearis posterior (Harrison Butler), (2) senile or acquired lenticonus, and (3) umbilication of the lens or monocular bilateral posterior lenticonus.

As far as terminology is concerned, the word "globus" describes the conditions more accurately because, with the exception of anterior lenticonus, the protrusions are more globular than conical in form. Before taking up the subject of posterior lenticonus in detail, it would be well to give a brief discussion of the various classifications.

DISCUSSION OF CLASSIFICATION

Lentiglobus. This condition is very rare and is differentiated from anterior lenticonus in that the projection is globular in shape instead of conical. The most probable cause is that, during intra-uterine life, the lens becomes permanently molded due to a rigid pupil.

Anterior lenticonus. This condition is extremely rare. The anterior surface of the lens is conical in form and the raised portion consists of clear cortex, while the nucleus remains normal. Since these cases often give the appearance of keratoconus, a careful examination is necessary to distinguish them.

Anterior lenticonus also develops during intra-uterine life and is thought to be due to an overstretching of the lens capsule; to a delayed separation of the lens vesicle; or to an adhesion of the cornea. Another plausible explanation is that of a weakened lens capsule. If there is a deficiency of the capsule, a type of anterior capsular cataract is produced. These two deformities are probably transitional stages of the same defect.

Lenticonus posterior. As Duke-Elder has pointed out, the projection is more globular than conical in shape so that the proper designation should be posterior lentiglobus. This condition is rare and is often confused with cases of false or abortive lenticonus. An uncomplicated case presents the characteristic oil-globule appearance of anterior lenticonus (Duke-Elder). (This description, however, cannot be applied with exactness to the case herein to be reported.)

In cases of posterior lenticonus, the central part of the lens is very myopic while the peripheral part may be emmetropic. Very

often the remains of the hyaloid artery are present. Dustlike opacities in the lens have been reported, as have occasional opacities in the infantile nucleus. Vogt described a bright-red reflex around the base of the globule. In my case, however, the edge of the globule appeared to be more like a glaucomatous cup.

In addition to a detailed slitlamp study of the posterior surface of the lens, a very valuable aid in differentiating this condition from pseudolenticonus was first demonstrated by Gullstrand.

While studying the movement of the Purkinje images on the posterior surface of the lens, Gullstrand noted the movement of the candle image on the posterior surface and could, thereby, determine the form and changes in the curvature of the surface. The posterior lenticular image is much smaller where the posterior surface of the lens is most strongly curved than in the surrounding area. If the image is caused to move about by moving the light, it elongates in passing from one zone to another and, in places, it disappears. These reflexes can demonstrate an essential change of form in the posterior segment of the lens. They can also show whether a portion of the lens near the posterior pole has protruded into the vitreous. The peculiar reflexes thus obtained can be compared to the images produced by a drop of oil on a lens.

Many theories have been advanced as to the etiologic factors in this condition, but the primary cause seems to be a congenital rent or weakness of the capsule. The idea that the globus is caused by traction from the hyaloid remnants does not seem plausible since hyaloid remnants are not found to exist in all cases and did not in mine.

The best assumption seems to be that the condition is an aberration of growth of the lens accompanied by a thinning of the capsule at the posterior pole. This probably occurs at the beginning, during, or after the fourth month (Ida Mann).

Lenticonus internum or lenticonus perinuclearis posterior (Harrison Butler). Harrison Butler reported this condition in a patient, aged 26 years, who had a typical case of lenticonus posterior in the other eye. The lenticonus internum consisted of an alteration in alignment of the zones of discontinuity in the posterior part of the lens without any alteration of the curve of the posterior surface. The adolescent nucleus appeared to be a sort of double bulge which, if it had been complete, would have formed a lenticonus (Ida Mann).

Senile or false lenticonus. This acquired anomaly of the nucleus, which is of normal form, occurs in elderly persons. The axial parts of the lens assume a high refractivity in advancing age or in cases of incipient cataract. This unusual picture has been observed in congenital cataractous changes in the fetal nucleus. Cases have been reported in which the lens has had a double focal point.

Umbilication of the lens. This condition could possibly be classified as an abortive form of monocular bilateral posterior lentiglobus that might be caused by the lens fibers not being long enough to meet at the suture involved.

Posterior lenticonus

Report of a case

History. This patient first consulted me when he was 47 years of age. He was born in this country and had had defective vision since birth. His father and mother were not related. He had four sisters and one brother. Because of poor vision, he left school at the third grade.

Ophthalmic examination. Vision in the right eye was reduced to 20/200. With a dilated pupil, it was improved to 20/200 plus. Vision in the left eye was 10/200. With dilatation, it was improved to 20/70.

Vision could not be improved with lenses nor with the stenopaic or pinhole disc. Examination of the right eye under homatropine disclosed spokelike lens opacities on the

nasal side in addition to the deformity of the posterior lens. In the left eye, besides the posterior lens deformity, there were spoke-like opacities below.

Treatment. In view of the fact that a dilated pupil improved the patient's vision and also because the definite signs of an incipient cataract already present suggested the possibility of a totally opaque lens, it was decided to perform an iridectomy. This procedure was carried out on each eye in such a position as to obtain the best vision. Figures 1 and 2 depict the condition following the iridectomies.

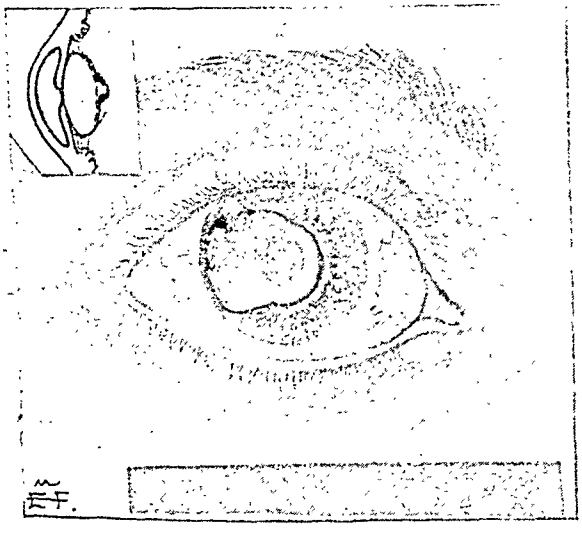

Fig. 1 (Doherty). This drawing made after the iridectomy of the right eye shows the condition of the posterior lens.

This operation provided an excellent opportunity to observe the pathologic conditions of the posteriors lens, but it brought very little improvement in vision. The presence of more dazzling probably accounted for the lack of improvement.

Slitlamp study of the posterior lens. In studying these two eyes with the slitlamp, the symmetry of the lesions in each eye was most noteworthy and certainly provides strong evidence that the condition was congenital in origin.

Throughout both lenses, more marked toward the periphery, were small linear flake-like opacities. The anterior Y was only partially seen and then only by careful manipulation of the slitlamp. The reflex from the conus caused this difficulty.

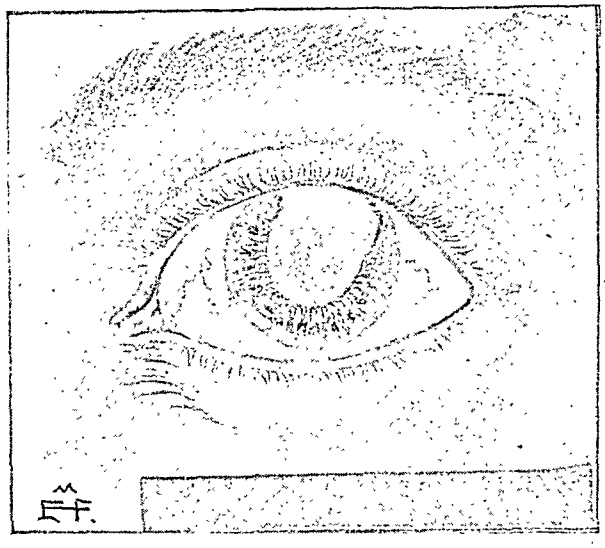

Fig. 2 (Doherty). Posterior lenticonus of the left eye. The drawing was made after an iridectomy.

The conus, itself, was cup-shaped. The ring reflex of Vogt, although present, was certainly not red. It was a brownish black. It was very distinct. When the slitlamp was moved, there seemed to be a second ring inside of the first. This was of a very light gray color with hazy borders and gave one the impression that it was a reflection or shadow rather than a real border. The general sheen of the conus was a light golden, and there were a number of opacities in the bottom of the conus when seen with the dot beam. These opacities looked something like crystals and, as the dot beam was moved from side to side, the general effect resembled slightly that of a kaleidoscope. Both eyes were essentially the same. There were no signs of the hyaloid artery, and the vitreous seemed to be normal.

Course. The lens opacities increased and, five years after the iridectomies, both lenses became entirely opaque and were removed. Vision at this time was: R.E., 20/30− with a +12.00D. sph.; L.E., 20/20−, with a +11.00D. sph. ⌒ +2.00D. cyl. ax. 45° (nasal).

Although every effort was made to remove the lenses with as little trauma as possible,

a laboratory examination after their removal showed no definite findings. About a week after the lenses were removed, there was severe hemorrhage in the left eye, and the anterior chamber was completely filled with blood. This gradually absorbed, but there was marked blood infiltration of the cornea which persisted for many months.

Conclusion

A discussion of deformities of the shape of the lens has been presented together with the report of an unusual case of posterior lenticonus. In conclusion, this question is proposed: "Would an intracapsular operation be considered in such a case?"

NOTES, CASES, INSTRUMENTS

HYALINE MEMBRANE OF THE IRIS*

JOSEPH LAVAL, M.D.
New York

REPORT OF TWO CASES

CASE 1

History. Sister M. B., aged 55 years, was born with congenital cataracts. In 1890, Dr. David Webster, Sr., performed bilateral optical iridectomies. In 1916, Dr. David Webster, the nephew, recorded 5/200 vision for the right eye and no light perception in the left eye which was due to absolute glaucoma. He enucleated the left eye at that time. In 1925, there was detachment of the retina in the right eye with complete loss of vision. In 1935, there was secondary glaucoma in this eye and on March 9, 1945, it was enucleated because of acute pain. At this time blood was noted in the anterior chamber and the eye was stony hard.

Pathologic findings. The globe is bulged temporally in the region of the optic nerve making it somewhat larger than normal; the ciliary body is barely visible. The retina is completely detached and there is blood in the anterior chamber and in the subretinal space.

Microscopic findings. The filtration angle is completely occluded by firm iris adhesions. The iris is necrotic and atrophied and has an occasional area of round-cell infiltration. The pigment epithelial layer of the iris is atrophic and cystic.

On the anterior surface of the iris lies a hyaline membrane that is continuous with Descemet's membrane. A layer of endothelial cells lies on the surface of the membrane which faces the aqueous, and these cells are similar in appearance to the endothelial cells of Descemet's membrane. The hyaline membrane is the same thickness as Descemet's except near the tip of the iris near the pupillary border where it becomes quite a bit thinner. There are many blood cells in the aqueous and an albuminous fluid.

The ciliary body is completely atrophic at the corona leaving only some hyalinized ciliary processes, the nonpigmented epithelium of which has proliferated moderately. The flat part of the ciliary body is only slightly atrophic. There is a thin remnant of cataractous lens matter but no lens fibers are seen.

The retina is completely detached and atrophic so that its constituent layers are not recognizable. The choroid is atrophic and has numerous excrescences of the lamina vitrea (drusen). The optic nerve is deeply cupped and atrophied. There is a formation of glial and fibrous tissue in front of the deep depression. Some blood lies between the retina and choroid.

CASE 2

History. G. L., a man, aged 46 years, always had had poor vision in the right eye. In 1915, the right eye was operated on by Dr. Thomas Curtin for cataract. There had been no vision in the eye since then. The left eye has always been myopic with corrected vision of 20/25 and has a zonular cataract. When seen by Dr. I. Hartshorne in November, 1945, the right eye was blind and the tension was 40 mm. Hg (Schiøtz). The globe was removed on November 24, 1945.

Pathologic findings. The globe is much larger than normal especially in the transverse diameter. There is thinning of the sclera and an increase in the size of the temporal portion of the globe. The optic nerve shows pronounced cupping. The ciliary body is barely visible.

Microscopic findings. The filtration angle is occluded by firm iris adhesions and a hyaline membrane continuous with Descemet's grows over the iris along its outer

*From the Laboratory of the Manhattan Eye, Ear and Throat Hospital.

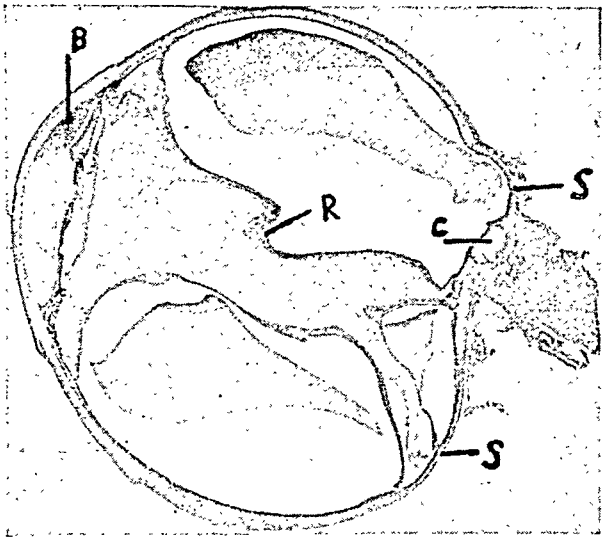

Fig. 1 (Laval). The sclera (S) is stretched and thinned posteriorly and there is moderate cupping (C). The retina (R) is completely detached. There is blood (B) in the anterior chamber.

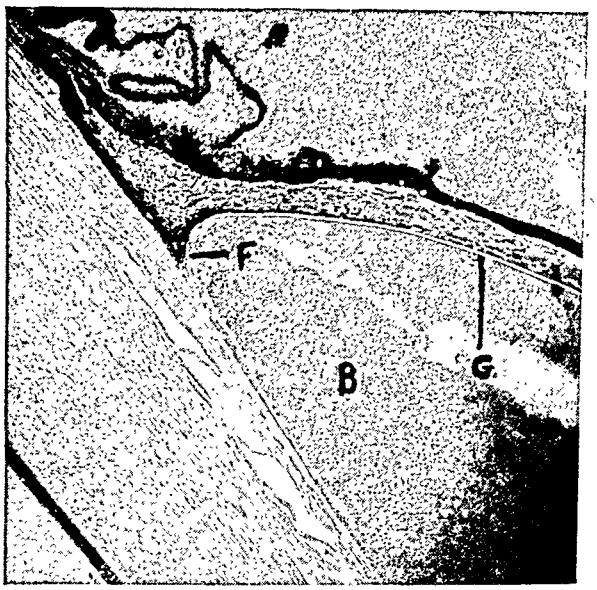

Fig. 2 (Laval). The glass membrane (G) lies on the anterior surface of the iris and is continuous around the filtration angle (F). The anterior chamber is filled with blood (B).

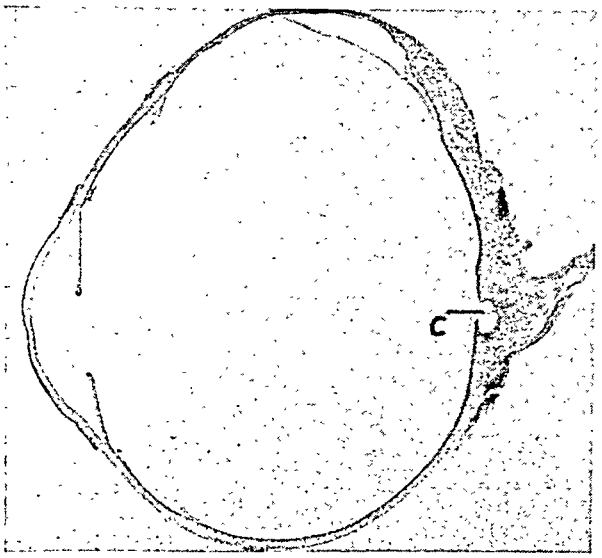

Fig. 3 (Laval). The globe is quite enlarged and there is pronounced cupping (C).

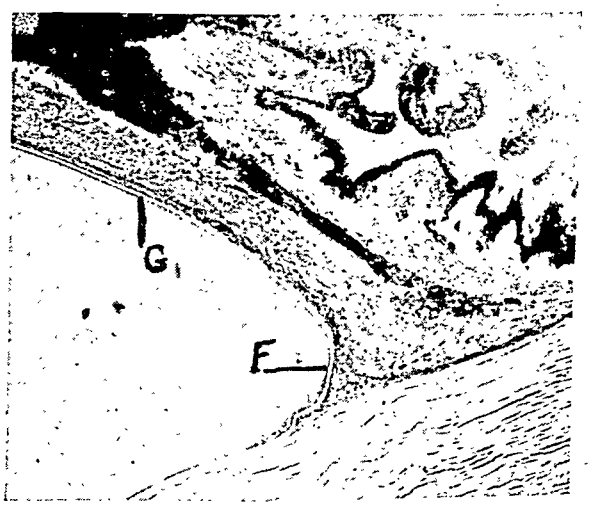

Fig. 4 (Laval). The glass membrane (G) lies on the anterior surface of the iris and is continuous around the filtration angle (F).

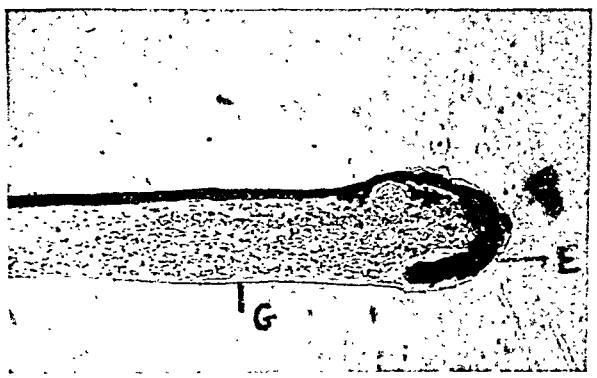

Fig. 5 (Laval). The glass membrane (G) becomes thicker near the pupillary area of the iris and ectropion (E) of the pigment epithelium of the iris is present.

surface. A layer of endothelial cells lies on this membrane facing the anterior chamber and is continuous with the endothelium of Descemet's.

The iris is markedly atrophic with ectropion of its pigment epithelium. The ciliary body is practically absent and is represented by a thin layer of fibrous tissue. A few atrophic processes remain and there is some proliferation of the nonpigmented epithelium.

The retina and choroid are intimately adherent with marked atrophy of the cellular layers of the retina. There is pronounced cupping of the optic nerve with some proliferation of connective tissue at the margins of the depression. The optic nerve is atrophic.

Comment

Collins and Mayou state, "a new formation of a hyaline membrane on the anterior surface of the iris may be produced beneath its layer of endothelial cells." It seems to be produced by the mesoblastic endothelial cells. In cases of infantile glaucoma, it may be the cause of the glaucoma by being continuous with Descemet's membrane around the angle. In the two cases reported here, both in adults, there was glaucoma. This may have been caused by the glass membrane growing over and around the filtration angle.

BILATERAL CHALCOSIS LENTIS WITH ENDOPHTHALMITIS OF THE RIGHT EYE

Abraham Schultz, M.D.
Chicago, Illinois

Report of a case

The destructive effect of penetrating copper particles upon the eye has been well recognized during the past 50 years. The intraocular reactions produced by this metal were first strikingly demonstrated by Leber,[1] in 1892. His classic work showed that the reaction of copper was influenced by the ocular tissues in which it became imbedded. When in contact with vascular tissue, such as iris, chemical suppuration rapidly occurred. Avascular tissue, however, such as lens or vitreous, usually tolerated the metal by enveloping it with a protective coating of albumin.

Because of the frequent inclusion of copper as an alloy of explosive missiles, the penetrating eye injuries incurred in World War II by these fragments were apt to produce grave ocular sequelae. The fate of an eye so injured depended primarily on the size, location, and percentage of copper contained in the intraocular foreign body. Such particles, although usually sterile because of the heat generated by their high velocity, often produced a chemical inflammation with rapid aseptic suppuration and final destruction of the globe.

Occasionally, however, these copper fragments may be tolerated in the eye for long periods, with preservation of good vision. The literature is replete with instances of this nature as reported by Würdemann,[2] Schwartz,[3] and others.[4]

When retained, these copper particles produce a constant chemical reaction with gradual development of ocular chalcosis.[5] Under these circumstances, the cornea may become impregnated with copper at the level of Descemet's membrane, especially about the limbus. Occasionally the vitreous becomes involved, and chronic irritation of the retina supervenes. More commonly, however, chalcosis lentis or copper cataract is the result of this chemical process. This was first recognized by Purtscher,[6] in 1918, during World War I, as diagnostic of retained intraocular copper particles which are slowly oxidized. It is a shallow, polychromatic opacity which is situated just beneath the anterior capsule of the lens in the form of a sunflower. Vogt[7] believed that this forma-

tion was facilitated by the posterior ridges of the iris as they rubbed against the anterior capsule of the lens, the center of which corresponds to the iris pupil.

The following case of bilateral chalcosis lentis is reported because of the remarkable ocular sequelae observed four years after the original injury.

Case report

History. A soldier, aged 21 years, with 16 months' service, was admitted to the ophthalmic service of an army general hospital April 4, 1942, complaining of pain, photophobia, and marked loss of vision in the right eye. These symptoms had suddenly appeared a month previously following a mild contusion of this eye which was accidentally incurred while working on a truck. Despite prompt treatment at the local station hospital, no improvement was noted, and he was transferred here for further observation and treatment.

Additional history revealed that four years previously, while still a civilian, he had sustained a perforating injury of his left eye as the result of a dynamite cap explosion. His left hand was also wounded at that time, requiring partial amputation of the thumb and forefinger. The injured eye gradually improved under conservative treatment, and he was released from the hospital three months later with complete restoration of vision. No ocular symptoms were noted since then until the present episode.

Ocular examination. Vision upon admission was light perception with poor projection in the right eye, and 20/20 in the left eye. A diffuse circumcorneal injection was present in the right eye, with tenderness over the ciliary region. No external signs of previous ocular trauma were evident. A definite aqueous flare was visible in the right anterior chamber, associated with a moderate increase of cells. The pupil was dilated and fixed as the result of previous atropinization. A serrated, gray, superficial opacity of the lens was grossly visible in the center of the pupillary area measuring 6 mm. in diameter.

Biomicroscopy under direct illumination revealed this opacity to consist of fine particles which were situated beneath the anterior capsule of the lens, producing a gray-green metallic sheen. These deposits were condensed into the shape of a sunflower, with a relatively clear center 2 mm. in diameter, from which about 40 slender petals of various lengths radiated peripherally. The remaining portion of the lens was not affected.

The vitreous appeared very turbid and was filled with much cellular and fibrinous exudate. The fundus, although partially obscured, revealed a severe bulbous detachment of the temporal half of the retina which overlaid the optic disc and extended diagonally from the 11- to the 5-o'clock positions.

The left eye showed no evidence of external injection. A small healed pigmented perforation was present in the nasal portion of the sclera 8 mm. from the limbus and 1 mm. above the lower lid margin. The aqueous fluid and vitreous appeared clear. A gray-green, superficial sunflower opacity, identical with that of the right lens, was situated beneath the anterior capsule of the left lens. The fundus revealed an old healed horizontal streak of atrophic chorioretinopathy in the extreme nasal periphery through which the sclera was visible. This was the site of the original intraocular path of the foreign body. A pale-green elliptical cyst which projected about 12 diopters into the vitreous was seen 3 disc diameters nasal to the optic nerve (fig. 1). The "tail" of this cyst was firmly imbedded in the retina, while its free anterior end contained a triangular metallic particle having a distinct copper luster.

Roentgenographic observations. Roentgen examination of both orbits revealed a minute metallic fragment in the left globe

corresponding to the position observed by ophthalmoscopy. Several fine metallic particles were also visible above the left frontal sinus. No metallic densities were observed in the right orbit.

Course in the hospital. The patient was placed on intensive foreign-protein therapy, with five increasing doses of triple typhoid vaccine which were injected intravenously at 2-day intervals. Chemotherapy in the form of sulfadiazine was administered for 10 days, attaining a level of 10.6 mgm. per 100 cc. of blood. This was followed by large doses of sodium salicylate for two weeks. Local atropinization of the right eye in conjunction with moist heat was continued throughout his hospitalization. All foci of infection including teeth, tonsils, and the genito-urinary tract were ruled out. The Mantoux reaction was negative with 0.01 mg. of old tuberculin. Laboratory studies which included the sedimentation rate and differential white count were within normal limits.

Despite all systemic and local measures the acute endophthalmitis of the right eye remained essentially unchanged. Because of the persistent suppuration in a hopelessly blind eye, enucleation was recommended. This procedure, however, was refused by the patient. After maximum hospitalization of six months was attained, he was transferred to a veterans facility for further observation and treatment. An opportunity to examine him 10 months later revealed a persistent endophthalmitis of the right eye with almost complete absorption of the lens. The left eye, containing the intraocular particle, remained quiescent, and the chalcosis lentis was unaltered.

Comment. Despite the absence of roentgenographic evidence of any metal in the right globe, the acute endophthalmitis in conjunction with the presence of chalcosis lentis in this eye, identical with the lens changes of the left eye containing the copper particle, must be due to a similar metal

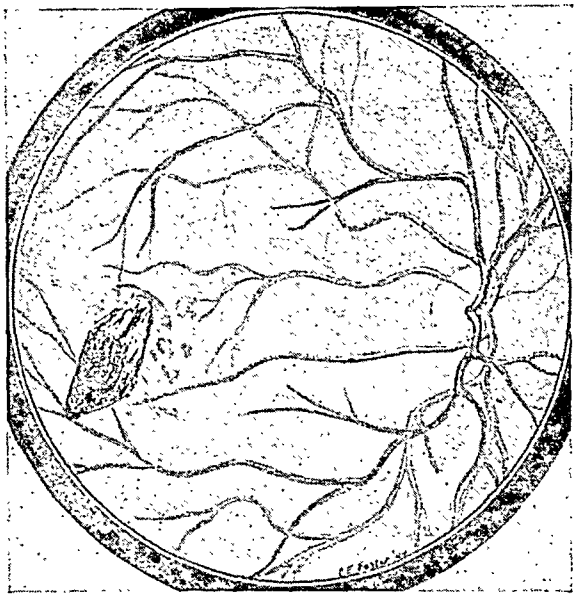

Fig. 1 (Schultz). Cyst containing copper particle imbedded in retina of right eye.

which had become absorbed. The presence of sympathetic ophthalmia in the right eye may be ruled out because of the quiescent left globe and characteristic copper changes in both lenses. The suppurative process in the right eye must, therefore, be caused by a perforating copper fragment which occurred at the time of the original injury four years previously but was not noted at the time because of the apparently more serious wound of the left eye. Both copper fragments then lay dormant four years, gradually producing a bilateral chalcosis lentis, with sudden onset of an aseptic suppuration of the right eye at the end of that time.

Summary and Conclusions

A case of bilateral chalcosis lentis is described with continued toleration of a copper particle in the left eye and subsequent severe endophthalmitis of the right eye four years after the original injury.

Intraocular copper fragments, even when apparently innocuous, usually produce a constant chemical change which may affect the cornea, lens, or vitreous. Chalcosis lentis, characterized by a sunflower metallic opacity beneath the anterior capsule of the lens, is

the most common sequela of these chemical changes. A severe aseptic suppuration of the eye, however, may suddenly occur years after the penetrating injury.

This case serves to emphasize the guarded prognosis that must be attached to all penetrating eye injuries, which, though quiescent, still retain intraocular metallic fragments. It also stresses the importance of examining both eyes carefully at time of injury, even though only one eye is apparently affected. Roentgen examination of both eyes is indicated in all questionable cases of bilateral involvement.

A TRIPLE-ARMED SUTURE FOR RESECTIONS

Jack V. Lisman, M.D.
New York

This suture is thought to be an improvement, as well as a simplication, of the two double-armed sutures generally used for the resection operation on the external ocular muscles. It has been used routinely for the past 18 months on the service of Dr. Wendell L. Hughes at the New York Eye and Ear Infirmary with satisfactory results.

The usual double-armed suture may be converted to a triple-armed suture by fixing a No.-3, French, open-eye needle to its center (fig. 1). The two end needles are passed through the marginal muscle fibers close to the upper and lower muscles edges. The central needle is passed through the muscle at its center from the outside in. The three needles are then passed through the muscle stump (fig. 2) and the central needle is cut free, leaving two complete sutures. There is no possibility of leaving any muscle tissue centrally that is not included in the suture, as might be the case when two separate double-armed sutures are used. The result is better than using two double-armed sutures.

The advantages are: (1) its simplicity, (2) the easier alignment of sutures in the muscle belly, (3) saving of suture material, (4) greater accuracy in placing the suture, (5) saving of time, especially important under general anesthesia, (6) less tissue trauma since there are only three muscle, tendon, and scleral punctures rather than the four made by the use of two separate sutures.

654 Madison Avenue (19).

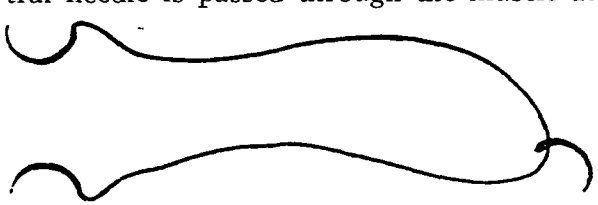

Fig. 1 (Lisman). A French-eye needle is fixed to the middle of a double-armed suture.

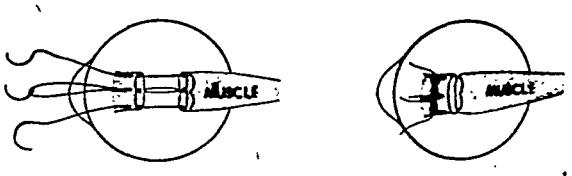

Fig. 2 (Lisman). The three needles are passed through muscle and stump. The needles are cut loose, leaving four ends which are tied.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

April 16, 1947

DR. HOWARD F. HILL, *presiding*

INTEGRATED IMPLANTS AND ARTIFICIAL EYES

DR. WENDELL L. HUGHES of Hempstead, Long Island, New York, presented a paper on this subject which was published in the Journal, 31: 303-310 (Mar.) 1948. A brief abstract follows.

The decision to use Vitallium was based on the following considerations. Plastics were rejected because of (1) insufficient strength for design contemplated, (2) possibility of wear and scratching in time, (3) occasional allergy, (4) effect of age, (5) unsatisfactory union of metal and plastics. Gold was rejected because of prohibitive cost, while tantulum was objectionable because of tissue reaction and because it was difficult to fabricate. Vitallium was decided upon because of its moderate cost, its strength, ability to be cast in any shape, and because its prolonged use in other regions of the body showed minimal tissue reaction.

The implants and surgery were described in detail. The implants to be used after enucleation are of two sizes, the smaller one being used to replace previously buried implants when the usual implant would be too large. The larger implant consists of a polished, smooth, posterior spherical portion 18 mm. in diameter, with an anterior portion approximating a truncated cone, ending in a flat face 10 mm. in diameter. On the anterior surface of the flattened portion is the depression which receives the peg extending from the rear surface of the prosthesis. Surrounding the neck of the implant is a ring attached to it by eight small bars. The recti muscles with a tab of sclera attached are fastened to the ring of the implant. Tenon's capsule is then pulled through the ring between the recti and sutured. The conjunctiva is then sewed around the flat anterior surface, anchoring it to the tissues passing over the ring.

In conclusion, Dr. Hughes summed up the advantages of this type of implant over the buried type as follows:

1. The motility of the implant is transmitted to the artificial eye because of the integration of the eye with the implant. The slippage between the buried type of implant and the eye is eliminated.

2. The position of the eye may be changed simply by altering the position of the peg on the back of the eye.

3. A stock plastic eye can frequently be used simply by placing a peg on the posterior surface to integrate it with the implant.

4. The motility is excellent in all directions as noted by measurements. In several of the cases reported, convergence was noted.

5. The normal fold of the upper lid is retained and the sinking in, so common with the ordinary artificial eye with a buried implant, is eliminated. This is due to the eye being supported by the implant through the medium of the peg on the back of the eye integrating it with the implant. The eye is held backwards so that the peg is held into the depression on the front of the implant by the normal tonicity and muscles of the lids. The lower lid no longer needs to support the entire weight of the eye plus the pressure exerted by the upper lid.

6. One piece metallic hollow construction of metal .002-inches thick is an advantage over any combination of two substances; metal, plastic or otherwise.

Discussion. Dr. H. B. C. Riemer asked

about the formation of granulation tissue at the conjunctival edge. Dr. Hughes said it had occurred once, at which time he simply cut it off. He did not know what happened to the edge of the epithelium around the implant, but as pure conjecture thought a connective-tissue layer is formed as a result of foreign body reaction at the junction with the implant.

Dr. Howard F. Hill inquired about the length of time the implants had remained in. Dr. Hughes replied that in all his completed cases the implants have been in longer than three months.

Dr. Riemer then asked in what type of case Dr. Hughes felt evisceration was safe, since Dr. Riemer thought the majority of Boston surgeons did not regard it as a safe operation.

Dr. Herman Grossman also asked about the relation of sympathetic ophthalmia to advisability of evisceration. Dr. Hughes replied that any suggestion of the presence of an intraocular tumor or injury through the ciliary body contraindicated doing an evisceration.

Dr. Grossman inquired about the removing of a buried implant and replacing it with Dr. Hughes' implant. Dr. Hughes said that there would not be room for a full-sized implant, but that he was going to try it with a smaller one. The only cases that are suitable are ones in which there is good fascial and conjunctival covering of the implant so that one can get strips connected with the recti and also strips of fascia to go between the recti around the ring. He felt it would be impossible to put an implant in a socket in which no implant was buried.

Development of Monoplex eye

Mr. Jardin of the American Optical Company (by invitation) spoke of the development of the Monoplex eye, which is an attempt to put the artificial eye on a standardized basis of colors, shapes, and sizes. This prosthesis is made of plastic and is subject to further adjustments in fit by a qualified technician.

Reporter.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

Section on Ophthalmology

April 24, 1947

Dr. Burton Chance, *chairman*

Rubeosis iridis diabetica

Dr. Joseph Waldman and Dr. David Naidoff (by invitation) presented the subject. Rubeosis iridis is a comparatively rare condition in which a noninflammatory proliferation of new blood vessels occurs on the anterior surface of the iris. It is usually associated with glaucoma. Salus first described the condition in 1928, and used the term rubeosis iridis diabetica when he observed it bilaterally in three diabetic patients, all of whom eventually developed glaucoma.

The appearance of the iris is characteristic; the anterior surface is covered by radially arranged new vessels, especially near the sphincter region where the individual vessels anastomose to give the appearance of a ring about the pupil. The vessels end at the pigment margin without extending over it. Beginning at this capillary net some larger vessels spread over the iris, and disappear in the angle of the anterior chamber.

Kurz, in 1937, first described the gonioscopic and pathologic findings. On gonioscopy he found large vessels to run peripherally into the angle where they divided into innumerable branches to connect directly with Schlemm's canal, and to form extensive peripheral synechias. With the development of atrophy of the iris, the vascular net in the rubeotic eye tended to disappear. Pathologic study revealed that the new vessels were unassociated with inflammation or with newly formed tissue, but lay in and

upon the iris itself. Hemorrhagic retinopathy and a tendency to vascular proliferations in and on the retina and optic nerve were frequent concomitant findings.

Hyphemia is common, and in all reported cases a recalcitrant glaucoma results which yields only temporarily or not at all to treatment, medical or surgical. In 1945, Fralick reviewed 32 reported cases of rubeosis iridis associated with diabetes and added three cases which he had observed; of the 35 cases only one failed to develop glaucoma and in this case, reported by Wegner in 1939, treatment was considered successful when an intracapsular cataract extraction was performed. Since then, Meyer and Steinberg, Scobee, Grury, and de Roetth have reported the use of cyclodiathermy in controlling the glaucoma in rubeosis iridis diabetica although this treatment resulted in atrophic eyes.

An interesting observation is the relationship between arterial hypertension and rubeosis; this was first mentioned by Kurz. Fralick, in his review, found that 16 of the 35 cases suffered from hypertension. It seems that diabetes and hypertension together in the same patient manifest a much higher percentage of vascular pathologic change than when either is present alone.

The following case is from the Number 2 eye service of the Jefferson Medical College Hospital.

CASE REPORT

M. G., a woman, aged 58 years, first learned that she suffered from diabetes in 1943. Treatment since then had been dietary and haphazard. Insulin had not been used. For the last six months she had also been treated for hypertension. In December, 1946, the patient had suffered sudden loss of vision in her left eye, and was told then that it was due to a severe vitreous hemorrhage. On February 24, 1947, one week before admission to the Hospital, the patient became aware of what she termed "pink vision" in her right eye, the good eye; everything at which she looked had a reddish hue. That night she suffered severe pain in the right eye, and the next morning vision was limited to light perception. She was seen by one of the members of the staff that day and a diagnosis of acute glaucoma was made. At this time hyphemia was present. Treatment consisted of eserine drops and hot compresses, but the elevated intraocular pressure, pain, and loss of vision persisted until her admission to the Hospital on March 1, 1947.

Eye examination. On admission the eye examination revealed vision to be O.D., light perception; and O.S., 4/60. The intraocular pressure was O.D., 65 mm. Hg. (Schiøtz); O.S., 16 mm. The right eye was severely congested throughout. Biomicroscopic examination showed the cornea to be edematous; many small gray keratic precipitates were present. The aqueous was slightly turbid. The iris stroma was atrophied, and a narrow ectropion uvea extended around the entire inner pupillary border. Just outside this pigmented margin of the pupil was a fine network of newly formed blood vessels, which covered the sphincter zone in a wreathlike fashion and gave a reddish hue to this portion of the iris. From this vascular zone on the surface of the iris several more or less straight and larger vessels coursed toward the base of the iris; some terminated in tufts of small capillary networks situated about the base of the iris; others disappeared behind the limbus. Uveal pigment and grayish debris were noted on the anterior surface of the lens which had suffered a general loss of transparency with other cataractous changes. Fundus examination was impossible because of the changes in the media as noted.

The left eye presented a normal external appearance. The vitreous was loaded with fine and coarse opacities. Many infiltrates typical of diabetes were noted in and about the macular area, and numerous retinal

hemorrhages, both punctate and flameshaped, were present throughout. The retinal arterioles showed marked sclerosis. Biomicroscopic examination revealed numerous fine gray and brown keratic precipitates. The anterior chamber was clear. Atrophy of the iris stroma and absorption of iris pigment were evident. On the iris, near the pupillary border, at about the 9-o'clock position, a tiny network of new vessels was noted. The lens changes were similar to those seen in the right eye.

General physical examination showed a blood pressure of 210/120 mm. Hg; generalized arteriosclerosis; and slight cardiac enlargement.

Significant laboratory findings were: Blood Kahn, negative; blood sugar, 235 mgm. percent; blood urea, nitrogen 25 mgm. percent; serum cholesterol, 222 mgm.; urea clearance, 35 percent; coagulation time, 3½ minutes; bleeding time, 1¼ minutes; capillary fragility (tourniquet test) normal. Urine showed 4+ albumen, trace of sugar, many red blood cells, and many epithelial casts. An electrocardiogram showed slight left axis deviation. There were no other findings indicative of myocardial change.

Diagnoses. O.D., rubeosis iridis diabetica and secondary glaucoma; O.S., diabetic retinopathy and retinal arteriolarsclerosis. Diabetes mellitus. Arteriosclerotic and hypertensive renal disease. Generalized arteriosclerosis.

Course. Miotics—eserine, prostigmin, mecholyl and D.F.P.—were all employed, without any decrease in the intraocular pressure; on the contrary, these drugs increased the pain and caused incessant vomiting which prevented proper control of the diabetes. Pilocarpine (8 percent) was then used, but the results were the same, even when the strength was reduced to one percent. After three weeks, since no beneficial results were obtained, all miotics were discontinued, and the patient became fairly comfortable, although vision was completely lost. From the time of admission the patient had received 20 mgm. of rutin four times daily. On April 4, 1947, the patient again suddenly experienced excruciating pain in the right eye. Examination then revealed a severe hyphemia with an intraocular pressure of 68 mm. Hg (Schiøtz). The pain has now diminished, but the anterior-chamber hemorrhage is still present. The patient's family was informed that operative procedures were usually unsatisfactory in these cases, and that enucleation was to be considered for the relief of intractable pain.

Discussion. Dr. Burton Chance: I recall a case of rubeosis in the service of the late Dr. Schwenk, 20 or more years ago, in a diabetic woman, who failed to return for further study because, so we were informed, she died from the severity of her general disease. I have not seen another case since.

Contaminated ophthalmic ointments

Dr. Louis Lehrfeld and Dr. Edward J. Donnelly discussed this subject. Ophthalmic ointments have been and are prescribed and used by eye surgeons throughout the civilized world. By far, the ointment most commonly used by the family physician is yellow oxide of mercury. The American lay public has used this ointment as a household remedy for external eye diseases. It is now to be replaced by sulfathiazole ointment. In the experience of one of us (Dr. Lehrfeld), such ointments as bichloride of mercury, boric acid, and ammoniated mercury have been used in collapsible tubes on numerous patients in office practice with a thought to economy until the last drip is expressed. At the Wills Hospital, it was our experience for years to use bichloride of mercury ointment (1:3,000) following all cataract operations merely because we had seen our predecessors do the same. Not more than seven years ago, we witnessed a corneal transplant performed by a well-known New York surgeon, in which the surgeon squeezed a goodly portion of an ointment from a collapsible tube into the patient's eye for antisepsis and lubrication. On another occasion, we saw motion pictures of a transplant by the same surgeon in which he advocated

the use of sulfathiazole (5 percent) immediately after the operation and then, at a later period, penicillin ointment.

Most ophthalmic surgeons and students of ophthalmology are inclined to play "follow the leader." It is not good form to question the masters who have obtained good results.

Personal experience of a continuous chain of infections following operations makes the surgeon stop to recount his steps with an effort to find out the missing link in asepsis and antisepsis.

When our attention was directed to the use of ointments in general, we dismissed at once the old ointment jar and directed our study toward the sterility and the maintenance of sterility of ointments commonly used in collapsible tubes.

It has been our experience that the ointment in fresh tubes, regardless of the name of the ointment, is different in color and consistency in the first sample expressed, compared with the second. It was also found that the nozzle of the tube was never free of ointment substance after a quantity was expressed. Pressure by the fingers left an extra quantity at the tip of the tube over which the cap was replaced. This overflow of ointment substance remained in the cap and on the nozzle of the tube until the next use. It is not always customary to express some of the ointment onto a towel or a pledget of cotton before using. In other words, the ophthalmologist has a false sense of security when he relies on the ointment in every collapsible tube being sterile until the last squeeze. It has been believed that the contents of the ophthalmic tube were sterile in the beginning and in the end. I feel certain that most ophthalmologists used ophthalmic ointsments in the treatment of corneal ulcers with the belief that the germicidal value of its contents was sufficient to destroy the bacteria present.

Strangely enough, you and I have never seen an ophthalmic ointment in a collapsible tube marked "sterile," and yet for years you and I have ordered ophthalmic ointments in the treatment of hordeola, blepharitis marginalis, ulcerative keratitis, and injuries to the eye with a smugness founded upon custom rather than scientific knowledge. We felt that the healing qualities of ointments were guaranteed by every textbook on ophthalmology. Fisher, Accousti, and Thompson (Bacterial contaminations in sulfonamide ointments, J.A.M.A., 122:855-858 (July) 1943) reported from the Warner Institute for Therapeutic Research that 5-percent sulfanilamide, sulfathiazole, or sulfadiazine ointments in a water-dispersible base may become contaminated with disease-producing organisms which these sulfonamides are not capable of killing.

Experiment on ophthalmic ointments

The authors wish to present evidence that most ophthalmic ointments in new and unused tubes are sterile. We wish to prove that once a fresh tube is opened the remaining contents are very frequently contaminated.

Data regarding culture media. The culture media used in this experiment was brain-heart infusion agar with sterile human blood. Approximately one inch of sample was expressed from each collapsible tube onto the culture media. The period of incubation varied from one week to 10 days. The first culture appeared, varying from 48 to 72 hours. The incubation temperature was 37°C.

The ophthalmic ointments used in this series of experiments were from six different manufacturers.

Cultures made. Cultures were made of the contents of 50 used tubes and 24 unused tubes of commonly known ophthalmic ointments as found on the open market. Three control Petri dishes were also observed, having been exposed the same time as cultured media.

Of the 50 tubes, which had been used more than once, a goodly proportion showed contamination by bacteria such as Staph. albus hemolyticus, Staph. aureus hemolyticus, fungi (species not determined), and other organisms, which were not identifiable by

microscopic examination alone. Eight of 15 tubes of 5-percent sulfathiazole ointment, which had already been used at least once, showed growth. Four of 11 tubes of bichloride of mercury (1:3,000) were found to be contaminated. Two of five tubes of penicillin ointment (500 units per gram) revealed growth. Two of seven tubes containing epinephrine bitartrate, which had been opened once or more, were positive. There was one positive out of six tubes of atropine ointment which had been used. Three pontocaine ointment tubes were found to be negative. A tube of eserine ointment (1 percent) which had been used on postoperative cases, showed many fungi. One borofax tube was negative.

Cultures of unused tubes. Twenty-four new tubes of ointment were selected from a stockpile of boxes containing 5-percent sulfathiazole ointment. One tube was selected from each supply box as a spot check (each original having 50 small boxes of ⅛ oz. each).

In 12 new unused tubes the first portion of ointment was cultured; all samples were negative. In another group of 12 new tubes, the entire contents of each tube were cultured. One was positive. Three controls consisting of blood agar were exposed for the same length of time as was required to smear the ointment from the tube. The three controls were negative, indicating there was no contamination from the outside atmosphere during the period of culturing.

There was sufficient information in all the experiments to indicate that the unused tube of ointment was, in most instances, sterile, while the used tubes were frequently contaminated.

The findings in this study call for a revaluation of the use of ophthalmic ointments in the eye postoperatively. Further, they call for the revaluation as to the use of ointments for ophthalmic conditions in general.

The authors appreciate the difficulty of sterilizing ophthalmic ointments. The composition of the tubes and of the ointments enters into the difficulty of marketing or preparing sterile ointments in collapsible tubes.

Conclusions. The authors do not have any evidence to prove that infections actually occur from the use of contaminated ointments. Surgeons of experience, however, do not wish to publicize overwhelming proof in the form of blind eyes. The authors do not have proof that the organisms found in the contamination were pathogenic bacteria. The mere fact that the ointments do contain organisms is sufficient proof that pathogenic bacteria may also be present. One may question why more infections do not occur following the use of ointment in used tubes. The answer can only be a conjecture. Either the lysozymes of the tears have their effect upon certain bacteria or the eye itself possesses a factor "X," which saves most patients from infection following intraocular surgery. Scientists do not willingly or knowingly place contaminated ointments into open wounds or even into a healthy eye.

Our experiments have convinced us that it would be well to discontinue the use of ointments postoperatively. We get along very well without them. Perhaps we, too, were formerly the subjects of habit and custom.

We are greatly surprised to learn that sulfathiazole ointment and penicillin ointment may become contaminated before the contents of the tube are exhausted. We have lost faith in the use of ointments. Our confidence can only be restored if an ointment could be produced sterile in containers for one application only. It is hoped that the experiments here reported may stimulate renewed interest in ophthalmic therapeutics.

Discussion. Dr. Louis Gershenfeld: I think we are indebted to Dr. Lehrfeld and Dr. Donnelly for the presentation of this paper on the sterility of ointments. Generally speaking, information like that comes from laboratory workers and, therefore, does not strike the ophthalmologist with the same force and meaning as it does when coming from an ophthalmic surgeon.

Some 25 years ago when I was very much concerned about the sterility of ampules used

for internal medication, I was at a meeting with the Commissioner of Food and Drugs. As you know, the Food and Drug Administration is interested primarily in the interstate-commerce traffic of food and drugs. During the discussion, I asked Mr. Campbell, the commissioner, whether or not his department had examined or investigated ampules on the open market. Mr. Campbell did not recall, but turned to two of his assistants and asked them. Their reply was they didn't think so. I then said to Mr. Campbell, "Don't you think it would be of more interest, perhaps, and certainly of greater value, if we concerned ourselves with the examination of ampules on the market and especially with the sterility of parenteral solutions than with such routine examinations as noting whether the strychnine content of Nux Vomica was 1.15 percent or 1.05 percent?"

Routine examinations are important, but it is of greater importance to make certain that solutions for direct injection, which may sooner or later reach the bloodstream, are sterile. I was surprised to learn nothing was being done as far as examining for sterility was concerned. My attention had been directed to this because a prominent internist had asked me to examine three identical ampules which he had. Upon examination, I found in each ampule a hemolytic Staph. aureus, which produced suppuration in rabbits. The internist had thought that something was wrong, since, of the nine other ampules of this lot which he had injected into his patients, abscesses had resulted in four of the cases. The other patients had never come back, and he was wondering what was the matter.

I immediately wrote an editorial for one of the journals, and it was at that time that the Food and Drug Administration proceeded to spend over $25,000 to look into the sterility of parenteral solutions throughout the country.

These points are mentioned primarily because I, too, then began to examine the ampules on the market. Very few of them stated that they were sterile. There was a statement as to contents—a solution of iron citrate, or a solution of morphine sulfate, or whatever the drug may have been. More recently the Sterile Advisory Board of the United States Pharmacopeia, of which I am a member, has become concerned with many of these sterile products.

Now we definitely define what parenteral means and, therefore, ampules and parenteral solutions must be sterile, whether labeled so or not. The Food and Drug Administration and the manufacturers accept this as such. The result is that this class of marketable products is sterile, and we have had practically no trouble on that score.

On the other hand, ointments are not sterile unless they are labeled sterile. I dare say there are very few ointment preparations on the market, whether used for ophthalmic work or for other surgical work, that are sterile. I have examined ointments in tubes and in jars and have found them to reveal the presence of bacteria.

The whole question of sterility is most intricate and complex. We must remember, of course, that the economic question affects the picture, although the question of price should not enter into the consideration if we want a finished preparation in which we have assurance that it is definitely sterile. When surgical catgut became official in the Pharmacopeia, members of our committee went on record to the effect that individual strands should be kept in individual hermetically sealed glass tubes. This form of marketing was first official in U.S.P. XII, and it is official in U.S.P. XIII, which recently made its appearance. At one time many strands of surgical catgut were in one container. This was objectionable and for many of the reasons which Dr. Lehrfeld presented here this evening.

In ointments we must remember many specific things. Dr. Lehrfeld has mentioned various ointments which, for the moment, one may think are bactericidal. However, we must remember that this is not always the case. The sulfonamides, for instance, are

only bacteriostatic. They are not bactericidal. They do not kill bacteria even if used internally, let alone in ointments.

One thing that we may forget is the fact that when we speak of bactericidal effect we seem to think that it means that every species of microörganism is killed. This is not so, although it may occur occasionally. The sulfonamides are only effective against certain particular groups of organisms. The same thing holds true for penicillin.

Even when a bactericidal agent is effective in suitable liquids, it may not be in ointments unless the proper base is used. In a petrolatum-phenol ointment, there will be very little antibacterial effect, but if a water miscible base is used, there will be an entirely different effect. These are some of the things which, of course, may play an important role.

With regard to the containers for ointments, I heartily endorse Dr. Lehrfeld's recommendation that, after surgery especially, a tube or container should be used only once in medicating an open wound. If an ointment is used in ophthalmic surgery, it certainly should be sterile. It is not a simple procedure, however, to market sterile ointments in small tubes or other individual containers if the expense has to be considered, because the process is an intricate, tedious, and long drawn-out one. The ointment tube itself, even those for ophthalmic use, are generally primarily tin. Some of them contain about three-fourths of one percent copper, added for hardening purposes. The larger tubes—½ oz., 1 oz., 4 oz., and larger —usually not used for ophthalmic products, are made of lead, lined with tin, about 7-percent tin; for toothpaste, 3-percent tin. Some of them may even have a plastic lining, but not the tubes for ophthalmic use.

It must be remembered that all tubes have to be sterilized. The ophthalmic tubes of pure tin with a small amount of copper can withstand heat up to 400°F. We use dry heat at 160°C. (320°F.) for sterilization. The closures are generally of Bakelite, which may hold up at this temperature. The individual sterile tubes then have to be filled under aseptic conditions with the sterile ointment. In many instances it may not be practical to sterilize the tube and contents or final containers. Individual sterile gelatine containers can also be used. The additional expense involved in the manufacture of sterile ointments must be kept in mind. Although the manufacturers will be delighted to cooperate in producing such preparations, you must remember what it will cost them.

The question has been raised as to whether or not a bacteriostatic agent can be incorporated in an ointment to produce a preparation that is self-sterilizing. Zinc peroxide has been mentioned. Zinc peroxide may be satisfactory, but in some instances you will find it possesses irritating effects, especially in the eye. Urea peroxide has been recommended for sulfonamide ointments, but frequently, upon standing, oxidation of the sulfonamide compounds occurs. The self-sterilizing agent must not only kill the bacteria present, but must also be nonirritating. A series of tests to prove that particular point will have to be conducted. Furthermore, one cannot just say that, because zinc peroxide, or urea peroxide, or whatever the agent may be is effective in combination with sulfonamide, it will be effective with other drugs. The question of effectiveness, stability, harmlessness, and so forth, are factors which must be taken into consideration.

It is possible to have individual containers for dispensing ophthalmic ointments and I, for one, definitely recommend and heartily endorse them. Certainly sterile preparations should be used for surgical purposes. However, unless requests are made specifically for sterile ointments, unless there is a demand for them, and unless individuals are willing to meet the additional expense involved, manufacturers will not market sterile ointments for use in ophthalmic surgery.

Dr. George J. Dublin. What I have to say is not relative to contaminated ophthalmic ointments, but rather to the effects of ordinary ophthalmic ointments, on the eye. I have noted for many years untoward re-

actions following the use of ophthalmic ointments.

These reactions were noted particularly in patients from whose corneas foreign bodies had been curetted. As usual, pontocaine or butyn ointment had been ordered. The corneal abrasion healed without much trouble, but I noticed that there were a considerable number of punctate staining areas over the cornea. These remained present for several days following the healing of the original corneal ulcer or corneal abrasion.

At first I thought that these abraided areas were due to some form of allergy. Later, the thought came to me that the punctate staining areas might be due to some form of mechanical irritation. We know that there is no ointment in which a drug is completely dissolved. Some of the drug always remains in crystal form. The small crystals within the ointment, by their mechanical action, cause corneal abrasions. I wondered at first why these patients complained of vague symptoms such as scratching, sensation of a foreign body, and tearing in the presence of a quiet eye, until I routinely stained each patient with fluoroscein. To my surprise, I found a great number of staining areas. To eliminate the possibility of these reactions being allergic in character, I used these ointments in the opposite eye, and noted the same reaction. I tried other types of ointments, and I found that, regardless of the type used, even boric-acid ointment, the same reaction was present in a majority of cases. I felt that an abraided cornea, the result of ophthalmic ointment, was an excellent medium for infection to develop. I reasoned that, instead of preventing an infection, I might be responsible for the development of a corneal ulcer. I have noted these reactions for several years, and consequently, I have not used ophthalmic ointments when I could possibly avoid them. In my opinion, liquid medication is equally efficacious, and probably it is considerably better to use it rather than ointments.

Dr. Louis Lehrfeld. I am very grateful to Dr. Gershenfeld and Dr. Dublin for their discussion. I should like to read part of a letter that was received by the pharmacist at the Wills Hospital following a question he asked as to whether ointment tubes were sterilized before ointment was inserted. The letter reads in part:

"We do not sterilize empty tubes except in the case of penicillin ophthalmic ointment where we use dry heat to sterilize empty tubes." Signed by Lanwermeyer, representing Abbott Laboratories.

Dr. Louis Gershenfeld (in closing). And this, in the case of penicillin, is the result of action by the Food and Drug Administration.

Vitreous infections and streptomycin

Dr. Irving H. Leopold, Dr. Richard Dennis, and Miss Marjorie Wiley, B.A. (by invitation), presented a paper on this subject which was published in the Journal, 30:1345-1352 (Nov.) 1947. A brief abstract follows:

Streptomycin penetrates poorly from the blood stream into the vitreous humor of normal rabbit eyes. Local methods of administrating streptomycin were studied and compared for their abilities to produce adequate vitreous-humor concentrations of streptomycin. Subconjunctival, anterior-chamber, and retrobulbar injection of streptomycin plus anterior-segment iontophoresis produced higher levels than that obtained by systemic administration. These methods were tried against the standard vitreous infections produced by bacteria coli.

Direct intravitreal injection of streptomycin, retrobulbar injection plus iontophoresis, and anterior-chamber injections reduced the severity of experimental vitreous infections due to bacteria coli. They were effective in the order listed.

Direct intravitreal injections of streptomycin produced retinochoroidal exudation and subsequent degeneration. In concentrations below 800 micrograms per injection, the damage was minimal and limited to the site of injection.

Discussion. Dr. Richard Dennis. I would

like to emphasize a couple of points and also add another. From the work that we have done, it seems that direct intravitreal injection is the most efficacious of the local methods of administering streptomycin. It also appears that the injection of reasonable quantities of streptomycin, at least up to 800 micrograms, can be done with no more damage than would follow a similar direct injection of saline solution. With improved methods in the refinement of production of the drug this will probably be more obvious. In a severely infected eye where other remedies have proved to be of no avail, the ophthalmologist would seem justified to try this method. For intravitreal injections, the solution should be as near isotonic as possible. In the lower concentrations this is best obtained by diluting the drug in physiologic saline. In higher concentrations, considerable osmotic effect occurs, and here it is best to dilute with distilled water.

Dr. Irving H. Leopold. For those who might try retrobulbar injections of streptomycin, it is necessary to point out that such injections may be painful. Intramuscular injections of streptomycin are painful to some individuals. Procaine does not interfere with the action of streptomycin, and could be used with or prior to retrobulbar streptomycin injections.

Role of the vertically acting muscles in concomitant strabismus

Dr. Edmund B. Spaeth presented a series of cases to illustrate the role which the vertically acting muscles must play in the causation of convergent as well as divergent strabismus. This is one basis on which to consider the etiology of strabismus. The cases illustrated a relationship between the conjugate muscles, with muscle overaction in one eye and with muscle underaction in the opposite eye. A degree of vertical deviation was always present but changed in each possible position of the lateral rotations. Further, muscle overactions were found to be quite common in the homolateral antagonistic muscles with and without contralateral conjugate muscle disturbances. The various possible combinations were all presented.

Disturbances in the vertically acting muscles modify to a marked degree the corrective surgery necessary. Certain rules for this were presented as to the sequence of the necessary operations (lateral and/or vertical) in the various situations seen.

Discussion. Dr. Glen G. Gibson. Once again we are deeply indebted to Dr. Spaeth for calling our attention to an extremely important and frequently neglected phase of ophthalmology.

The time has come when we can no longer neglect this subject of the vertical deviation in horizontal strabismus. I feel that this is an important paper for two reasons.

It is important, first, because it brings us intimately in contact with the author's extensive surgical experience in these very interesting cases.

It is also an important paper, because the literature in the past has been inadequate in guiding us in the handling of these cases. It illustrates the fact that we, as clinicians, are in need of precise definitions by which we can understand each other more thoroughly when we speak of such terms as spasm, overaction, vertical component, and vertical element.

This paper is too inclusive and extensive to permit a discussion of all the aspects of it, and I feel that I may best serve our purpose at the moment by summarizing briefly what Dr. Spaeth has really said.

He has pointed out that there are cases of pure horizontal deviation without any vertical element. He has also pointed out that if we study these cases carefully we can determine that many of them have a very slight degree of vertical imbalance, either hypertropia or hyperphoria. The careful study of these cases is rewarded by much better surgical result. There are two main groups in which we encounter combined vertical and horizontal tropias. The first group is primarily a concomitant strabismus

in which there is a secondary vertical deviation. The most common of these is the type in which there is bilateral inferior oblique overaction. The inferior oblique overaction is merely the secondary participation of these muscles in the esotropia. The second type of these cases are usually paralytic cases. These are primarily vertical deviations in which the horizontal deviation is merely the secondary device that the patient uses to get away from the disturbing diplopia that results in these vertical cases.

Now the differential diagnosis of these two types is relatively easy when we consider that the one in which the horizontal deviation is primary is the one in which the inferior oblique excess is bilateral. It is equal, and it is symmetrical. In other words both inferior obliques participate equally in these cases. In the cases which are primarily paralytic in origin, the deviation is always different in each eye. They are not symmetrical.

Now there is a third type of mixed deviation that one encounters in which the deviation has become so concomitant that it is impossible to tell just precisely which muscle was primarily involved. Some people will not admit that cases which were originally paralytic become progressively more and more concomitant as time passes, so that it is impossible to identify which is the originally offending muscle. I feel, however, these cases do occur and quite frequently. It is embarrassing to deal with these cases when it is impossible to say which of the muscles is primarily at fault. This is due to the fact that these paralytic bases become progressively more and more concomitant as time goes by.

Dr. Spaeth has called attention to the fact that the sensory correspondence is vitally important in these cases. I would like to cite two cases which illustrate this all important point. Two young men, aged 22 years, each had 10 prism diopters of left hyperphoria when measured in the primary position.

In the first case, the onset of the deviation was at the age of 22 years, in an individual who presumably had normal eyes and normal binocular vision until he was in an automobile accident, after which he developed a typical left superior oblique paresis. A complete myotomy, performed on the inferior oblique of the offending eye, reduced the hyperphoria to one-half prism diopter. This excellent surgical result with a relatively minor operation was possible because this young man had normal binocular sensory correspondence before the onset of the condition.

In the second case, the findings were essentially the same, but the history was entirely different, and a much greater surgical intervention was necessary. This was also a superior oblique case. The onset, however, was at two years of age, and we know, by inference, that the patient had very abnormal sensory correspondence and that the surgeon would get very little help from the binocular reflex in maintaining alignment. Even the deviation was essentially difficult. Although the diagnosis was the same as in the first case, a much more extensive surgical procedure had to be instituted because of the extremely abnormal sensory correspondence. A myotomy of the inferior oblique on the offending side, combined with a 3-mm. recession of the contralateral inferior rectus, was performed. The residual hyperphoria after the operation was three prism diopters, even though a more extensive procedure had been done. This is a point we must understand very thoroughly before interfering with these vertical cases—it is very important to know of the status of the sensory mechanism before operation.

Dr. Spaeth has called attention to the importance of recognizing inhibitional palsy in these cases. I agree with him that it is a very important point. They must be recognized. I would refer those who are not thoroughly familiar with this aspect of the subject to an article in the *Transactions of the American Ophthalmological Society* by Dr. Adler which is very clear on this particular subject. This condition is also explained

nicely but less clearly in the textbook of Chavasse. Dr. Spaeth has called attention to the fact that more than a cosmetic result is desired. The ideal sought is to obtain binocular vision, if possible.

A most important factor in obtaining binocular vision in these cases is the age at which surgery is instituted. It is not necessary to operate on these cases before the patients are three years of age, and, likewise, it is desirable to operate on them before they get past four years of age. In other words, the ideal time for surgery is between three and four years of age. Children treated at that time are still young enough to develop normal binocular vision. Dr. Spaeth has pointed out that, in this group of vertical disturbances associated with horizontal deviation, the results are frequently better than they are in the purely horizontal cases. It has also been my experience that we are much more satisfied with the surgery on the vertical muscles when the diagnosis and the treatment have been correctly performed.

Dr. George F. J. Kelly. I should like to ask Dr. Spaeth what his experience has been in cases of torticollis due to paralysis of an oblique muscle. When does the torticollis disappear after correction of the oblique muscle defect?

There is another point. If I heard you correctly, you said that when both a vertical component and a lateral component are present, whichever is the greater is operated on first. I also think I understood you to say that, when you correct the horizontal component, you always get an improvement in the vertical, and that, when you correct the vertical, you may get no alteration in the horizontal. Would it not be worthwhile to operate on the horizontal, because surely there will be some correction on the vertical, and maybe it would not be necessary to do so much on the vertical subsequently?

Dr. Edmund B. Spaeth (closing). Three things that Dr. Gibson brought out are, I think, quite true. The first emphasizes what White said right here on this floor many years ago: "Seventy-five percent of concomitant strabismus is accompanied by a vertical deviation." Too often nothing is done about it.

Dr. Gibson spoke about this matter of, "So many millimeters of recession or resection." This is more a delusion than a fact. There are many other things which enter into a vertical surgical situation. To correct vertical deviations by millimeters is quite impossible. It is disheartening to see the lack of results one will obtain in any type of surgery on an inferior oblique muscle when, instead of surgery on an inferior oblique muscle, one should have done the opposite surgery, resection or recession, upon the superior oblique muscle. It is only by a comparison of the total amplitude of the action of the conjugate yoke muscle to the muscle involved that one can decide whether an inferior oblique muscle or a superior oblique muscle should have been operated in these instances.

As to torticollis, there is no problem about this except that of the duration of time. If torticollis is not improved by monocular occlusion prior to the surgery, it will be a long-standing affair before the torticollis disappears.

As to the sequence of surgery in the vertical and horizontal, I have been distressed and embarrassed several times to find that subsequent surgery on the verticals has upset the previous surgical result on the laterals. If the vertical component is the greater, it is wise to take care of that before the lateral is even touched, because one cannot tell what certain effect this will have upon the lateral deviation.

George F. J. Kelly,
Clerk.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

SOCIETY PROCEEDINGS

One of the most attractive and popular features of the JOURNAL is that of "Society Proceedings." For a great many years, it has been a part of the JOURNAL to which the reader turns with the hope that something of utility, interest, and instruction will be forthcoming. Seldom has this hope been disappointed.

If properly reported, the society meeting can be easily visualized, as if you were there in person. The personality and experience of the essayist or demonstrator are displayed to advantage or disadvantage. Triumphs are scored, mistakes are revealed, and discussions, for the most part exceedingly shrewd and helpful, probe into the subject with acute discernment.

The proceedings, however, must not be taken too seriously or else the informality, that is so essential, is lost. You are permitted to theorize and speculate freely; something, perhaps, that is out of place in a formal presentation. You are also permitted to bring in personal experiences in discussing similar cases that you have had under observation,

without worrying too much about your style of delivery or the vocabulary you use. Questions are asked, and sometimes the answer is obviously avoided. All of these sidelights are reported in the proceedings, and it is necessary that they be reported, for otherwise the human touch is lost, and the spirit of the meeting and its spontaneity vanish.

Many times an opinion is expressed during a case report which throws a new light upon the subject, an idea that stimulates the reader's mind to elaborate more fully either in his own thoughts or, what is more significant, into action.

For example, in one of the meetings of the New York Society for Clinical Ophthalmology, Dr. Jack V. Lisman mentioned that the glaucoma associated with rubeosis iridis responds better to mydriatics than to miotics and thought that this is probably due to a mechanical squeezing out of blood from the capillaries of the iris as the pupil dilates. There is a great deal of food for thought here, and one should be stimulated by this to study further the problem of the control of such glaucoma.

Many other examples could be cited. As a matter of fact, if one went through all the society proceedings published in the JOURNAL during the last 10 years or more, and made a note of striking and unusual remarks, enough ideas for research would thus be engendered to keep one fully occupied for a long time.

The arranging and editing of the proceedings is a difficult task, skillfully performed by our Dr. Lyle. The form in which they are received often leaves much work to be done in order to make them readable without sacrifice of ideas, opinions, or individual style. The most important job, therefore, is that of the recorder or clerk of the society.

It is not every individual who has the knack of getting down on paper the essential matter presented at a meeting, and it is very easy to misquote or to leave out very interesting facts. Each society owes it to itself and to ophthalmology to give considerable thought to this factor and to choose with care one of its members for this important chore.

The large and wealthy organizations can hire a stenographer, but there is still work for the clerk in editing and coördinating the remarks. The smaller societies may not consider themselves able to afford the services of a professional stenographer. In this event, the entire burden falls on the clerk. For this reason, many organizations (and there are some 95 state and local ophthalmic societies in the United States) don't bother to keep a record of their meetings, or to send their proceedings in for publication.

This is a pity because many thoughts, ideas, and opinions are forever lost. The younger men who may hesitate to get up and discuss a paper before one of our national organizations, express themselves freely, as a rule, in their local meetings, and it is their fresh outlook and young ideas that we all need so badly.

It could probably be arranged, without increasing the dues too much, to hire a stenographer or to put in a wire recorder at every meeting of each society. The choice of a good clerk should not be too difficult, for in every community there is at least one individual who is qualified and eager to collect and to edit, perhaps in a preliminary fashion, the remarks that are made at a meeting.

The assignment is an important one. More organizations should be represented in the "Society Proceedings," and the JOURNAL will always welcome these contributions.

Derrick Vail.

THE VIRUSES

Vitamins and viruses were both discovered just 50 years ago, and in the intervening span few scientific revelations have so profoundly altered biologic thought. The first animal virus recognized—that of foot-and-mouth disease by Loeffler in 1898—is still the smallest yet identified. Since then virus infections have been found in every

form of life, including the lowly bacteria, and of the several hundred viruses now known, 35 affect man. No part of the ocular apparatus is immune, as the diverse complications of measles, mumps, and epidemic encephalitis illustrate. Certain viruses have a specific affinity for the eye only, as is apparent in trachoma and epidemic keratoconjunctivitis, and conceivably possible in sympathetic ophthalmia.

The mists of mystery about the viruses have cleared considerably. The term "filterable virus" is now dated. The size of virus particles has been accurately estimated through graded collodion filters, ultracentrifugation, and electron microphotography. The measurements range from 300 to 10 millimicrons. Progressive simplification in structure and function parallels the diminution in size. A group of the largest viruses, which includes psittacosis and the agents of lymphogranuloma inguinale, inclusion blennorrhea, and trachoma, have a close antigenic kinship, and are related to the rickettsiae in metabolism and staining qualities. Burnet, who maintains that all human viruses had a primary animal habitat, intimates that psittacosis continues the original strain while the others are specialized mutants. In contrast to the smaller viruses these exhibit some susceptibility to the sulfonamides, the ocular infections seemingly responding best to sulfacetamide (30 percent) locally used.

The viruses have descended presumably from a rickettsialike organism to their present state by successive extensions of their dependency upon the host. The virus group are obligate intracellular parasites who demand not only board and room, but digestion and respiration as well. With the delegation of more and more of their vital processes to the host cell, the viruses become smaller and smaller until the process of evolution in reverse arrives at the terminus, a gene-pattern molecule capable of reproduction only. The smallest viruses are not overmuch larger than the serum globulin molecule, which measures six millimicrons. Following the successful crystallization of the enzymes, urease by Sumner and pepsin by Northrop, Stanley, in 1935, demonstrated that a living virus, that of tobacco mosaic, could also be isolated in crystalline form. Since then numerous plant viruses have been so segregated; a typical example, the tomato bushy stunt virus, has been obtained in true 12-sided crystals absolutely homogeneous in size and shape, the particle diameter being 25 millimicrons; the molecular weight, 10 million; water of hydration, 70 percent. Like all virus molecules studied it is a complex of pure nucleoprotein.

The parasitized cells tend to react to the virus load by proliferation, but an excessive burden results in necrosis. In some virus diseases, as in the Rous sarcoma of hens, the hyperplatic response cannot be distinguished from neoplasm. Clinically the viruses can be roughly classified as pantropic, of which mumps is an example, dermatropic like herpes simplex, neurotropic like herpes zoster, and tumor forming like molluscum contagiosum and the common wart. The formation of inclusion bodies when present is pathognomonic of virus disease. These are colonies of elementary bodies, the infectious agent, which were first noted by Paschen in vaccinia and smallpox in 1906, and by Halberstädter and Prowazek in trachoma in 1907. By differential centrifugation the elementary bodies have been separated in purity, and, in 1931, Parker demonstrated that one elementary body could produce vaccinia. Thygeson removed all doubt concerning the role of the elementary bodies in trachoma by infecting a human volunteer solely with them.

An outstanding feat in virus control was the cultivation of sundry species on the chorio-allantoic membrane of the developing hen's egg by Goodpasture and Woodruff in 1931. From a yellow-fever virus serially transferred to chicken embryos from which the cerebrospinal system was removed, Theiler developed the invaluable strain, now known as 17 D, which although innocuous to man conferred complete immunity. This con-

ditioned mutant was in a way a fortunate accident, as the result has never been experimentally duplicated. Trachoma and inclusion blennorrhea are specifically human diseases, and their viruses cannot be grown in the chick embryo or animal tissues.

The viruses vary vastly in the antigenic response produced—from a solid immunity in herpes zoster to none in herpes simplex and trachoma. The first invasion of herpes is in the universally occurring aphthous stomatitis of childhood. The virus thence persists in apparent latency for life until spurred to activity by some factor, local or general, as the injection of typhoid vaccine or exposure to high temperature. Protection from viruses can be secured so far by prophylactic means only, which in order of effectiveness are active immunity, passive immunity, and quarantine. After the virus has penetrated into susceptible cells, it is safe from antibody attack, and serum injections then are of dubious value. As Rivers showed in 1929, if normal cornea is inoculated with vaccinia virus and then cultivated in antivaccinal plasma, typical lesions will nevertheless develop; while if the cells are bathed in immune serum before the addition of the virus, infection is prevented.

The successful treatment of virus diseases of the eye has been limited to sulfonamide medication in the psittacosis group, the removal of virus growths such as warts and molluscum contagiosum, and iodine cauterization of herpetic lesions. Viruses are not affected by ether and are destroyed by antiseptics with much greater difficulty than bacteria, for which reason 0.5-percent phenol can be used effectively as the standard preservative of vaccinia virus. The peculiar potency of iodine is probably due to its deleterious oxidizing activity. The viruses like the germinal cells are sensitive, too, to radiation. In experiments with herpes, Gundersen showed that ultraviolet rays are not the answer, nor probably are beta rays. In the eye, the local action of antiviral remedies can be easily observed. Now that radioactive isotopes are available, perhaps the proper radiation could be given by incorporating radioactive iodine in Cowen's solution and simply instilling the eye drops at proper intervals.

Numerous questions in regard to the local mechanisms of resistance to virus disease require solution. Why are some eyes more susceptible than others to the herpes and influenza viruses? Does the conjunctival secretion contain a substance capable of inactivating certain viruses? If so, it is probably something other than lysozyme. Why is the gastro-intestinal tract immune to virus infection? Is it because of the proteases and nucleinases present, and what action do these enzymes have on viruses? If virus disease is to be conquered, these problems among others must be resolved.

James E. Lebensohn.

A COURSE FOR ORTHOPTIC TECHNICIANS

Orthoptics as an important part of ophthalmic practice has become well established, after two earlier upsurges followed by recessions. It is an essential part in the intelligent treatment of many ocular muscle abnormalities, especially those associated with strabismus. Such opposition as there has been by ophthalmologists to orthoptics has been based largely on lack of understanding of its possibilities and limitations, furthered by disinclination to devote the necessary amount of time to this training and, to be honest, the disinclination to expend energy on meticulous and tedious work with uncoöperative and naturally unappreciative little children. Combine all of this with the recognized fact that complete success is the exception rather than the rule and that many cases prove, after much sweat and tears, to be quite unresponsive to treatment, and the reasons for the cold shoulders that many eye surgeons have turned to muscle and fusion training become obvious.

Granting that the practice of orthoptics is worthwhile and admitting that most oculists will not incorporate it into their personal activities, the obvious answer is the development of technicians. This has not proved easy. Few eye physicians were sufficiently conversant with the subject to be competent instructors and of those so qualified only a minimal number had the time, the facilities, or the inclination to give such teaching. Gradually, however, a small number of orthoptists, the earliest in the field being largely self-trained, became technicians in response to the demands of the ophthalmologists. There are as yet less than 100 certificated technicians practicing in the United States. By certificated, reference is made to certification by the American Orthoptic Council, which, coming into existence some 10 years ago, has sponsored and helped conduct examinations of those technicians desiring to take them who had met the preliminary requirements of the Council. The procedure is similar to that carried on for ophthalmologists by the American Board of Ophthalmology.

One of the principal difficulties for these prospective technicians, for whom there are of course no internships available for preliminary training, has been to get basic instruction and practical experience. This has been done in a somewhat unsatisfactory manner by university, clinic, and private preceptorships. Some students have received excellent ground work, others poor. There has been no uniformity. Not only has the training in many cases been sketchy, but it has been impossible to find enough places for the training of those desiring to study orthoptics. As a result there are not enough orthoptists for the ophthalmologists who wish to employ such qualified workers.

One step toward solution of this problem appeared to the American Orthoptic Council to be centralization of basic training preliminary to practical training. The former has been the more difficult to obtain, whereas there are many clinics, groups, and private offices where the latter can be learned, provided that a good foundation has been previously acquired.

Accordingly, largely through the efforts of Dr. Walter Lancaster, a course in fundamentals is to be given this year utilizing the facilities of Nasson College in Springvale, in the township of Sanford, Maine, June 28th to August 28th for prospective orthoptic technicians. The course will be under the direction of Dr. Lancaster who will also give an important part of the instruction. Among others who have generously volunteered to contribute an average of a week of their time to the program are Dr. LeGrand Hardy, who has undoubtedly done more than any other man toward the establishment of the American Orthoptic Council, of which for its first nine years he was president, and toward organizing the American Association of Orthoptic Technicians. He has given life and impetus to the entire program. On the faculty will be Drs. Adler, Swan, Costenbader, Regan, Beach, Burian, and Fralick. Tentative understandings have been arrived at with other ophthalmologists, but, because at the moment of writing the plans have not been completed, their names are omitted. Several widely known certificated orthoptists will be present to give lectures and individual instruction in the use of the special instruments that they employ.

Among the subjects included in this course are Anatomy, Physiology, Refraction, Optics, Diagnosis, and Treatment. Important also are courses in psychology, especially as applied to the child.

Following this two months' course, technicians will receive assignments throughout the country for their practical instruction which, at most places, will be for from eight to ten months. Thereafter, if their work has been satisfactory, they will be recommended for examination for certification.

The plan appears to be a sound one for unifying instruction and ultimately providing more technicians and should receive coöperation from ophthalmologists on whose

good will much of its success depends. The specifications of the course are published in "News Items" in this issue of the JOURNAL for the benefit of those desiring such information. It is anticipated that this course will prove such a success that it will be repeated annually.

Lawrence T. Post.

OBITUARY

CHARLES PORTER SMALL
(1863-1947)

Dr. Charles Porter Small was born at Bangor, Maine, November 16, 1863, the son of the Rev. Albion Keith Small and Thankful Lincoln Small. He died at Princeton, Illinois, September 25, 1947.

After his graduation from the Fall River, Massachusetts, High School in 1882, Dr. Small entered Colby College from which he was graduated in 1886. In 1889, he received his medical degree from Bowdoin Medical College and served a two-year interneship at the Maine General Hospital.

For two years, 1890 to 1892, he was in general practice at Waterville, Maine, but, in 1892, he came to the new University of Chicago and became its first physician in charge of student health.

Five years later, after preparation in Vienna, Dr. Small entered the field of ophthalmology and practiced his specialty in Chicago until his retirement nearly 40 years later. During these years, he was clinical associate of the Eye Department, Rush Medical College; clinical assistant, Northwestern University Medical School, and instructor in ophthalmology at the Chicago Polyclinic Hospital.

In 1914, Dr. Small became associated with Dr. Casey Wood, both in the practice of ophthalmology and in the editorship of the *Ophthalmic Record,* of which he was the secretary-treasurer. This publication was absorbed by the *American Journal of Ophthalmology* in 1919. Dr. Small was also a collaborator on the *American Encyclopedia of Ophthalmology, the Ophthalmic Yearbook,* and editor of the Eye Section of the *Practical Medicine Series.*

During World War I, Dr. Small served as a captain in the Aviation Examination Unit and was stationed both at Rock Island, Illinois, and Washington, D.C.

Dr. Small was a member of the American Medical Association, the Illinois State and the Chicago Medical Societies, the Physician's Club, Delta Kappa Epsilon, Phi Chi, and the Chicago Ophthalmological Society of which he was president in 1925.

E. V. L. Brown.

CORRESPONDENCE

CONCERNING DR. VAN HEUVEN

Editor,
American Journal of Ophthalmology:

On occasion of your report of Dr. van Heuven's speech at the January (1947) meeting of the Cleveland Ophthalmological Club (Am. J. Ophth., 30: 535 (April) 1947) I want to declare:

On the contrary, Dr. van Heuven's political feelings during the German occupation were very ambiguous. In the course of the occupation, he secretly subscribed to the Nazi-organization of Physicians (Nederlandts Artsenkamer). Furthermore, he published scientific articles in German journals (Zeitschrift für Psychologie und Physiologie der Sinnesorganen).

For these and other reasons his name was struck out from the list of the Dutch Medical Association after the liberation and to escape difficulties, he withdrew his name from the Dutch Ophthalmological Society.

(Signed) G. H. Jonkers,
Former Medical Staff Officer,
Dutch Underground Forces,
Utrecht, Holland.

Corneal transplantation: Truth and myth

Editor,
American Journal of Ophthalmology:

"A unique case of Elschnig, reported by Ascher, was cited of a 12-year-old boy whose one eye suffered from deep keratitis. The cornea of this eye was trephined without receiving a graft. After seven years, the defect was replaced by completely transparent tissue."

This I read in the excellent paper by Katzin and Kuo in the February issue of the JOURNAL, and I felt as if I were dreaming. Never had I heard of such a case; so, I went over my old publications and found on page 352 of the 1919 paper, quoted by Katzin and Kuo, their description as translated in the JOURNAL but with a headline saying in italics that this was a lamellar keratectomy; that is, a removal of the uppermost layers of the corneal parenchyma with preservation of the deeper strata. From the authors' quotation, however, it seemed to be a penetrating, not lamellar, trephination without replacement of an implant.

Elschnig's original, but always highly conscientious indications, never would have arrived at such a hazardous procedure. Even then, the operation quoted by Katzin and Kuo was a beautiful result and, most probably, the first successful lamellar keratectomy ever performed. How happy would Elschnig be to see that "his" corneal transplantation for which he fought through five lustrums, finally has been recognized as a useful procedure in well-selected cases, and is not just a fancy of a periculant imagination; that even his indications and contraindications essentially prevail.

A minor error in the quotation of the recent authors is that they located my histologic investigations in the 1919 clinical paper; the publication about the histology of keratoplasty appeared four years later, in Graefe's Arch. f. Ophth., 111:446-459, 1923.

(Signed) K. W. Ascher,
Cincinnati, Ohio.

Ophthalmic findings for and against sympathectomy for hypertension

Editor,
American Journal of Ophthalmology:

There is a wave of "jitterbug" surgery spreading through the large medical centers of the United States purporting to give relief by surgery from symptoms incident to hypertension. Thoracolumbar sympathectomy is one of the spectacular new-style procedures.

The ophthalmologist is especially concerned (or was at least concerned yesterday) in this new life-saving phenomena, because it is necessary that he classify the fundus findings into the artificial and arbitrary grading of Keith and Wagener, who designated four grades of vascular disease.

If the arteriolar changes in the eyes of the patient are graded in the first two groups indicating a very mild or a mild-plus type of sclerosis without any hemorrhages, then the patient is a good risk for sympathectomy in one or two stages, the operation being subdiaphragmatic or transdiaphragmatic or combined subdiaphragmatic and superdiaphragmatic. The surgeon has his choice depending upon how much courage he has.

In recent months, sympathectomy for the relief of hypertension has been recommended to include all stages of retinal arterial disease, regardless of the experience and objections of the older ophthalmologists who know that young adults with hypertension, associated with explosive vascular changes and including fluid and cellular infiltration of the optic nerve, are doomed to live a very short life.

Smithwick was first inclined to confine sympathectomy to moderate grades of arterior changes in the retina. Bolder surgeons are claiming results in cases of advanced retinopathy.

Dr. Arthur Bedell delivered a very splendid paper at the Philadelphia College of Physicians on January 21, 1948, proving by case records that sympathectomy was a dangerous operation in patients exhibiting a retinopathy

having grades three and four of vascular and retinal changes. Despite this experience, it was brought out in discussion by two surgeons present that sympathectomy might be extended to advantage to all grades of retinal destruction.

In the June (1947) issue of the *Pennsylvania Medical Journal* is a report by John Wesley Shirer, Pittsburgh, indicating that there is a possibility of prolonging the life of patients regardless of the stage of vascular disease as found in the retina.

Recently I treated a woman for hypertensive retinopathy associated with choked discs of both eyes accompanied by multiple vascular ruptures. The medical consultant insisted upon a sympathectomy on the grounds that my patient, who is now 50 years of age, might live five years longer. I refuse to accede to his recommendation. The patient is still living and comparatively happy to date.

Another patient seen by me in the past month, a young man in his early forties, has a malignant hypertension accompanied by definite kidney damage and retinal changes of an advanced type showing edema of the discs and tremendous retinal hemorrhages and star figures. Much against my advice a sympathectomy was performed on the patient a few weeks ago. At this present moment he is convalescing and the outcome is guarded.

Several years ago, two cases of sympathectomy performed for retinitis pigmentosa were reported at the Philadelphia College of Physicians. One of these patients recently applied to me for certification for blind pension. One does not read much in the literature today about sympathectomy for retinitis pigmentosa.

In my student days there was a Dr. Janesco, a foreigner who came to this country to display his skill in the treatment of glaucoma by cervical sympathectomy. Of course no one performs this operation for glaucoma today. Spectacular surgery has its day in print like Cueism and Mesmerism.

The point of issue is that the ophthalmologists should not be easily persuaded by the surgeons to recommend surgical intervention in cases of hypertension of long standing with extensive retinal damage. Merely reducing the pressure for the patient by a serious surgical procedure at a time when that patient is critically ill is neither wise nor logical.

I doubt whether anyone wishes to live or to have death postponed when there is present a constant threat of hemiplegia, coronary disease, or renal disease developing at a later period, incapacitating him to a life of invalidism. Unless the patient can be given reasonable assurance of his ability to return to a normal way of feeling, thinking, and acting, then the surgeon should not recommend such a serious operation as sympathectomy which is but a temporizing procedure.

We older ophthalmologists should hold to our philosophic point of view that just living is not life. When surgeons give statistics to the effect that the patient may live five years or more, we oldsters, in turn, should ask whether that patient will live a normal life or merely live every day in fear that he may not be able to reach the other side of the street.

I wish to join with Dr. Bedell and all other ophthalmologists who have had years of experience in recognizing the inescapable and not reversible path of certain systemic diseases as reflected in the eyes.

Miraculous things are happening in medicine, but these are principally in the field of preventive medicine. No one wishes to discourage the young surgical scientist from trying something new, but at no time must he achieve that aim by hastening the end by one minute, or by prolonging life for five years or more, when that is attended by mental suffering.

He must not play with God.

(Signed) Louis Lehrfeld,
Philadelphia, Pennsylvania.

Appeal for donations of slitlamps and other instruments for China

Editor,
American Journal of Ophthalmology:

For the past several years a nationwide campaign has been carried on in China to combat trachoma. This is largely supported by the National Blind Welfare Association whose sister organization in the United States is the Institute for Chinese Blind, 156 Fifth Avenue, New York City. The former secretary of the campaign organization, Dr. Pang Hsien Chen, writes that the need for instruments and supplies is most urgent. Six centers and 21 full- and part-time clinics have been set up in Free China but such equipment as slitlamps, ophthalmoscopes, operative instruments, tonometers, microscopes, and so forth, are lacking. Accordingly, the Howe Library of Ophthalmology is acting as a clearing house for the sending of available material to China. It is hoped that those ophthalmologists, and others, who have used slitlamps or other ophthalmologic equipment which they care to part with for this purpose, will contact us and arrangements will be made, so long as funds for transportation become available, to send them to China. All communications should be addressed to Miss Jeanette Loessl, Howe Library of Ophthalmology, 243 Charles Street, Boston, Massachusetts.

(Signed) David G. Cogan,
Boston, Massachusetts.

BOOK REVIEWS

CLINICAL NEURO-OPHTHALMOLOGY. By Frank B. Walsh, M.D., F.R.C.S. (Ed.). Baltimore 2, Maryland, Williams & Wilkins Company, 1947. Clothbound, 1,532 pages, illustrated. Price, $15.00.

It is impossible to do justice to a 1,500-page text in a brief review. Naturally one could not read the whole of it without delaying the review unduly. It is understandable that such an ambitious undertaking as the composition of this treatise required 10 years as the author tells his readers in his foreword. Furthermore, the accomplishment over so long a period must have entailed frequent rewritings even before the book was finished because of new material available during that time.

Examination of the table of contents which in itself covers 15 pages reveals the wide scope of this book and the many ramifications which are included. The first 90 pages are devoted to the visual pathways; their anatomy; descriptions of lesions in various parts of these nerves and tracts and the resulting disorders. Chapter two, of 60 pages, covers the anatomy and pathology and topical diagnosis of the other cranial nerves that have some relation to vision.

Throughout the book there is a multiplicity of illustrative cases, perhaps the most fascinating part of a fascinating book. One gets started on a subject and can lay the book down only with great reluctance.

The wealth of material would be unbelievable if it were not realized that, because of the size and importance of the Hopkins group of hospitals, much of the most unusual clinical material in our country finds its way through those doors.

The chapter on "Infections and Parasitic Invasions of the Nervous System and Their Ocular Signs, Including an Outline of Nervous System and Ocular Syphilis" covers almost 200 pages, the latter "inclusion" occupying about 80 pages. The frequent mention of numbers of pages is cited to impress upon the mind the completeness of this textbook, and it must be taken into account that the convenient two-column form is used, the pages are large, and the print easy to read. Many beautiful illustrations help to clarify and dramatize the text. Most of these cuts are from photographs although there are also excellent line cuts.

As is to be expected, "Tumors and Related Conditions" cover about one sixth of the book. The Johns Hopkins Hospital has been

traditionally a Mecca for the study and treatment of intracranial neoplasms since the pioneering work of Cushing and his famous successor, the late Dr. Dandy, has attracted there an abundant wealth of this material.

The reviewer is impressed with the extensive references. The author obviously did an enormous amount of collateral reading to make the book different from other texts on this subject. This and his own personal observations make the book a pleasantly intimate one.

The principal adverse criticism has chiefly to do with the size and weight of the book which is very difficult to handle. One keeps asking himself why not the same material in two volumes.

There is an excellent index of over 100 pages, the compilation of which alone must have required endless hours.

In summary, this is a wonderful reference book and, in addition, is so interestingly written that many pleasant hours can be spent rambling through its pages with only the thought of diversion.

Lawrence T. Post.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF AUSTRALIA. Volume IV, 1944, and Volume V, 1945.

After three years the Ophthalmological Society of Australia has again published a record of its meetings. In a group of essays various aspects of industrial ophthalmology are discussed. E. C. Black records some observations on the eye injuries of railway employees and considers methods of preventing them. L. D. Wright and A. L. Tostevin call attention to the importance of lighting in eyesight conservation.

Several papers deal with tropical ophthalmology. It is pointed out that there is an increased incidence of herpes-simplex keratitis in a population heavily infected with malaria but that there is little likelihood of precipitating a dendritic ulcer in a single case of therapeutic malaria.

J. Bruce Hamilton contributes an important analysis of tuberculous lesions of the eye. Among others, phlyctenulosis, Eales's disease, and heterochromic cyclitis are supposed allergic tuberculous eye infections. Three contributions add further clarity to the problem of congenital defects in infants following maternal rubella. An extensive and valuable analysis of crossed cerebral dominance is contributed by J. Ringland Anderson and Celia Weigall. Problems arise from the presence of a master hand and a master eye on opposite sides, and understanding of this condition is of the greatest importance in the management of diplopia and strabismus. The entire essay should be read.

In Volume V of the year 1945, C. G. McDonald contributes a comprehensive discussion of diseases of the arteries and their relationship to the eye. A table of salient facts makes perspicuous the corresponding names in pathologic classification, clinical classification, and clinical manifestation. This long discussion holds little that is not well known to the ophthalmologist about the fundus but presents with the utmost clarity the knowledge of internal medicine which is of the greatest use to the ophthalmologist in understanding processes of which he himself observes only a part.

The remainder of the volume consists of short interesting essays on a great variety of topics. There are several papers on phases of cataract extraction, one on ocular manifestations of malnutrition in returned prisoners of war, one on toxoplasmosis, one on sarcoidosis, and one on traumatic monocular glaucoma. The author of the last-named reports 18 cases and believes it to be a clinical entity which is conspicuously absent in ophthalmologic literature.

F. H. Haessler.

TRANSACTIONS OF THE SOCIÉTÉ BELGE D'OPHTHALMOLOGIE. No. 2. Jubilee meetings of September 28, 29, and 30, 1946, pp. 1-175.

This memorial volume opens with a short history of the Société Belge d'Ophthalmologie and its most famous members. It also contains many interesting and original papers. M. Alaerts reports on the human eye in the works of art. In discussing several of the most famous paintings, the author demonstrates the importance of the positions of the eyeballs, the lids, and their surroundings and stresses the variations in the expression of the face by making the most minute changes in the position of any of those structures. These facts are especially instructive for surgeons who not only intend to correct deformities or vicious scars but who also try to give to their patients a pleasant appearance, more compatible with their social life.

Beauvieux discusses the apparent blindness of the new-born, the gray pseudo-atrophy of the optic nerve. The author considers it to be a transitory congenital malformation, namely, a late development of the myelin-sheaths of the optic pathways. The prognosis is much more favorable than that of permanent blindness in retinal atrophy, which has comparatively small disc changes or disseminated chorioretinitis of syphilitic origin.

F. W. Law (London) reports on ophthalmic experiences and achievements during the war years. Zeeman describes his investigations of disturbances of the posterior ciliary arteries. Amsler emphasizes the increasing importance of diagnostic anterior-chamber paracentesis, the chemical and cytologic examination of the aqueous, the fluorescein test, and the quantitative grading of the Tyndall-phenomenon in clinical work. Those tests, although still incomplete, should lead to a better knowledge of the inadequately known vegetative functions of the eye.

G. Renard reports three case histories on sympathetic ophthalmia cured by subconjunctival injections of a 33-percent solution of a sulfonamide in increasing doses. E. Wolff recommends daylight in slitlamp examinations of precorneal films. G. P. Sourdille discusses such technical details in corneal transplants as retrobulbar alcohol injection in hypertension, iridectomy to prevent secondary adhesions, and the advantages of a light-weight trephine. H. Mantiulio surveys his and other authors' experiences on nicotinic acid as a retinal vasodilator.

Mme. S. Schiff-Wertheimer and Le Menn studied the relationship of retinitis proliferans and retinal detachment and they distinguish three different groups which not only differ in their clinical picture but also in their reactions to surgery and to clinical and anatomic cures. G. Renard presented four patients with central retinitis, apparently of tuberculous origin, characterized by the delicacy of the retinal lesions, the severe disturbance of vision, and the complete spontaneous recovery.

Alice R. Deutsch.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

5

DIAGNOSIS AND THERAPY

Cattaneo, D., and Carlevaro, G. **An ophthalmodynamometer for the measurement of the pressure in the ciliary vessels.** Ann. di ottal. e clin. ocul. 72:711-718, Dec., 1946.

The instrument described and pictured is like the familiar impression tonometer in general construction and appearance. The aluminum plunger works against two opposing springs so adjusted that the curve of variation for the different weights is as rectilinear as possible. This system of compensating springs makes it possible to shift the range of measurement, which is about 50 mm. Hg, to the interval required in the individual case. Instead of the footplate of the tonometer there is a totally reflecting prism, the surface of which measures about two square millimeters and is slightly curved to fit the sclera. With the aid of a loupe the examiner may observe the obliteration of the blood column in the vessels when the prism is applied to the eye. The instrument may also be used for measuring the pressure in the retinal vessels.

Seidel's and Duke-Elder's observations with respect to ophthalmodynamometry are reviewed, and an attempt is made to establish criteria for evaluation of the measurements obtained.

Harry K. Messenger.

Clark, W. B. **Local use of "sulfamylon" (Para-[aminoethyl]-benzene sulfonamide hydrochloride).** Arch. Ophth. 38:682-683, Nov., 1947.

Clark reports favorably on the use of "sulfamylon" in controlling contaminations with B. pyocyaneus. In no case was a sensitivity to the drug encountered.

R. W. Danielson.

Gilbert, W. **The prophylaxis and treatment of expulsive hemorrhage.** Klin. Monatsbl. f. Augenh. 112:149-156, 1947.

General and local lesions in the blood vessels and hypertension of at least 180 mm. predispose to expulsive hemorrhage. These conditions are frequently combined with high myopia and sometimes with other abnormalities of the eye such as corneal opacities or glaucoma. The danger lies in the opening of the vascular channels as well as in the sudden release

of the intraocular pressure. The author advises a preparatory iridectomy and venesection immediately before the cataract operation itself. The second eye of a patient who lost one eye through expulsive hemorrhage may be trephined prophylactically in the equatorial region of the bulbus. Posterior trephining in combination with venesection and a large conjunctival flap may sometimes save an eye that is undergoing an expulsive postoperative hemorrhage. Most eyes are, however, lost and prophylaxis is the most important factor. (20 references.)

Max Hirschfelder.

McGuire, W. P. **A corneal scissors.** Am. J. Ophth. 31:217, Feb., 1948.

Selinger, Elias. **Iontophoresis with contact lens type and eyecup electrodes.** Arch. Ophth. 38:645-653, Nov., 1947.

Selinger discusses the theory of ion transfer and the technique of using his instrument. In order to drive the proper ions into the tissues, one should know whether one wants to carry the ions with the positive or with the negative electric charge. The electrodes are then arranged in such a way that the flow of the current is through the tissues of the eye toward the indifferent electrode held in the hands.

A list of drugs arranged according to the polarity of the electrode to be used is given. Since iontophoresis causes a concentration of ions in the tissues and also prolongs the action of drugs, only weak solutions should be used. The following concentrations of the drugs have been found effective by different authorities: penicillin, 1,000 Oxford units per cc.; sulfonamide drugs, 5 percent; atropine, 0.25 percent; pilocarpine, 0.1 percent; acetylcholine, 1:400; quinine salts, 0.5 percent; calcium salts, 0.5 percent; epinephrine, 1:20,000; zinc sulfate, 0.25 percent.

R. W. Danielson.

Valerio, Mario. **Advantages of the combined use of heparin and dicumarol in the treatment of thromboses of the retinal veins.** Ann. di ottal. e clin. ocul. 72:719-725, Dec., 1946.

Heparin acts rapidly and briefly, and must be given intravenously. The action of dicumarol is preceded by a period of latency but is prolonged. Dicumarol may be given orally, and is much more economical than the very costly heparin. By the combined use of the two a maximal effect can be obtained promptly, and the required concentration of prothrombin in the blood can be maintained more readily than by the use of either drug alone.

Anticoagulant therapy is the treatment of choice in thromboses of the central retinal vein, but the dosage must be carefully regulated and the treatment prolonged. Treatment must be started early if good results are to be expected and sometimes should be supplemented with roentgenotherapy.

Harry K. Messenger.

6

OCULAR MOTILITY

Ambrose, Anthony. **Diagnostic muscle chart for determination of tropias, phorias, diplopia and muscle action.** Arch. Ophth. 38:681, Nov., 1947.

A chart is presented for use in the determination of tropias, phorias, diplopia and extraocular muscle action.

R. W. Danielson.

Berke, R. N. **Tenotomy of the superior oblique muscle for hypertropia.** Arch. Ophth. 38:605-644, Nov., 1947.

Berke discusses the operations that have previously been devised for relief from overaction of the superior oblique, and concludes that the condition is best treated by tenotomy or tenectomy of the offending muscle. This operation is best done under Tenon's capsule on the nasal

side of the superior rectus according to the technic here described. For adults local anesthesia is sufficient. For children a general anesthesia is necessary. Simple tenotomy will produce from 5 to 10 degrees of correction. A tenectomy will produce from 10 to 30 degrees of correction, depending on the amount of tendon removed and the amount of overaction present. This operation does not produce paralysis if the sheath is not severed with the tendon.

In the past nine years, 20 tenotomies or tenectomies were done on 13 consecutive patients. In none of these patients was a discernible weakness of the superior oblique muscle produced. In four out of ten tenotomies the tendons were presumably incompletely severed and the results were unsatisfactory. In all the tenectomies the result was good. (13 case reports are given.)

R. W. Danielson.

Candler, R. G. **The response of personnel affected by head injury to orthoptic treatment. Tr. Ophth. Soc. U. Kingdom** 65:57-63, 1945.

The author states that experience supports the view that orthoptic treatment provides a helpful background for recovery in defects of convergence and accommodation. The psychological approach which is possible with the treatment provides valuable help in the restoration of visual confidence for those patients with temporary paresis of extrinsic ocular muscles. Beulah Cushman.

7

CONJUNCTIVA, CORNEA, SCLERA

Almeida Reboucas, J. **Corneal ulcer from diplobacillus liquefaciens (Petit).** Rev. brasil. oftal. 6:87-99, Dec., 1947.

After describing the characteristics of this organism, the author relates a clinical case in a man of 27 years. A corneal ulcer was successfully treated with subconjunctival injection of penicillin dissolved in a 2-percent solution of novocaine, supplemented with 7-percent sodium sulphathiazole and 5-percent ointment of the same drug. The author distinguishes the Petit diplobacillus from the Morax-Axenfeld. With the former, corneal ulcer is always primary. The organism liquefies gelatin, grows abundantly on plain agar at ordinary temperature, and does not produce acid with the sugars. (References.) W. H. Crisp.

Bietti, Giambattista. **Results of penicillin therapy of trachoma.** Boll. d'ocul. 26: 209-226, April, 1947.

One hundred and fifteen patients received calcium or soduim penicillin, most of them an ointment containing 500 to 1000 Oxford units per gram, which was applied 4 to 12 times each day. Previous to, and during the medication, scrapings from the conjunctiva were searched for inclusion bodies and for evidence of secondary infection. The latter disappeared within 2 to 4 days after therapy started; the trachoma bodies took longer to disintegrate. The patients felt a definite relief after 24 hours; the conjunctival discharge regressed before the sixth day. Papillary hypertrophy and the typical granules receded slowly. Frequency of application enhanced the amelioration. In 43 cases of fresh trachoma, complete or almost complete healing was observed after 135 to 200 days of treatment. General treatment with sulfa drugs was followed by improvement in 10 patients of this group when penicillin had failed. For corneal complications penicillin was superior to the sulfa drugs. Xerophthalmia was favorably influenced as long as the therapy lasted. No untoward reactions were encountered in the whole group.

The prophylactic significance of this treatment is stressed. (5 photomicrographs.) K. W. Ascher.

Colenza, Domenico. **Marginal degeneration of the cornea.** Boll. d'ocul. 26:254-269, April, 1947.

Two cases of marginal corneal dystrophy, one of them coincident with a unilateral herpes zoster are reported. This lead the author to assume a neurodystrophic etiologic factor to explain this rare degenerative corneal disease. (Extensive bibliography.) K. W. Ascher.

Giardini, Aniceto and Farina, Luigi. **Conjunctival microsporid in the course of inflammatory cutaneous microsporia.** Ann. di ottal. e clin. ocul. 72:690-698, Nov., 1946.

The authors describe an acute conjunctivitis in the left eye of a 9-year-old girl who for two months had had an inflammatory microsporia on the back of her right hand. The conjunctivitis was characterized by typical lymphatic follicles localized predominantly in the lower cul-de-sac and by vesicles and hypertrophied papillae on the upper tarsal conjunctiva. Numerous eosinophils were found in smears, but no fungi or pathogenic organisms in either smears or cultures. Inclusion bodies were sought but not found. Microsporum lanosum was recovered from the lesion on the hand. A subcutaneous injection of trichophytin produced a generalized reaction, a focal reaction at the seat of the skin lesion, and a marked accentuation of the conjunctival manifestations. A second injection (for therapeutic ends) was followed in addition by a conjunctivitis in the right eye, which previously had been normal.

The skin lesion regressed under local treatment and with subcutaneous injections of trichophytin, and healed within twenty days. The ocular lesion also regressed, but a little more slowly. The eye was normal after forty days. It had received no local treatment other than irrigations with physiologic salt solution twice a day.

On the basis of the data pertaining to this case and of the very few similar cases reported in the literature the authors regard the conjunctival lesion as a microsporid, that is, a localized manifestation of an allergic state directly dependent on a mycotic focus in the skin.

Katzin, H. M., and Kuo, P. K. **Histologic study of experimental corneal transplantation.** Am. J. Ophth. 31:171-190, Feb., 1948. (16 figures, 2 tables, 47 references.)

Law, Frank W. **Treatment of corneal nebulae by contramine.** Tr. Ophth. Soc. U. Kingdom. 65:173-179, 1945.

The author reports on the experimental work that Col. W. W. Jeudwine had carried out before his death. The work was so nearly completed that it was considered wise to report the results.

Contramine is the carbon disulphide product of di-ethylamine. The drug acts by virtue of its sulphur atom which has the effect of dispersing protein which has undergone the abnormal chemicophysical changes of dehydration and rehydration. The dispersion effected has an influence in causing the dissolution of fibrous tissue in the process of formation. The action is stated to be directly upon the protein in the blood, which is contracted and causes a diminution or disappearance of the lesions and manifestations. The preparation is toxic if the protein becomes overcontracted as a result of overdose.

Treatment is carried out with a small dose of 0.025 gm. to 0.125 gm. Six weekly injections constitute a course and four courses were given with an interval of

three months between courses. Twenty-five patients were treated and a table of the vision before and after treatment is included.

Six patients with recent corneal nebulae showed definite improvement and five of the nineteen with long standing conditions showed definite improvement, seven showed no improvement, five showed an improvement of one line, three of two lines and one of three lines on the Snellen chart.

The author concludes that the cases presented are not truly relevant but do provide adequate reasons for further trial. (2 tables.) Beulah Cushman.

Lordan, J. P. **Ophthalmological progress: sight restoration by corneal transplant.** California Med. 68:90-94, Feb., 1948.

The author surveys the early literature on the subject and reviews the present knowledge. The advantages of the different methods of keratoplasty are summarized and the technique of handling donor tissue is described. The establishment of eye banks has greatly facilitated the procurement of suitable graft material. O. H. Ellis.

Nairac, M. L. **An unusual case of symmetrical, bilateral, non-traumatic iris prolapse.** Brit. J. Ophth. 31:700-702, Nov., 1947.

On the Island of Mauritius, a young Negro woman complained of a sudden burning pain in the right eye followed by a fluid discharge. The following day the left eye became similarly affected. Pain and photophobia were intense. She was first seen two weeks later when each eye presented a large staphyloma in the upper quadrant. The pupils were irregular and drawn up. There were no signs of injury or even of any inflammation. The pupils dilated well to atropine. After cauterization with the electric cautery (the left bleb ruptured during the process) and covering the defects with thick conjunctival flaps healing occurred uneventfully. The most probable etiological explanation is that acute conjunctivitis with corneal ulcers was present and that these were ruptured by blepharospasm and rubbing. The curious aspect was the absolute symmetry of the lesions.

Morris Kaplan.

Rosso, Silvio. **Retrobulbar alcohol injections: indications, therapeutic action, and possible applications in postoperative complications of keratoplasty.** Ann. di ottal. e clin. ocul. 72:671-678, Nov., 1946.

Because of an early iritic reaction (photophobia, lacrimation, ciliary injection) following keratoplasty a patient was given a retrobulbar injection of 40 percent alcohol about ten days postoperatively. The irritation was relieved, and about three weeks later when the bandage was removed the cornea was clear; two months later the vision was nearly 10/10.

Another patient, who had previously had an unsuccessful keratoplasty, underwent a second operation of the same kind. For two weeks the transplant remained clear, but then became cloudy, and there was a rise of ocular tension. Two retrobulbar injections of 60 per cent alcohol were given at an interval of 12 days, and six weeks later the transparency of the graft was satisfactory.

An alcohol injection gives rise to anesthesia or hypesthesia, vasodilatation, and hypotension, alters the osmotic pressure of the blood and of the tissues, and causes dehydration. If injected into the region of the opticociliary nerves the alcohol causes temporary lowering of the ocular tension. Likewise vasomotor reactions produced by alcohol seem to mobilize those histiocytic elements which participate actively in the repair of corneal lesions. Because of the sedative effect of the alcohol the graft is exposed to less risk.

The strength recommended is 40 percent and one cc. is considered sufficient.

Sydenstricker, V. P., Hall, W. K., Bowles, L. L., and Schmidt, H. J. **The corneal vascularization resulting from deficiencies of amino acids in the rat.** J. Nutrition 34:481-487, Nov. 10, 1947.

Rats of the Wistar strain were divided into control and deficiency diet groups. Quite regularly the first sign of ocular reaction to deficiency of amino acids or of protein is congestion of the scleral conjunctiva and engorgement of the limbal plexus. Following soon after this is slight thickening and diffuse corneal clouding, probably due to edema. Capillary "sprouts" shoot from the marginal limbal vessels. Diffuse nebular corneal opacities were seen in some. Phenylalanine, violeucine, threomine, valine, and arginine deficiency diets resulted in vascularization of the cornea. Protein-low diets in which any one of the ten essential vitamins is absent may result in vascularization of the cornea in the rat. F. M. Crage.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Esente, Ivan. **On a case of a mesodermal cyst of the iris in an eyeball with a previous perforating wound of the cornea.** Ann. di ottal. e clin. ocul. 72:597-609, Oct., 1946.

A case of a serous mesodermal cyst of the iris in the right eye of a 39-year-old man is described. Four years before the cyst was discovered the cornea of the affected eye had suffered a small perforating wound in the part overlying the cyst. Pathologic examination showed that both the inner and outer walls of the cyst were lined with endothelium, hence its truly mesodermal nature. For an explanation of the pathogenesis of the cyst Esente favors the theory of Hosch (1874), according to which trauma may result in obstruction of a crypt of the iris and thus cause a retention cyst, especially, adds Esente, in an eye such as this, which was genetically imperfect, as shown by extensive congenital pigment deposits on the anterior capsule of the lens and by the anomalous ("spherular") character of the pigment border of the iris.

The literature of iris cysts and their pathogenesis is reviewed at length.

Taliercio, A. **A case of iridocyclitis and optic neuritis from a focus of infection in the appendix.** Ann. di ottal. e clin. ocul. 72:663-670, Nov., 1946.

A 26-year-old agricultural worker had suffered for a year with severe and painful iridocyclitis that had resisted all treatment. Because of attacks of right-sided abdominal pain a diagnosis of chronic appendicitis was made, and an appendectomy was performed. Ten days later the eye was strikingly improved. Pain and tenderness had disappeared, the circumcorneal injection was much less, and a great part of the exudate in the anterior chamber had been absorbed. Previously the entire lower half of the cornea had been covered with thick lardaceous exudates. The fundus could now be seen for the first time, and it was noted that the optic disc was hyperemic and had blurred margins. Three weeks later the iridocyclitis was inactive, and the hyperemia of the disc had given way to pallor.

There can be no doubt of a causal relation between the appendicitis and the

ocular inflammation. The question of focal infection in general is reviewed, with particular reference to the work of Rosenow and his followers. It seems probable to Taliercio that the disease of the eye is due not to the presence of bacteria in the ocular tissues but to bacterial toxins with an elective tropism for ocular tissues. Harry K. Messenger.

Unger, Kuno. **Neurofibromatosis iridis. (Recklinghausen's disease).** Arch. Ophth. 38:654-659, Nov., 1947.

Two cases of neurofibromatosis involving the iris are reported with a short discussion of the disease in general.

9

GLAUCOMA AND OCULAR TENSION

Comberg, W. **Mydriatics in the treatment of glaucoma.** Klin. Monatsbl. f. Augenh. 112:134-135, 1947.

Atropine and scopolamine may relieve the pain in blind or nearly blind eyes with absolute glaucoma. One can disregard the effect of the medication on the intraocular pressure. The relief from pain is due to a relaxation of the iris and a complete immobilization of the sphincter.

Max Hirschfelder.

Denig, R. **The restitution of the outflow from the anterior chamber by iridotorsion in primary glaucoma.** Klin. Monatsbl. f. Augenh. 112:97-99, 1947.

The author discusses certain aspects of his iridotorsion. The proper incision and a special spatula knife are described. It is stated that the opening in the sclera (1 mm. high and 3 mm. long) prevents the plugging of the filtering hole with iris tissue. The danger of prolapse of vitreous and ciliary body is less than in the sclerectomy of LaGrange. Denig also prefers iridotorsion in acute glaucoma.

Max Hirschfelder.

Denig, R. **Needle diathermy and its significance for sympathetic ophthalmia.** Klin Monatsbl. f. Augenh. 112:99-103, 1947.

The article reviews the history of diathermy puncture of the ciliary body from the early operation with Paquelin cautery of Fiore to the recent diathermy cautery of Strebel and Vogt. Animal experiments to investigate the mode of action of needle diathermy have never resulted in a permanent lowering of the intraocular pressure, chiefly owing to the fact that the vasomotor psychoreflex is primitive in animals. This lack of a strong psychoreflex with accompanying strong sympathetic reactions also explains the absence of primary glaucoma and sympathetic ophthalmia in animals. Needle diathermy destroys the vasomotor capillary nerves and in human beings extinguishes the sensory vasomotor reflex and psychoreflex. This results in a lowering of the intraocular pressure and, in secondary glaucoma, benefits the cyclitic inflammation. These considerations favor Vogt's diathermy puncture. According to the author's theory an undamaged uveal prolapse merely produces a glaucoma because of constant stimulation of the sensory vasomotor reflex which may possibly be increased through an exaggerated psychoreflex. In contrast, constant stimulation of a damaged and torn uveal prolapse leads by means of the vasomotor psychoreflex through direct reaction to a chemotactic inflammation which may involve the second eye in a sympathetic ophthalmia through an indirect reaction. The application of several diathermy punctures in both eyes should be helpful in sympathetic ophthalmia and should act by a depression of vasomotor reflexes and sympathetic reactions. Diathermy punc-

ture is not the surgery of choice for ordinary glaucoma. There are too many unknown factors such as the number of the destroyed capillaries, the variable behavior of the vasomotor psychoreflex, the impossibility of its destruction through the punctures: The procedure is indicated only in absolute malignant hemorrhagic glaucoma and in aphacic glaucoma.

Max Hirschfelder.

Gerard, R. **Contribution to the study of incomplete glaucoma.** Arch. d'opht. 7: 511-520, 1947.

Gerard states that the classical conception that increased intraocular pressure is primary in glaucoma, and that all symptoms are derived from this hypertension, must be abandoned. He refers to the new conception, introduced by R. Weekers, of incomplete glaucoma in which glaucoma without hypertension is one of the most typical forms. He reports five examples of this form and states that the pupillary alterations, field defects, and excavations of the disc are characteristic and differ essentially from the symptoms of optic atrophy. He states that the nerve changes noted in glaucoma without hypertension are not due to compression of the nerve by sclerosed intracranial vessels. Gerard concludes that chronic simple glaucoma results from alterations in the intraocular blood vessels. The article is documented by numerous visual field studies.

Phillips Thygeson.

Günther, G. **The intraocular pressure in absolute primary glaucoma.** Klin. Monatsbl. f. Augenh. 112:124-133, 1947.

The behavior of the intraocular pressure in 60 cases of primary absolute glaucoma was investigated. The tension curve showed the normal variation of higher night values in 56 percent of the untreated cases. In 36 percent the curves did not follow any regular pattern, and 8 percent had a continually high tension. The other eye of the same patient followed the normal pattern in 66 percent of the cases. The amplitude between highest and lowest tension was 10 mm. or less in one third, 20 mm. in another third with over 20 mm. in one fourth of the cases. These values were established during a twenty-four hour period. Medication with miotics leads to greater variations in the daily curve. Parallelism of the tension curve in the two eyes occurred in one half of the cases, but was sometimes lost after surgery. Cases of absolute glaucoma with pressures of less than 40 mm. responded well to miotics, whereas a return to normal values was rare whenever the initial tension ranged between 50 and 100 mm. Only one quarter of the patients with an eye blind from primary glaucoma had had adequate and correct treatment. Proper treatment could, in the author's opinion, have prevented blindness in at least 25 out of the 60 eyes and would have had a possible chance of success in 21 others. Early diagnosis and treatment are of paramount importance.

Max Hirschfelder.

Mügge, F. **Trephine-cyclodialysis as operation for primary glaucoma.** Klin. Monatsbl. f. Augenh. 112:104-113, 1947.

Trephine-cyclodialysis was first described in 1934 by Sallman and is, in the experience of the author, more efficient than the usual antiglaucoma operations. The operation opens the way for drainage of aqueous into the subconjunctival space. The trephine opening is made 7 to 8 mm. from the limbus in the lower outer sclera. With the patient in sitting position during the postoperative period any possible hemorrhage will drain readily through the trephine opening. A 1.5 or 2.5-mm. trephine is used. The cyclodialysis involves one-third of the total iris root. The article reports successful results in 82 percent of 28 cases, compared to only 50 percent with the Elliot trephine which

was, however, done, in more unfavorable cases. Permanent results and no postoperative infections are claimed. The theory of cyclodiathermy puncture is discussed. Mügge believes that it has an irritative influence on the secretory function of the ciliary body and that it increases the flow of aqueous. He believes that the procedure should be reserved for painful secondary glaucoma.

Max Hirschfelder.

Radnót, M. **The effect of testosteron preparations on the intraocular pressure.** Ophthalmologica 114:168-171, Sept., 1947.

Injections of a testosteron preparation named Androfort raised the ocular tension in three patients with chronic simple glaucoma.

Peter C. Kronfeld.

Toledo, Renato de. **Propedeutics of glaucoma.** Arq. brasil. de oftal. 9:101-120, 1946.

The author devotes twenty pages to a general review of the subject under various headings, including day and night variations in tension, provocative tests, gonioscopy, and clinical records. He includes a printed form of record to be used in the accumulation of clinical data.

CRYSTALLINE LENS

Alger, L. J. **Use of absorbable corneoscleral sutures in cataract surgery.** Arch. Ophth. 38:665-667, Nov., 1947.

Alger reports favorable on the use of 0000 plain surgical gut for corneoscleral sutures in cataract surgery.

R. W. Danielson.

Duverger, C., and Brégeat, P. **Some details on the intracapsular extraction of cataract.** Arch. d'opht. 7:379-389, 1947.

The authors describe their technique for intracapsular extraction. They dilate the pupil with adrenalin, administered subconjunctivally, just before operation. They use cocaine for topical anesthesia and procaine for Van Lint akinesia and retrobulbar injection. A superior rectus suture and Pley speculum are then employed. Incision with conjunctival flap is made with keratome and enlarged with scissors to the extent of one-half the circumference of the globe. A single peripheral or ordinary iridectomy is made after a single security suture has been placed at 12 o'clock.

For extraction they use the Green forceps, grasping the lens near the equator and making counter pressure with the Arruga or Daviel spoon. The rupture of the first zonular fibers below is made by lateral movements with the forceps. If the capsule should tear, traction is continued and the operation completed as an extracapsular extraction. If the complication of vitreous loss occurs, the peripheral iridectomy is always converted into a complete iridectomy except when the vitreous is entirely fluid. After the single security suture has been tied, the iris is replaced and additional sutures are then placed on each side and tied in half knots. Eserine and penicillin or a sulfonamide solution are then instilled and a monocular dressing applied. On the following day, daily instillations of 1-percent atropine sulphate solution are begun. The patients become ambulatory on the sixth or seventh day.

The authors stress particularly the advantages of keratome incision and enlargement of the wound with scissors.

RETINA AND VITREOUS

Appelmans, M. **Angiomatosis of the retina in the child.** Arch. d'opht. 7:489-510, 1947.

The author reviews the history of von Hippel's disease and refers to Charles Deval's description of it in his textbook published in 1862 and entitled, "Traite theorique et pratique des maladies des yeux." This was before the development of the ophthalmoscope and it was not until 1882 that E. Fuchs described the ophthalmoscopic appearance of the disease. Appelmans reports a case in a boy of four years. The right eye developed strasbismus at the age of two, and at four years of age the father noted a metallic reflex in the pupil. Ophthalmoscopic examination revealed a lobulated grayish vascular tumor of the retina with numerous white and yellow spots scattered over the surface. The left eye was normal. The tumor increased in size steadily over an observation period of two years. The blind eye was enucleated and microscopic study showed a complete detachment of the retina with a capillary angioma infiltrating the inner layers. Foci of glial proliferation were disseminated widely.

Appelmans discusses in detail the differential diagnosis, both clinical and microscopic, of this tumor from retinoblastoma, pseudoglioma, and Coats's disease. He notes that angiomatosis becomes bilateral in more than half of the cases and that the menace of cerebellar, medullary, and visceral lesions may continue until as late as the forty-fifth year. He notes the congenital and hereditary nature of the disease. Phillips Thygeson.

This is a brief summary of the various "signs" of hypertension in the ocular background. W. H. Crisp.

Baillart, P. **Retinal hypotension.** Ann. di ottal. e clin. ocul. 72:705-710, Dec., 1946.

A diagnosis of retinal hypotension is made when application of the ophthalmodynamometer to the eye with a weight of less than 25 grams produces pulsation in the retinal arteries. In retinal hypotension, if the difference between the diastolic and systolic pressures is small, the blood stream does not have sufficient force to overcome the capillary resistance, and the hydrostatic pressure is insufficient to permit the normal metabolic exchanges between the blood and the tissues. The ocular symptoms, which are on the basis of local syncope, include the sensation of black spots before the eyes, transitory episodes of blindness, and accommodative and retinal asthenopia, which makes prolonged use of the eyes very trying. Failure of the capillary circulation may lead to loss of conductivity or even eventual atrophy of the nerve fibers. Gunn's dots in the macula are often associated with retinal hypotension, and closure of the central retinal vein may be due to a local hypotension or at least to a circulatory deficit. Sometimes the effects of retinal hypotension are mistaken for those of angiospasm, which likewise produces retinal anemia, but the con-

dition is only aggravated by the use of vasodilators, which are contraindicated in retinal hypotension.

Therapy is ineffectual but recognition of retinal hypotension clarifies certain functional disturbances and warns of possible threats to vision.

Harry K. Messenger.

Busacca, A. **The appearance of the normal fundus studied by the stereo-ophthalmoscope.** Arch. d'opht. 7:361-378, 1947.

Busacca employed the contact and glass and slit-lamp of Goldmann to study the fundus of the normal eye. He states that the technique is simple and that the examination can be made a routine clinical procedure. With pupils fully dilated it is possible to study an area having a radius of six disc diameters from the fovea centralis. Busacca used a magnification of 9.5 diameters.

The stereoscopic details of the normal macular region in adults of various ages are described and illustrated with drawings in black and white and in color. The author states that stereo-ophthalmoscopy is the only satisfactory method for a minute study of the details of the fovea centralis which he describes in minute detail. He compares the ophthalmoscopic findings with the histologic details and this adds considerable interest and value to his exposition. He notes that with stereo-ophthalmoscopy it is possible to distinguish in the fundus a series of surfaces and layer which enables one to estimate the depth and character of pathologic lesions. Phillips Thygeson,

Campos, Raffaele. **Detachment of the vitreous and detachment of the retina.** Ann. di ottal. e clin. ocul. 72:679-689, Nov., 1946.

Campus reports his study of detachment of the vitreous in 28 patients with unilateral detachment of the retina. For examination of the vitreous he used a modified slit lamp with an arc light and Lindner's angulated microscope. In place of a contact lens (with its obvious disadvantages) for eliminating the refractive power of the cornea he adopted Hruby's suggestion of using a plano-concave lens of 55D, worn by the patient in a trial frame. Such a lens has a useful surface of 20 mm., and for examining the vitreous in detail at various depths weaker minus lenses can be substituted for it.

In five patients, between 20 and 47 years of age, either emmetropic or with myopia not exceeding 1.25D, he found no detachment of the vitreous either in the sound eye or in the eye affected with detachment of the retina.

In another group of 5 patients, 55 to 65 years of age either emmetropic or with myopia not exceeding 6.00D he found a slight detachment of the vitreous in all the affected eyes and a very marked detachment of the vitreous in the sound eye of three of these patients.

In 18 patients, 19 to 57 years of age, with high myopia (7.50-22.00D) he found a slight detachment of the vitreous in nearly all the eyes affected with detachment of the retina, whereas there was a complete posterior detachment of the vitreous in the sound eyes in almost every case. Campos calls it a "curtain-like" detachment because the posterior portion of the hyaloid membrane is hung like a curtain at some distance in front of the retina.

From these assembled data it is inferred that in detachment of the vitreous the fundamental factors are age and high myopia rather than detachment of the retina. There is no parallelism in the degree of detachment of the one and of the other; in fact, it can be said that highly myopic eyes with a "complete" detachment of the vitreous are less likely to suffer detachment of the retina than those eyes with only a slight detachment of the vitreous or none at all. Hence the presence of a "complete" detachment of the

vitreous in a highly myopic eye is of good prognostic significance. The fact that detachment of the retina in these cases is usually associated with slight rather than with extensive detachment of the vitreous confirms the theory of Gonin-Lindner regarding the importance of adhesions between vitreous and retina in the genesis of retinal tears: the vitreous by its inertia, when the eye is rotated, exerts traction upon the retina at points of adhesion. When the vitreous is not adherent there is no traction, and hence no tear or detachment of the retina.

After operation for reattaching the retina the detachment of the vitreous was generally greater than before. This is readily understandable, since the replacement of the retina only increases the gap between it and the vitreous. The position of the latter is not affected by the operation. Harry K. Messenger.

Contardo, René. **Central serous retinitis or recurrent macular edema.** Ophth. ibero am. 8:251-256, 1946.

Macular edema in a woman of 35 years and a man of 48 years is described. Marked improvement followed ingestion and injection of methylic antigen. The corrected vision improved in the first case from 6/10 to 6/6 in one patient and from 5/30 to 5/10 in the other. Each case was believed to have a tuberculous origin. In the asthmatic patient the general condition also improved. (References.)

W. H. Crisp.

Doggart, J. H. **Symptoms of macular degeneration.** Tr. Ophth. Soc. U. Kingdom 65:180-186, 1945.

The unobtrusive course of many macular lesions leads to difficulty in the interpretation of the clinical history The following symptoms are given that may arise in macular disorders: Failure of central vision which may be slow or rapid, blurred vision, apparent bending of straight lines, incompleteness or discontinuity of objects, capacity to see objects relatively clearly by eccentric vision, positive scotoma, changes in apparent size of objects, uniocular diplopia, and interference with color vision. The history of visual disturbance accompanied or immediately preceded by aching behind the affected eye seems to increase the likelihood that inflammation and not degeneration may be responsible for the damage in question. When a macular abnormality remains limited to one eye for years it is all the more likely to be traumatic or inflammatory in origin.

Fialho Sylvio, Abreu. **Retinal arteries or arterioles.** Rev. brasil de oftal. 6:101-106, Dec., 1947.

This article is largely a series of quotations from Wagener's discussion of the subject (Trans. Amer. Ophth. Soc., 1946).

W. H. Crisp.

Gandolfi, Carlo. **The importance of cilioretinal arteries in circulatory lesions of the retina.** Ann. di ottal. e clin. ocul. 72:610-615, Oct., 1946.

In a case of occlusion of the central retinal artery presented by Gandolfi the central vision was eventually unimpaired, thanks to a large cilioretinal artery, though the visual field was much reduced. In a second case occlusion of a cilioretinal artery, notwithstanding the integrity of the central retinal vessels, resulted in a persistent paracentral scotoma. It was noteworthy that in this second case the central vision was likewise unimpaired.

Harry K. Messenger.

Granström, K. O. **Nomenclature in retinal changes associated with internal diseases, particularly hypertensive diseases and diabetes mellitus.** Acta. Med. Scandinav. suppl. 196, pp. 40-44, 1947.

In order to diminish the confusion in

describing the findings in patients with hypertension the author recommends that the "hypertensive fundus" be divided into the following four stages: 1. The arteries are narrowed and have an irregular lumen. The light reflex is broadened and there is arterio-venous compression. 2. The vascular changes are more marked and there are mild retinal changes. 3. Vessel changes are advanced and are associated with pronounced retinal hemorrhages and white exudates. 4. The classic albuminuric retinitis appears with edematous changes in the retina and swelling of the optic disc.

A similar classification is recommended for the findings in the toxemia of pregnancy.

The "diabetic fundus" is also grouped into four stages. These are characterized by: 1. isolated hemorrhages in the retina, usually round, 2. more severe hemorrhages with white spots in the retina, 3. many deep hemorrhages and many more white spots, and 4. severe hemorrhages into the vitreous with a proliferating retinitis. H. C. Weinberg.

Longhena, Luisa. **Concerning the etiology of the retinal detachment.** Boll.d' ocul. 26:227-253, April, 1947.

Exact biomicroscopic examination of 43 patients suffering from retinal detachment convinced the author that a chronic serous uveitis causes most if not all retinal detachments. This mild and latent inflammation is not a sequel of the retinal lesion; it can be observed before the development of the detachment and also in the other eye with completely normal retina. Longhena found that tuberculosis may be the most frequent cause of this chronic uveal inflammation; in some cases it may also be lues. Contributing factors were hyperglycemia, hyperazothemia, hypertensive heart disease. Eyes showing traces of this uveitis should never be operated on for the retinal detachment; local and general treatment of the uveal disease is indicated instead.

K. W. Ascher.

Morone, Giulio. **Tono-optic reactions of the pupil in tapeto-retinal degeneration.** Arch. di. ottal. 51:1-28, Jan.-Feb.-Mar., 1947.

The literature concerning the concept that tapeto-retinal degenerations arise from disturbances of the diencephalic hypophyseal system is reviewed. Changes in the tono-optic reaction of the pupil are said to arise from a similar disturbance and have been observed in cases of retinitis pigmentosa.

The author carried out pupillographic studies on patients who had disturbances of this system. He concluded that changes could exist without altering the pupillogram. Positive findings were of value but negative findings were not conclusive. Of the twelve cases of tapeto-retinal degenerations only one of retinitis pigmentosa had positive findings. The author believes that no definite connection can be demonstrated between disturbances of the diencephalo-hypophyseal system and retinal degeneration. If they do exist together it is probably because of their close association embryologically.

Francis P. Guida.

Rados, Andrew. **Macular hole with extensive peripheral detachment of retina.** Arch. Ophth. 38:596-604, Nov., 1947.

After a discussion of the literature and a clinical description of macular hole, the author reports a case complicated by a retinal detachment. There follows a discussion of the difference between macular holes and peripheral holes and the reasons why the latter are so much more apt to cause retinal detachment; the insertions of the extraocular muscles seem to be the most potent factor. OPTIC NERVE AND CHIASM

Magnus, J. A. **A case of pseudo-glaucoma.** Brit. J. Ophth. 31:692-696, Nov., 1947.

A 74-year-old man presented himself for a change of reading glasses. Both fundi showed deeply cupped and somewhat pale discs. The tension was normal and repeated provocative tests failed to change this tension. In the right eye the field had a marked nasal step that reached the fixation point and a typical arcuate nerve fiber bundle scotoma. In the left eye the field showed a general peripheral depression. X-ray studies of the sella showed calcification of the internal carotid arteries.

It is possible that the pressure atrophy of the nerves caused a softening and degeneration of the fibers which resulted in a recession of the lamina and the cupping. The author believes that this was a pseudo-glaucoma due entirely to the pressure of the calcified arteries.

Morris Kaplan.

Wagner, F. **Clinical and histological findings in the optic nerve in acute wood alcohol poisoning.** Klin. Monatsbl. f. Augenh. 112:167-171, 1947.

Sudden amaurosis and papilledema occurred in a patient with methyl alcohol poisoning. After death edema of the brain was found. The eyes showed an extensive non-inflammatory edema of the optic nerve but no degeneration. The author believes that the edema is the cause of the sudden decrease in sight and that degeneration of the optic nerve and ganglion cells in the retina is a later result of the poison. He recommends lumbar puncture for early treatment. (Bibliography.)

EYEBALL, ORBIT, SINUSES

Campos, R. **Concerning a special form of variable exophthalmos: exophthalmos with intermittent aggravation.** Arch. d'opht. 7:390-401, 1947.

Campos reports the case of a 15-year-old girl with an exophthalmos of two years duration and diminished vision in the affected eye. The exophthalmos had

progressed rapidly in the two months before the first examination. At that time the exophthalmometer reading was 22 mm. as compared to 17 mm. in the normal eye. However, when the patient's head was lowered the exophthalmos increased to 24 mm. It was reducible by pressure, non-pulsating, and auscultation revealed no bruit. There was no palpable tumor and movements were normal except for slight limitation of abduction. The Graefe, Moebius, Stellwag, and Geoffroy signs were negative. Vision was 10/10 in the normal eye and 2/10 in the other. Fundoscopic examination revealed a circumpapillary retinal edema. X-ray examination of the orbit showed two small round opaque bodies in the upper outer quadrant. At operation a number of large dilated varicose veins were seen and removed. After the operation vision improved to 5/10 and the exophthalmos was reduced to one millimeter of protrusion but there was slight ptosis and limitation of abduction and adduction. The radiopaque bodies were believed to be phleboliths.

The author considers the sign of increased exophthalmos after inclination of the head to be pathognomonic of varices of the orbit. He discusses in detail the different forms of variable exophthalmos and offers a classification.

Phillips Thygeson.

Lyons, F. M. **Contracted socket. The splint method of postoperative control.** Brit. J. Ophth. 31:703-709, Nov., 1947.

In the contracted socket the conjunctiva that remains should not be removed as in the operations based on the Wheeler procedure. This conjunctiva should be meticulously left or placed over the tarsal plates as far back as the fornix, if possible; this materially cuts down the incidence of entropion and affords a much more natural resilience and adaptability of the new socket.

In addition to this preservation of the conjunctiva a new method of keeping the acrylic mold in place after operation is most necessary to prevent return to the contracted state. The author has made a group of acrylic molds patterned after standard prostheses of varying size and into which is incorporated a steel nut which receives a short steel rod.

General anesthesia is used and a wide canthotomy performed. All adhesions are released and the conjunctiva preserved along the tarsal plates. The caruncle is preserved if possible. The largest mold over which the lids will close is selected and fitted with its steel rod. The socket is insufflated with penicillin and sulphathiazole powder. A thin epidermal graft is taken and made to cover the mold evenly. It is then placed in the socket, the rod removed and the previously placed canthotomy sutures tied. The lids are not sutured together. A pressure dressing is applied and left in place for six days. Then the sound eye is uncovered. A plaster of paris headdress is put on into which is incorporated a metal plate and clasp which will hold the rod to be replaced into the mold on the seventh day. On the seventh day the mold is eased out of the socket which is then irrigated with warm saline solution. The patient is allowed to be up and about and the mold is removed twice weekly until tendency to contracture is past. At that time, a final prosthesis is fitted. The molds and the splint arrangement can be used repeatedly. (3 illustrations.) Morris Kaplan.

EYELIDS, LACRIMAL APPARATUS

Bakker, A. **Xanthelasmata and autonomic nervous system. A new syndrome.** Brit. J. Ophth. 31:686-689, Nov., 1947.

Xanthelasmata are entirely harmless tumors usually found near the eye-lids. Bakker has found that they are much more common than is generally assumed and are often associated with various types of allergic disease. He studies four generations of a family in which both diseases were present to an uncommonly large degree. He feels satisfied that there is a relation between the two and feels that both are due to a labile autonomic nervous system. This dysfunction of the vegetative nervous system might be due to an imbalance of the cholesterol metabolism since many investigators have found an increased amount of cholesterol in the blood of patients with xanthelasma.

Morris Kaplan.

Corrado, M. **Erythematous dermatitis of the lids from penicillin.** Ann. di ottal. e clin. ocul. 72:455-466, Aug., 1946.

A case of allergic erythematous dermatitis of the lids that followed the therapeutic use of penicillin ointment (1000 units per gram) in the conjunctival sac is described. The diagnosis of allergy was confirmed by skin tests, and the patient was found to have an allergic diathesis (delayed sedimentation rate, exaggerated reflexes, and dermographia). It was subsequently found by experimentation on the same patient that intravenous injection of vitamin C for three days delayed the appearance of the allergic phenomena and lessened their severity.

The differential diagnosis of three types of hypersensitivity is discussed. Intolerance is a toxic reaction, like the reaction to a toxic dose of the offending substance in a normal individual. Idiosyncrasy is a primitive reaction that is not secondary to sensitization. Allergy is secondary to sensitization

Harry K. Messenger.

Foster, J. **Plastic repair of the lids.** Tr. Ophth. Soc. U. Kingdom. 65:113-135, 1945.

In plastic surgery the author highly recommends the use of hooks for retraction, patterns of Mackintosh, cigarette-tinfoil or cellophane, the plastic pen for outlining donor areas and the Gillies needle holder for intradermal suturing. He also advises the use of kationic soap antiseptic which neither alters the appearance of the skin nor kills grafts and the tissue glue (the patient's own plasma painted on the recipient area and an extract of his macerated white cells on the graft which produces adhesion of a skin graft in a few minutes and partial vascularization in 48 hours without a compressive dressing). Slight injuries may demand no more than simple suture. Fibrous tissue must be excised from the lids before skin is grafted in the treatment of ectropion. The use of hook traction aids in the excision of palpable fibrous bands.

Damage to the conjunctiva must be treated as skin injury with the excision of fibrous tissue and the supply of an epithelial covering. The author has found the use of oral mucous membrane preferable in the repair of a contracted socket. Damage to all three layers of the lid can frequently be repaired by the use of the sutures in layers. The repair of the canaliculus is most important if there has been a loss of tissue at the inner canthus. (27 figures.)

Beulah Cushman.

Grignolo, Antonio. **Possibilities and limits of penicillin therapy of blepharitis.** Boll. d'ocul. 26:117-127, Feb., 1947.

Eleven cases of squamous blepharitis and 39 cases of ulcerative blepharitis were observed for a period of two and seven months under penicillin treatment, and after discontinuation of the applications. An ointment containing 500 to 1,000 units per gram was used. In squamous blepharitis the results were negligible, and in ulcerous blepharitis possibly more rapid and more durable cures were achieved. Only one out of 39 ulcerous lesions did not respond. In one-half of the cured cases there was recurrence which responded well to repeated therapy. Cultures were taken from the lid borders and the germs obtained were tested for their penicillin resistance; there was no obvious parallelism between in-vitro response and therapeutic effect. The author attributes more importance to the "constitutional terrain" and stresses the importance of general treatment in conjunction with local applications. Among four tables, the second deserves especial attention for its meticulous and elucidating exposition of all pertinent data on 39 patients: their age, diagnosis, duration of disease, strength of ointment and frequency of application, systemic additional treatment, results, period of observation, recurrences, final result, microorganisms, isolated and inhibitory effect of penicillin in vitro. K. W. Ascher.

Macomber, W. B., and Berkeley, W. T. **Use of Neck Tubed Pedicles in Reconstruction of Defects of the Face.** Plast. and Reconstruct. Surg. 2:585, Nov., 1947.

Tubed pedicle skin from the neck is advocated for facial reconstruction because of greater similarity of skin color and texture, greater vascularity, ideal thickness, proximity of tissue, and production of minimal defect in donor area.

The tension on the tube and surrounding tissue must not exceed normal skin tension, and the tube should be constructed of sufficient length so that the defect can be easily reached by the flap. The width of the average neck tube is 4.5 to 5 cm., and the length varies in every case depending on the distance to the defect as mentioned above. In long neck tubes when the 3-to-1 length-to-width ratio is exceeded a central bridge is required. This serves as a relay to prevent ischemia or poor venous return, and the tube at this point should be greater in diameter than the rest of the tube to prevent constriction and circulatory embarrassment. Tubes can be used to bring skin and subcutaneous tissue, and also to carry additional neck skin to the face in the form of a flap. If these flaps are large, however, they should be transferred only after primary, secondary and sometimes tertiary delays. Surgical incisions in the neck should conform to Langer's lines, which run transversely across the neck. The formation of a tube in a vertical direction on the neck will result in a bowstring type of scar which will necessitate a Z-plasty for correction.

Twenty photographs and two plates of drawings are used to illustrate four case reports. The cases show large facial defects, and in one patient with extensive damage the eyelid is corrected with the end of the tube. Alston Callahan.

Marín Amat, M. **My surgical procedure for entropion of the lower lid.** Arch. Soc. oft. hisp.-amer. 7:808-814, Aug., 1947.

Marín Amat resents not having his operation included in Arruga's last book on surgery of the eye, and in Castroviejo's course on surgery of the cornea and the lids. He originally reported the technique in 1915. He attaches the lower lid to the orbital aponeurosis, at a point midway between the border of the lid and the inferior orbital border, with three to five sutures. An incision parallel to the border

of the lower lid and 5 mm. from it is made through the skin and the orbicularis. The protruding fibers of the orbicularis are excised; the sutures pass through the lower lip of the skin incision, through the orbital aponeurosis, and through the upper lip of the skin incision. The author has performed the operation in over a thousand cases and considers his procedure simple, rapid in execution, and functionally and cosmetically efficacious. (5 illustrations.) Ray K. Daily.

Radnót, M. **Rare tumors of the caruncle.** Ophthalmologica 113:270-275, May, 1947.

Some authors consider the caruncle as an island of skin. This view is only partly correct. The caruncle resembles skin in that it contains sebaceous glands and hair follicles but differs from skin in that it harbors accessory lacrimal glands and glands of Moll's type and in that its epithelium shows no keratinization. The more common tumors of the caruncle are papillomas, angiomas, nevi and dermoid cysts. The author reports in detail two unusual neoplasms of the caruncle. One, in a white man, 69 years of age, proved to be a cyst lined by several layers of oncocytes, a specific mucous cell first described by Hamperl (Virchow's Arch. 282:724, 1931). The cyst probably originated from an accessory tear gland. The second case in a white man, 67 years of age, was a local recurrence of a giant cell sarcoma. Peter C. Kronfeld.

Scuderi, G. **Leishmaniasis of the eyelid associated with keratitis.** Rassegna ital. d'ottal. 16:335-356, Sept.-Oct., 1947.

Instances of the presence of the Leishman protozoon have frequently been reported from Italy. The classification, staining peculiarities and structure of the trypanosome are described, as well as its cultural characteristics.

Two cases are reported in which there was an involvement of the prelacrimal region. In both there was a marked edema of the upper eyelid and the region of the lacrimal sac. Both were observed in the ulcerative stage. Ulceration of the cornea by the Leishman trypanosome is of a deep destructive type, similar to a pneumococcus ulcer, but first resembles a phlyctenule. The pain is severe and usually the whole cornea is involved and perforation occurs after three to four months. In the two cases reported the use of atabrine checked the keratitis promptly. (2 figures.)

Eugene M. Blake.

Seidenari, Roberto. **Study of the motility of the lacrimal sac after rhinostomy.** Boll. d'ocul. 26:103-116, Feb., 1947.

Raverdino's dacryocystorhinostomy method was used to study the mechanism of the lacrymal sac. A fine rubber ball, introduced into the drainage tube during the operation, was connected with a Marey's drum, the excursions of which were transmitted to a kymograph. Curves obtained showed that, even after the operation of dacryostomy, the lacrimal sac preserved its contractions. Whereas Roser, Schirmer, Hyrtl, von Graefe, Fuchs and others assumed that the lacrimal sac becomes dilated during blinking, which results in aspiration of the tears from the lacrimal puncta, the opposite opinion was supported by Aubaret, Arlt, Rochat, and others. In three of five patients examined, blinking produced a dilatation of the sac; in the other two patients, a contraction or compression of the sac was indicated by the kymograph curve. Differences in the anatomic relations of the orbicularis tendon are the cause for these discrepancies. Four pictures explain the insertion of the tubing into the stump of the sac, one photograph shows the patient seated at the kymograph, and four kymograph curves are reproduced. K. W. Ascher.

Stallard, H. B. **Plastic repair of the lids.** Tr. Ophth. Soc. U. Kingdom. 65:68-112, 1945.

In dealing with a healed wound the original defect must be reproduced by thorough excision of scar tissue and undermining of the skin edges before the reconstruction is planned. A drawing of the defect with photographs, radiographs and diagrams of the surgical procedure should accompany the patient to the operating room.

A small defect may be repaired by simple suture of the adjacent tissues or by undermining and sliding these together, but there must be no tension in such a procedure. In larger defects free grafts are used and it is desirable to use eyelid skin whenever possible. With extensive skin loss split-skin grafts (thick razor) are taken from the hairless area over the medial aspect of the upper arm or an epidermal graft (thin razor) is used.

Irregular bony surfaces should be covered by a sliding or rotation flap. The pedicle flap from the frontotemporal region is usually necessary for the reconstruction of the eyelids, although it seldom remains cosmetically or functionally very pleasing. A wandering pedicle graft may be taken from the abdominal wall to wrist and then to the eyelid or from the pectoral region to the neck and then to the eyelid.

Few instruments are used in plastic surgery but they must be in perfect condition. The technique of plastic surgery must be precise, purposeful, clean and finished. The handling of tissue must be minimal and hemostasis complete. Illustrations give the use of the different methods of closure and the use of the different types of flaps. (64 figures.)

Beulah Cushman.

Steinreich, O. S., and Callahan, Alston. **Reconstruction of the face and all four eyelids.** Am. J. Surg. 74:838-843, Dec., 1947.

A case is reported of a man who, from a severe gasoline burn, developed severe ectropion of all four eyelids, marked facial deformity with ectropion of the right side of the mouth, and granulating third-degree burns of the left parietal region of the scalp. Emergency skin grafting at an overseas hospital was successful in protecting the cornea from drying, and the vision remained 20/20 in each eye. The emergency procedures had not been performed with the purpose of ultimately correcting the deformities.

Six months after the injury, all four eyelids were repaired at one stage under ether endotracheal anesthesia. Incisions were made in the skin of the lids about 5 cm. from and concentric with the lid margins. All cicatricial tissue was removed from the lids and the margins of each pair of lids were united with a subtotal lid adhesion. Crescentic patterns of the required skin were made of transparent celluloid sheets, and an area of split-thickness skin of adequate size for these patterns was removed from the left chest with the Padgett dermatome. Pressure was applied by tying the alternate sutures of the juncture of the graft with the recipient skin over "torpedoes" of cotton wrapped with gauze, saturated in sulfathiazole and cod liver oil. Minor lid repairs were necessary. The tarsorrhaphy uniting the left lids was divided after four months, that uniting the right lids after nine months.

The scalp was repaired with 32 square inches of skin removed from the left side of the back with the Padgett dermatome. The face and lip ectropion was reconstructed with full-thickness skin transferred from the upper arm by means of a bicipital tube graft from each arm. In turn each tube was detached distally from the arm, and attached to the face; later detached entirely from the arm, and the skin

unrolled and migrated to correct the facial defects.

The final results seemed satisfactory.

Four photographs in full color and three in black and white illustrate the article. Alston Callahan.

Stern, H. J. **Autohaemo-therapy in hordeolosis.** Brit. J. Ophth. 31:766-769, Dec., 1947.

The author recommends the use of intramuscular injection of the patient's own blood in hordeolosis and has found it an effective, inexpensive form of therapy. He believes that abandonment of this treatment has followed indiscriminate use in a multitude of conditions with disappointing results. The treatment may cause a desensitization through stimulation of the reticulo-endothelial system and the formation of specific antibodies. Its use in hordeolosis by the author has been followed by lasting effects and few recurrences. O. H. Ellis.

TUMORS

Alagna, Gaspare. **Tumors of the reticulo-endothelial system of the eye. A reticulo-endothelioma of the conjunctiva in a patient with Kaposi's disease. A histopathogenetic contribution.** Ann. di ottal. e clin. ocul. 72:641-662, Nov., 1946.

A case of Kaposi's disease (multiple angiomatous wine-red spots and nodules of the skin on various parts of the body) in a 61-year-old man is described. About six years after the onset of the skin affection a tumor arose in the submucous layer of the conjunctiva, which on histologic examination proved to be a reticulo-endothelioma (or reticulo-histiocytoma) of angioblastic tendency.

The principal pathogenetic theories of Kaposi's disease are reviewed. The occurrence of this conjunctival tumor, which is probably not a metastasis but a local new growth arising from pre-existing reticulo-endothelial elements in the conjunctiva, confirms the theory that the disease is a generalized reticulo-endotheliosis, sometimes with special characteristics, and may be occasioned by an inherent anatomic and functional inferiority of the reticulo-endothelial system. Harry K. Messenger.

Borges Dias, Artur. **Malignant melanoma in the eyeball.** Arqu. brasil. de oftal. 10:92-95, 1946.

The single clinical record is of a case of malignant melanoma in a white male child aged 2½ years. There was appreciable softening of the bony floor of the orbit, especially on the temporal side.

W. H. Crisp.

Clifton, F., and Gordon, W. H. **A case of an adenoma arising in a sweat gland of the upper eyelid.** Brit. J. Ophth. 31:697-700, Nov., 1947.

A 70-year-old woman noted a mass in the upper eyelid that had grown slowly for five years. It had begun as a small crust on the edge of the lid. It was painless, firm, freely-movable, and could be transilluminated freely. It was easily removed in a tight capsule and the wound healed with good cosmetic result. The pathologic diagnosis was adenoma arising from a sweat gland. (3 illustrations.)

Morris Kaplan.

Cory, J. W. E. **Glaucoma secondary to fibrocystic disease of the bone.** Brit. J. Ophth. 31:731-737, Dec., 1947.

In a 58-year-old man the globe was displaced outwards and forwards by pressure of the tumor from within the orbit which obstructed venous drainage and thereby produced secondary glaucoma. X-ray films showed the condition to be fibrocystic disease of the bone; however, the full Hans Schüller-Christian syn-

drome was not present. It was not possible to determine whether the optic atrophy was due to the glaucoma or to secondary pressure on the optic nerve by the tumor. (5 figures.) O. H. Ellis.

Fairclough, W. A. **Direct inheritance in retinoblastoma.** Supp. New Zealand M. J. pp. 35-36, 1947.

A 50-year-old father who died of primary carcinoma of the liver, had both eyes enucleated at the age of two years. Three of his four children had retinoblastoma. Irwin E. Gaynon.

Gordüren, Süreyya. **Carcinoma of the eye.** Göz kliniği 5:105-112, 1947.

The author found 18 carcinomas in the region of the eye in 51,000 patients during the last five years. There were 11 carcinomas of the lids and most of these were at the external canthus, which he attributes to the application of irritants to this region by the villagers. There were seven epitheliomas of the conjunctiva and cornea. He saw no carcinomas of the lacrimal sac, orbit, or uvea.

F. H. Haessler.

Halpert, B., and Patzer, R. **Maxillary tumor of retinal anlage.** Surgery 22:837-841, Nov., 1947.

The authors report a benign neoplasm removed from the maxilla of a six-months-old infant, composed of tissue elements of the retina. They believe that this is the first growth of this nature ever recorded. The external carotid artery was ligated just before removal. Six days later the fundus of each eye was normal.

Bennett W. Muir.

Pascheff, C. **Studies on melanotic tumors of the eye.** Annuaire of the University of Sofia. 26:147-177, 1946-47.

With clinical and histologic reports Pascheff illustrates the various ocular neoplasms which originate from pigmented cells, and points out the part played by the melanotic cells in the morphology of the various melanotic tumors. The melanocytes comprise the melanoblasts of the retina, the melanophores of the uvea, the pigmented nevus cells, and the melanoblasts of the basal epithelial cells of the conjunctiva. Among the latter are included the melanocytes with granular dendritic processes, which Pascheff discovered in the basal epithelial cells of the limbal conjunctiva in spring catarrh, and which are identical with the cells of Langerhans' found in the epidermis.

All cells containing melanin may form hyperplasias or neoplasms. Melanohyperplasias are benign, and melanoblastomas are malignant. The melanohyperplasias are classified as follows: 1. Melanosis, congenital or acquired, which is manifested in strong pigmentation. 2. Melanoma, which may be epitheliomelanoma, melanophoroma, and epitheliomelanophoroma. 3. Pigmented nevus. The melanoblastomas are divided into melanoepithelioblastoma, melanophoroblastoma and melanonevoblastoma.

Melanoblasts form floccules in the iris and retina. Melanophores grow into melanophoromas in the uvea, and especially the iris, sometimes erroneously called nevus of the iris. Pigmented nevus cells form pigmented nevi which are seen on the corneal limbus and on the skin. Mixed hyperplasia, consisting of melanophores and melanoblasts are described in a report of a melanopapillofibroma of the conjunctiva. The same type of cells are the source of malignant tumors. Melanoblasts of the conjunctival epithelium form melanoepitheliomas of the conjunctiva. Melanoblasts of the retinal pigment epithelium form a melanoepithelioma of the retina, which was first reported by the author at the ophthalmological congress in Amsterdam. An interesting case of a cylindropapilloblastoma of the parsiliaris of the retina is reported for the first time in this article. Melanophores are responsible

for melanofibrosarcomas of the uvea, especially of the choroid, the conjunctiva, and the orbit. On the conjunctiva they are usually pedunculated. Melanofibrosarcoma or melanophoroblastoma of the orbit was described first by the author in 1929. Melanonevoblastomas of the conjunctiva, originating in the pigmented nevus cells are as malignant as melanoepitheliomas, from which they are differentiated by their typical nests. All blastomas are unilateral and malignant, and should be promptly and radically excised before glandular involvement takes place. Ray K. Daily.

INJURIES

Cortés, Hernán. **Traumatic aphakia and aniridia caused by contusion of the globe.** Arch. Soc. oft. hisp.-amer. 7:779-786, Aug., 1947.

Cortés reports a case of traumatic aphakia and aniridia in a man with an old degeneration of the macula in the uninjured eye. Because of the poor vision of the uninjured eye enucleation of the injured eye, which was indicated by the gravity of the injury, would have left the patient totally disabled. Conservative treatment was thus almost forced. Two months after the injury the scleral perforation was healed, the fundus was visible, and there were pale gray floating masses in the inferior portion of the eye. There were small holes in the periphery of the retina but the retina was attached everywhere. There was no sign of iris, and vitreous was floating in the anterior chamber. With the aphacic correction vision was better than two-thirds. The problem of industrial compensation is commented upon. In the discussion of the report Sanchez Mosquera described another unusual experience. One eye of a woman with bilateral senile cataract was injured by the horn of a cow. When the acute symptoms of trauma subsided, it was found that the cataract was dislocated, and her corrected vision was 0.5. Ray K. Daily.

Davids, B. **After-treatment of perforating eye injuries.** Klin. Monatsbl. f. Augenh. 112:136-148, 1947.

This paper is based on the therapeutic procedures used in 168 perforating war injuries of the eye which did not require immediate or very early enucleation. Certain phases occur in the course of a perforating injury. At first the mechanical destruction and possible infection of the wound stand in the foreground. Next to the surgical care and local mydriatics intensive foreign protein and fever treatment as well as chemotherapy with sulfonamides and penicillin are most important at this stage. After a few days the eye has either a panophthalmitis or it enters the stage of a chronic uveitis. A few of the eyes may heal quickly. The chronic uveitis of the majority of patients is the result of toxic reactions brought about by bacteria and by protein from destroyed tissues. Retained foreign bodies may cause an aseptic inflammation or have a chemical or electrolytic effect on the eye. Allergic tissue reactions appear in this phase as a result of the antigenic effect of bacteria and body protein. Foreign protein is strongly contraindicated in this stage. Anti-allergic measures are indicated and the author recommends calcium and pyramidon. Later on small doses of foreign protein may be used for desensitization. Retained non-magnetic foreign bodies like glass and small stones may be well tolerated and may become encapsulated. The prophylaxis against sympathetic ophthalmia includes the decrease of the hyperergic reaction through calcium, nonspecific desensitization through mild doses of foreign protein, chemotherapy, mydriatics in the uninjured eye and cautious removal of foci

of infection. Under the routine outlined 131 bulbi were retained with useful vision in one-third of them. (References.)

Max Hirschfelder.

Ferguson, W. J. W. **The treatment of intra-ocular foreign bodies.** Practitioner. 158:400-405, May, 1947.

This article summarizes the ophthalmologist's approach to the problem of the intra-ocular foreign body. The author stresses the importance of X-ray examination of all perforating ocular wounds in which there is the slightest suspicion of a possible retained foreign body. Methods for X-ray localization of the foreign body are mentioned.

In general, if the injury has not been of sufficient magnitude to destroy the eye, extraction of the foreign body is indicated. The most favorable cases are those in which the foreign body is magnetic. In these instances the giant magnet is used for extraction of the foreign body. The anterior route is selected if the foreign body is in the lens, iris, or anterior chamber. The posterior route, with incision through the sclera and choroid, is used when the foreign body lies in the vitreous chamber. The author mentions the use of surface diathermy at the sclerotomy site to reduce bleeding and also to reduce the risk of postoperative retinal detachment. When the foreign body is nonmagnetic, an attempt should be made to remove it with forceps if such an approach is feasible. Foreign bodies embedded in the cornea or sclera may be allowed to remain if the removal is difficult and if the foreign body produces no irritation.

The author mentions as complications of foreign body removal the occurrence of septic inflammation, iridocyclitis, and sympathetic uveitis. Of greatest importance in removal of intraocular foreign bodies is the minimizing of surgical trauma.

R. W. Danielson.

Haik, G. M. **Intraocular foreign bodies.** J.A.M.A. 135:894-900, Dec. 6, 1947.

It is desirable to have the patient recumbent en route from the injury to the ophthalmologist, and the less is done by the first aid persons the better. Emergency removal is practically never indicated unless the globe is hopelessly and totally lost. Sympathetic ophthalmia allows a 21-day period of grace, and there were but 15 cases reported in the last war. Chemotherapy, antibiotics, and fever therapy (canned milk was used in place of fresh milk often, and worked well) are very desirable.

At the author's military installation they did not hesitate to use pentothal for adequate examination in all bilateral and serious injuries. X-ray localizations are discussed, and it is noted that they are sometimes incorrect, and that no detail for their efficiency should be overlooked. They also used a Carney locator, similar in principle to the Berman, but fashioned out of odds and ends available in a theater of war but useful for magnetic bodies only.

For extraction of magnetic particles, the magnet was used. Non-magnetic ones were left alone, or removed, depending upon the situation. The author stresses the importance of closure of all perforat-

ing wounds of the globe by diathermy. (5 figures, abstract of discussion.)

Bennett W. Muir.

Hoffmann, E. A. **Personal experiences with the least traumatizing removal of introcular iron.** Klin. Monatsbl. f. Augenh. 112:156-167, 1947.

Even the smallest pieces of iron and steel should be removed from the eyeball, unless one deals with an only eye and is certain of a rustless or very slowly rusting alloy. The sideroscope is useful in determining the presence of iron. X-ray localization after the method of Comberg (contactglass with lead markings) is most widely used and is especially useful in the modification of Leydhecker which permits two exposures with the patient supine. In doubtful cases with negative findings this method is supplemented by the skeleton-free X-ray after Vogt or the surgical skeleton-free X-ray after Franceschetti. Occasionally one can visualize a foreign body with the ophthalmoscope, and, in certain rare instances, the proof of intraocular iron is brought about by chemical analysis of the aqueous or its spectralanalysis. The presence of several pieces in the same eye should not be overlooked. The article discusses in detail the best method of removal of magnetic foreign bodies from the various locations. Iron can be tolerated in the scleral tissue, but should be removed from the sclera in double perforation. It is better to remove foreign bodies in the anterior chamber through a fresh incision after a few days of initial chemotherapy rather than immediately through the wound. The methods for removal of iron in the iris, lens and vitreous are discussed. For ciliary and retinal magnetic foreign bodies transcleral removal is strongly recommended and the danger of producing retinal detachment by using the giant magnet and the anterior route is stressed. A triangular scleral flap is described as a useful opening for such transcleral removals, especially if combined with diathermy cautery as a precaution against possible retinal detachment.

Max Hirschfelder.

Man, H. X. **A case of monocular diplopia.** Ann. d'ocul. 180:475-480. Aug., 1947.

Among the frequent structural causes of monocular diplopia are refractive and other changes in the cornea and lens with or without spastic accommodation; also peripheral holes in the iris which under proper conditions may form a second pupil. In the case reported a very small iris hole, traumatic in origin, was observed peripherally at 3 o'clock. With both eyes open, macular images are fused and the patient has binocular single vision. The extra-macular image in the left eye causes a crossed diplopia because both the iris hole and the retinal image are located temporal to the macula. When the eye was directed up and to the right the displacement of the retinal image was increased. The cornea was tatooed to cover the iris hole and eliminate the second image.

Chas. A. Bahn.

Orzalesi, Francesco. **Another communication concerning diathermy treatment of wounds of the corpus ciliare.** Boll. d'ocul. 26:81-86, Feb., 1947.

In a preliminary publication (Rassegna Medica Sarda, 1946) the author suggested destruction of the injured part of the ciliary body after traumatic lesions to the latter. It seems that this procedure will reduce the danger of sympathetic ophthalmia and will hasten the healing of ciliary body wounds by sealing against the entrance of possible infection. Orzalesi concedes that the number of patients observed and the time elapsed does not yet justify definite conclusions. (2 figures.)

Rees, T. R. **Perforating wound of orbit; report of a case.** M. Ann. District of Columbia 16:548-549, Oct., 1947.

A twig penetrated the left upper lid of a three year old boy and entered the orbit and intracranial cavity. It injured the optic, oculomotor, troclear, ophthalmic branch of the trigeminal, and the abducens nerve. The eyeball was completely fixed, anesthetized and blind. The twig rested in the interpeduncular space and was removed with forceps along the path of entrance. The eyeball was destroyed.

Irwin E. Gaynon.

Terol Altet, J. M. **Comments on 1500 cases of industrial injuries.** Arch. Soc. oft. hisp.-amer. 7:771-778, Aug., 1947.

Foreign bodies of the cornea constituted 75.41 percent of the injuries in this group. Biomicroscopic exploration of eyes suspected of a foreign body is obligatory. Their management requires anesthesia, exploration of the lacrimal passages, and asepsis of the conjunctiva. Foreign bodies should be carefully removed with a minimum of epithelial damage, and their removal should be followed by the introduction of an antiseptic ointment into the conjunctival sac, and bandage of the eye. The eye should be inspected with the slit-lamp on the following day for remains of the foreign body or rust and the patient should not be discharged until the epithelium has completely regenerated. Conjunctival foreign bodies were of no consequence. Corneal ulcers constituted 15 percent of the cases. Some occurred subsequent to the delayed removal of a foreign body. They were treated with an antiseptic ointment, and atropine, when indicated by a ciliary congestion. In four cases, or 0.26 percent extensive ulcerations developed which were controlled by surgical attention to the lacrimal passages, foreign protein injections, and atropine and antiseptic ointments locally. Subconjunctival hemorrhages caused by contusion absorbed spontaneously. Contusion of the globe with hyphema occurred in 0.2 percent of the patients. One patient with a recurrent hyphema and a secondary glaucoma was found to have an old iridocyclitis.

Injuries and burns of the lids presented no therapeutic problems. The excellent results achieved in two severe conjunctival burns with sulphuric acid and ammonia are attributed to the prompt removal of the necrotic conjunctiva and transplantation of buccal mucous membrane. The difficulty of a differential diagnosis between a traumatic and a self-inflicted conjunctivitis is illustrated with a case report. In two cases of ocular perforation the patient made an excellent recovery under treatment with sulfanilamide, foreign protein, and atropine and noviform locally. One eye with an intraocular foreign body ended in phthisis of the globe.

The good results obtained in this large group of injuries are attributed to the education of the workers to the importance of prompt ophthalmologic assistance, to the adequate use of protective measures, to the great efficacy of modern anti-infectious agents and to the progress in modern surgery. The author urges that industrial protective measures be enforced by deprivation of compensation for workers who fail to use them, and by punitive measures for employers who neglect to provide them.

Wilder, H. C. **Intraocular foreign bodies in soldiers.** Am. J. Ophth. 31:57-64, Jan., 1948. (35 figures.)

Wright, R. E., and Duncan, H. A. **Experiences with the giant electromagnet in the extraction of intraocular foreign bodies of a metallic nature, in the recent war.** Rev. oto-neuro-oftal. 22:51-54, May-June, 1947.

A soldier sustained a wound of the left eye, amongst other injuries, in a land-mine explosion. A metallic foreign body was found in the retina about three disc diameters below the papilla. Using the giant electromagnet and a posterior sclerotomy the foreign body was not easily removed. Success was achieved only after 75 four-second applications of the magnet at a second operation. As a result of experience with this case the authors feel that ordinarily the posterior route should be used when the foreign body is in the posterior segment and the incision should be as close to the foreign body as possible without injuring important structures. A fine pointed terminal should be used, the surgeon must persevere, the patient cooperate, and the magnet be first-rate. A knowledge of the physical and chemical characteristics of the foreign body is essential. In war-time rudimentary localizing procedures must be used to the utmost. Repeated applications of the magnet increases the susceptibility of the foreign body to extraction. Superficial diathermy coagulation of the sclera in the vicinity of a foreign body can produce an uncontrollable reaction. A portable electromagnet should be installed in stations in the theatre of operations. Edward Saskin.

SYSTEMIC DISEASE AND PARASITES

Abbott, K. H., and Camp, J. D. **Extensive symmetrical cerebral calcification and chorioretinitis in identical twins. (Toxoplasmosis.)** Bull. Los Angeles Neurol. Soc. 12:38-48, March, 1947.

The authors present case reports of identical twins each with bilaterally symmetrical, extensive dense calcification in the cerebrum with minor involvement of the cerebellum. Bilateral extensive chorioretinitis, with choroidal exudate associated with retinal angiomatosis was present. Since blood serum from each of the twins neutralized toxoplasma organisms it was concluded that the causal factor was probably chronic toxoplasmosis. (8 figures.) O. H. Ellis.

Appelmans, M. **Chronic superficial punctate keratitis due to onchocerciasis.** Ophthalmologica 114:129-146, Sept., 1947.

Onchocerciasis has received a good deal of attention in the Belgian literature, apparently because of the relatively high incidence of this parasitic disease in Belgians who had spent part of their lives in the Belgian Congo. Appelmans of Louvain now describes two cases of chronic superficial punctate keratitis in former residents of the Belgian Congo. The keratitis was associated with mild ciliary injection and photophobia; all other ocular structures appeared normal. Both patients showed a chronic nodular dermatosis and marked eosinophilia in the blood. Small pieces of the clinically uninvolved conjunctiva were removed for biopsy and were found to contain innumerable larvae of onchocera volvolus. The whole subject of onchocerciasis in Africa and Central America is reviewed. The larvae reach the eye through their own motility and not through the blood stream. Their specific affinity to the conjunctiva (first described by Applemans in 1935) greatly facilitates the diagnosis. The only form of treatment known up to now is the surgical extirpation of the nodules containing the parasite. For the cases of corneal involvement without nodules in the skin the author recommends five-per cent calomel ointment applied locally. He repeatedly refers to the study of the eye manifestations of onchocerciasis in Guatemala by William B. Clark (Arch. of Ophth. 36:644, 1946). Peter C. Kronfeld.

v. Bahr, G. **Intraocular vascular proliferations in diabetes mellitus.** Acta. Med. Scandinav. suppl. 196, pp. 24-39, 1947.

A characteristic feature of diabetes mellitus is the formation of new vessels. In the iris they are superficial and produce rubeosis iridis. These new vessels also appear in the retina and often extend into the vitreous as a retinitis proliferans. The author's cases illustrate retinitis proliferans in which the formation of new vessels is primary. Usually it is secondary to hemorrhages into the retina and vitreous. In three of the author's cases there were signs of renal damage which was very suggestive of intercapillary glomerulosclerosis (Kimmelstiel-Wilson syndrome).

New vessels are often found in the skin of diabetics and this rubeosis diabetica often gives young diabetics a red color to their face, hands and feet. The conjunctiva also may show dilated vessels with an increased number of capillary loops in diabetes. There may also be a number of military aneurysms, and a number of small vascular branches giving one the impression of vascular proliferation. H. C. Weinberg.

Ciotola, Guido. **A case of hydroa vacciniformis with ocular manifestations.** Boll. d'ocul. 25:520-536, Oct.-Dec., 1946.

A 20-year-old farmer became affected with lesions of the skin after exposure to the sun each spring since he was six or seven years old. Serosanguinous vesicles appeared on the skin of the face and dorsal part of the hands and left scars like small pox. At the age of nine or ten years the patient's right cornea became affected by opacities which were associated with photophobia and lacrimation and occurred at the time of the skin eruption. Two years later the same opacities developed in the left cornea. The bulbar conjunctiva of both eyes at both sides of the limbus on the horizontal meridian was yellowish, slightly thickened and adherent to the sclera. The vision was 2/10 in both eyes.

The cases reported in the literature are summarized and discussed. It is assumed that the lesion resulted from the action of ultraviolet rays on a skin that is sensitized by products of altered metabolism, such as hematoporphyrin. (3 figures, bibliography.) Melchiore Lombardo.

Di Luca, Giuseppe. **Changes of ocular fundus in the diagnosis of affections of the cerebral circulation.** Riv. oto-neuro-oftal. 22:161-176, May-June, 1947.

In a preceding work the writer called attention to a symptom complex based on the fact that when the blood flow of the carotid artery is stopped, the systolic retinal pressure of the affected side becomes lower than the systolic pressure of the other side and it remains lower on compressing the common carotid of the same side. The compression may bring about no general reaction or it may provoke symptoms of cerebral ischemia. The writer now reports four patients with general hypertension, in three of which sudden monolateral blindness occurred. The retinal artery systolic pressure was lower on the affected side. In the first patient, who had endoarteritis, the blindness was due to spasm of the central artery of the retina. A disturbance of circulation in the territory of both the internal carotid by the compression of the common carotid could be excluded. In the second and third cases no changes in the intracranial carotid territory were present. In the fourth case with normal vision in both eyes and severe general symptoms on compression of the carotid it was possible to determine that the lumen of the internal carotid was reduced in size but not occluded. The writer thinks that the compression of the common carotid is a useful functional test. (Bibliography.)

Melchiore Lombardo.

Etchemendigaray, A. N. **Changes in accommodation due to intestinal para-**

sites. Anal. argent. de oftal. 7:125-128, Oct.-Nov.-Dec., 1946.

The author feels that intestinal parasites throw a toxin into the blood-stream that causes a temporary weakness of accommodation. He does not state conclusively whether or not these toxins act directly on the ciliary muscle or on the oculomotor center. Ten observed patients with weakness of accommodation are presented from whose intestines ameba histolytica, Giardia cysts, Blastocystis hominis, or trichomonas were isolated. No statement is made regarding response to therapy. Edward Saskin.

Focosi, Marcello. **Ocular complications of acute lymphocytic meningitis and possible connections with acute poliomyelitis.** Boll. d'ocul. 26:417-432, July, 1947.

Two cases of benign acute lymphocytic meningitis with sixth nerve paralysis are described. All signs and symptoms disappeared rather quickly in both cases; one of them was probably due to the virus causing acute anterior poliomyelitis. (Three pages of references.)

K. W. Ascher.

Matteucci, P. **Schizophrenic syndrome and visual apparatus.** Riv. oto-neuro-oftal. 21:312-321, Sept.-Dec., 1946.

The writer studied the ocular motility and retinal circulation in schizophrenic patients to determine whether functional and organic changes of the eye are present. In 117 patients systematic researches were made in regard to the reflexes of the pupil, the extrinsic ocular motility, the retinal circulation and the ocular tension. Only the retinal hypotension may have some importance in this syndrome. (Bibliography.) Melchiore Lombardo.

Panzardi, Domenico. **Concerning the appearance of lens opacities in target cell anemia (Cooley).** Boll. d'ocul. 26:189-192, March, 1947.

In 1943, Holt observed lens opacities in a patient with Cooley's anemia. The author, working in Sassari, Sardinia, where the erythroblastic anemia is rather common, studied biomicroscopically the lenses of nine patients suffering from Cooley's disease. No cataracts, not even small congenital lens opacities, were encountered in all these patients. Hypocalcemia was found; cataract, however, seems to be a rare or incidental occurrence in patients suffering from target cell anemia. K. W. Ascher.

Panzardi, Domenico. **Unusual involvement of conjunctiva, cornea, and episclera in herpetic eye diseases.** Boll. d'ocul. 26:465-470, July, 1947.

A 43-year-old woman developed in short succession transient lesions in her right and left conjunctiva, in her left cornea, and in her right episclera. A labial herpes was also observed and inoculation in rabbit cornea corroborated the assumed diagnosis of herpes febrilis. (10 references.) K. W. Ascher.

Widerman, Arnold. **Eruptive fever with stomatitis and ophthalmia.** Ann. Int. Med. 27:830-834, Nov., 1947.

The author reports two cases of this disease also known as the Stevens-Johnson disease. The ocular symptoms and signs were itching, injection of the conjunctiva and sclera, and purulent secretion, all characteristic of moderate conjunctivitis.

Bullous lesions on the mucosa of the mouth and nose and sometimes vesicles or ulcers on the penis may occur. Constitutional symptoms are frequently present, usually severe, and are associated with high temperature and varying toxicity. Purulent conjunctivitis and corneal disease may result from secondary invaders. Panophthalmitis and even death has occurred. Stomatitis, Vincent's type especially, venereal disease, allergy, and

acute exanthemata must be differentiated from this disease. F. M. Crage.

CONGENITAL DEFORMITIES, HEREDITY

Beattie, P. H. **A consideration of aniridia with a pedigree.** Brit. J. Ophth. 31:649-676, Nov., 1947.

Five generations of a family with aniridia are carefully studied. Each member was not individually studied, but sufficient data were obtained from responsible sources to show that this dominant characteristic appeared in about one-half of all members. There were no cases of an affected person mating with an affected person; no consanguineous marriages were recorded. Environment was proved to have no effect whatever.

Thirty-one patients of this family group were personally studied by the author. Four patients had coloboma of iris or hypoplasia of the iris or both; ten had partial or complete aniridia of both eyes; twelve had bilateral aniridia and ectopia lentis; and one had partial aniridia in the right eye and coloboma in the left. These defects followed no definite pattern either in the same generation or succeeding ones but seemed to occur haphazardly in children of affected or normal parents. No fetal eye with aniridia became available for study and little is known about the embryology of the condition. No eye of this family became available for histologic study. As in other reported family studies of aniridia, lens opacities and glaucoma occurred much more frequently than average and the treatment of these conditions was much more difficult and associated with many more complications than usual.

Each examined member is described in detail. (58 references, 5 plates.)

Morris Kaplan.

Cohen, E. S. **A case of anophthalmia.** Harper Hosp. Bull, 5:135-138, Oct., 1947.

Microscopic examination of the tissue behind the conjunctiva failed to reveal any evidence of the layers of the optic cup. The lids and conjunctiva were normal. The left orbit was reduced in size. The optic foramen was normal on both sides. Irwin E. Gaynon.

Diethelm, W. **Ectopia lentis without arachnodactylia.** Ophthalmologica 114: 16-32, July, 1947.

The author's main point is to stress the existence of a hereditary, recessive form of ectopia of the lens and pupil without any signs of mesodermal dystrophy. In support of this view a family is described which, upon thorough examination, failed to show any signs of mesodermal dystrophy. The parents were first cousins and had normal eyes. Of the three children, one girl had ectopia lentis, one boy had ectopio lentis and pupillae and one girl had normal eyes.

P. C. Kronfeld.

Gát, L. **A case of persistent pupillary membrane.** Ophthalmologica 114:52-54, July, 1947.

Gát describes a congenital iris anomaly characterized by multiple radial white strands which take off from the ciliary portion of the iris and form a wreath-like structure in the anterior chamber in front of and concentric with the pupil.

Peter C. Kronfeld.

Hughes, H. L. **A case of bilateral coloboma of the optic disc.** Brit. J. Ophth. 31:689-692, Nov., 1947.

A patient is described who presented the typical fundus of coloboma of the optic disc. The vision in one eye was perception of light and the corrected vision of the other eye was 6/5. Many such cases of bilateral coloboma have been recorded and in most of them one eye was blind and the other exhibited nearly normal vision. The lesion is ascribed to defec-

tive closure of the optic cup at its extreme posterior position. Morris Kaplan.

Marin Enciso, M., and Lopez Gracia, E. **A case of Marfan's syndrome.** Arch. Soc. oft. hisp.-amer. 7:818-821, Aug., 1947.

A case of Marfan's syndrome with subluxated lenses and secondary rise of tension was treated by means of anti-glaucomatous iridectomies, followed about a month later with lens extractions. The lenses were extracted with a Kalt forceps, one arm of which was introduced in front of the lens, and one behind it. There was no vitreous loss, and the post-operative course was uneventful.

Ray K. Daily.

Meeker, L. H., and Aebli, R. **Cyclopean eye and lateral proboscis with normal one-half face.** Arch. Ophth. 38:159-173, Aug., 1947.

A case is reported in which cyclopean eye, lateral proboscis, cleft palate and cleft lip are associated. The cyclopean eye had a double cornea, with two irises and two pupils. The involved side also showed subnormal development of the skull. There was marked mental retardation.

Comparison of this case with the cases previously reported strongly suggests that the defects are the result of incomplete separation of monozygotic twins. Hereditary influences are of importance not only in the occurrence of the individual anomalies but in the formation of the twins on which their development depends. John C. Long.

20

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Fairclough, W. A. **Industrial lighting.** Supp. New Zealand M. J., pp. 2-12, 1947.

A proper balance of light between the background and the work object secures the greatest comfort and efficiency. Visual acuity rises rapidly as illumination approaches five foot candles and then slowly until it reaches its maximum at 100 foot candles. Shadows and glare must be avoided. A daylight fluorescent lamp is most efficient. It produces one-half the total heat and one-fourth of the radiant heat of the incandescent lamp, and produces a high level of daylight quality over large areas without the use of excessive wattage or production of excessive heat.

Irwin E. Gaynon.

Kuhn, H. S. **Vision in industry.** Tr. Am. Acad. Ophth. pp. 54-63, Sept.-Oct., 1947.

In the medical and surgical care of eye injuries, the man with the injured eye should be sent promptly and directly to the plant ophthalmologist, and not first to untrained consulting physicians. Of emergency importance is the prompt and careful removal of foreign bodies, ocular and intraocular, as well as precise lid suturing. The use of ointments in caustic or acid burns is routinely discouraged.

A fair knowledge of the toxic hazards to which workers' eyes are exposed is essential. This includes not only the grouping of toxic agents physically and chemically, but also their uses in specific industries as well as their ectogenous or endogenous contact and course. Immediate and copious water irrigation is the most important factor in emergency treatment. This is best accomplished by immersing the head in a pail of water and opening the eyes. Alkali burns tend to heal slowly and imperfectly.

Close cooperation is essential for management, industrial workers and industrial ophthalmologists, and is usually best obtained through a medical director or consultant. Fact finding data secured by testing procedures should be carefully evaluated before they are used. The difference between the success and the failure is frequently determined by an understanding of the visual requirements of the operations in a plant. Although basic

principles are primarily important, their individual applications are more important. This is the lesson learned from ten years of progress in industrial ophthalmology.

Illumination and color problems are usually best solved by a consultant.

Chas. A. Bahn.

MacMillan, J. A. **Notes on the history of ophthalmology in Canada.** Am. J. Ophth. 31:199-206, Feb., 1948. (6 references, sources.)

Pechdo, M. and Gayral, L. L. **Pathogenesis and physiopathology of nystagmus in coal miners.** Arch. d'opht. 7:521-528, 1947.

Miner's nystagmus is a common and important occupational disease whose prophylaxis, treatment, and pathogenesis still remain unsolved. The authors state that Joseph Pechdo in 1893 postulated that toxic gases acted upon the central nervous system to produce nystagmus but that his report was neglected as a result of claims by Belgian and English ophthalmologists that faulty illumination in the mines produced the condition. Since then, however, much evidence has been advancd to support the theory of the role of toxic agents, and improved illumination alone has not reduced the incidence of nystagmus. The toxic products in coal mines are principally gaseous and the ordinary coal gas consists above all of methane but includes also hydrogen sulfide, carbon monoxide, and carbon dioxide. The gas content is particularly high in certain dead-end galleries. The authors note that certain mines are particularly apt to produce nystagmus. They conclude that treatment is primarily aeration before the nystagmus becomes fixed and that prophylaxis is entirely one of proper ventilation. Phillips Thygeson.

Price, Leo. **Eyesight conservation in garment industry.** Tr. Am. Acad. Ophth. pp. 39-46, Sept.-Oct., 1947.

The trend and purpose of industrial ophthalmology apparently includes the ophthalmic and optical examination of all employees by ophthalmologists, optometrists and other technicians; the fitting and dispensing of glasses at wholesale cost to employer or employee, job analysis, illumination problems, and more or less responsibility for the medical care of all ophthalmic and bodily diseases which might effect industrial visual efficiency. The mechanics of this program is illustrated by the experience of a large union with an organized eye and health center. Glasses were dispensed at an average cost of $5.34 per pair through the optical department. The concession privilege had previously proved unsatisfactory.

In the industrial prescription for glasses each individual should decide his specific working distance preferably by demonstration at work, and prescriptions for glasses must be in terms of specific individual requirements rather than those of the average. Especially in industrial workers past 40 years of age, exophoria may be created by indiscriminate refraction. Hand workers required fewer special working glasses because they can more frequently adjust themselves to the working distance necessitated by the lens that is worn. Workers with evidences of muscle imbalance, infections, and diseases such as cataract, diabetes, and glaucoma were treated at the Health Center or elsewhere.

This contribution should interest especially those who wish to follow the economic and technical trends and purposes of industrial ophthalmology and their relationship to the more or less socialized medicine of tomorrow.

Chas. A. Bahn.

Vail, Derrick. The prestige of ophthalmology. J.A.M.A. 135:71-73, Sept. 13, 1947.

The author feels that what should and does concern the ophthalmologist is the ignorance about his specialty observed in fellow physicians and the indifference they often show to his special knowledge and work. Some of the factors he believes are responsible for this decrease in ophthalmologic influence are the exclusiveness and withdrawal from the general medical field, and the segregation of his activities. The ophthalmologist's work is often performed in special eye hospitals and pathologic laboratories. The eye, ear, nose and throat specialist who is poorly qualified in ophthalmology, however capable he may be in otolaryngology, is responsible for a share of our loss of prestige. The solution lies in insisting that these men be given satisfactory training in ophthalmology. It is surprising and shocking to learn that even some physicians do not know the difference between ophthalmologist and optometrist.

The system of rebates is a blot on ophthalmologists and nothing can be said in extenuation of this widespread evil. There has been a gradual loss of part of the field of endeavor of the ophthalmologist to the neurologist, the neurosurgeon and the plastic surgeon, obviously because the ophthalmologists have not made good as a group. The solution lies in more and better training in order to offer convincing proof that the ophthalmologist knows more about neuro-ophthalmology than does the neurologist and that he can do better plastic repairs on the lids and adnexa that can the plastic surgeon. It is a sad truth that there is little ophthalmic representation in the general medical and surgical groups, and the only remedy is to take a more active part in the affairs of medical practice. Spectacular and notorious publicity can only be harmful and it is the duty of ophthalmologists as individuals and as a group to do all in their power to control it. Theodore M. Shapira.

Woods, A. C. The present policies of the American Board of Ophthalmology. Tr. Am. Acad. Ophth. pp. 5-15, Sept.-Oct., 1947.

A middle of the road policy is advised for the American Board of Examiners which should consider itself, and should be considered, as an agency whose duty is to determine and pass upon the clinical fitness of candidates as safe practitioners of ophthalmology. The history and accomplishments are detailed; its virtues and its potential vices are impersonally discussed.

The power which the Board has acquired should be used wisely, and not abused. Although open to criticism, the standards set by the Board have, on the whole, been reasonable and fair. Its certification indicates that the diplomate has had adequate and organized training which is presumed under normal conditions to produce a reasonably safe and competent ophthalmologist.

The one year preliminary internship is considered unwise. It tends to lower rather than to raise the level of ophthalmology for the reason that it tends to divert a number of excellent candidates from the study of ophthalmology. Forced to take this year at their graduation, they are often diverted into other fields. A properly organized service in ophthalmology should include the necessary training in general medicine and surgery. The second criticism involves all specialty boards including that of ophthalmology and is directed against their insistence on a certain basic training. These requirements are often so loosely specified that it is all but impossible to plan a program of study, or else so elaborate that they

require specially designed courses of instruction, which it is difficult, if not impossible, to obtain. The essential thing is that the candidate for certification have an adequate understanding of the basic sciences relating to his specialty, and not that he have pursued a designated course of study. A third criticism relates to the policy of some boards to insist that certification by the boards be a prerequisite for membership and promotion on hospital staffs. Education is essentially and primarily the duty and responsibility of medical schools and teaching hospitals, and not that of specialty examining boards. The continuance of this policy in teaching hospitals and research institutions will be disastrous. Many qualified investigators and specialists who services are vital would thus be debarred from entering important institutions and hospitals, and from promotion, unless they obtained the extensive clinical knowledge which the board required, much of which is relatively useless to them in the capacity they serve. The net result of this policy would be that medical schools and teaching hospitals would be sold into a form of bondage to clinical groups. Appointments and promotions would obviously be subject to the powers of an outside agency.

The last criticism is directed against the national societies, which require certification of specialty boards as an essential for membership. Although this policy tends to uphold the power, dignity and policy of these boards and insures for the membership of the societies a reasonable grade of clinical efficiency and training, it blocks the path of ophthalmic progress inasmuch as it excludes from membership specially trained men, such as pathologists and bacteriologists, who are devoting their lives to the investigations of ophthalmological problems. Each medical society should assume its own responsibility for the fitness and competence of its membership. The specialty boards are agencies whose sole duty is to determine and pass upon the clinical fitness of applicants as safe practitioners. They should not be given the right to veto candidates for membership in national societies. The national societies should admit without the distinction of class and caste, all fit medical men who are primarily interested in ophthalmology. Chas. A. Bahn.

News items should reach the editor by the 12th of the month

DEATHS

Dr. William H. Chaffers, Lewiston, Maine, died November 29, 1947, aged 60 years.

Dr. William Tarun, Baltimore, Maryland, died November 21, 1947, aged 77 years.

ANNOUNCEMENTS

STUDY COUNCIL COURSE

Since the courses offered by the Ophthalmological Study Council have proved of value in enabling students to obtain residencies and to prepare for the examinations of the American Board of Ophthalmology, the council will offer another course on the basic subjects of ophthalmology at Westbrook Junior College, Portland, Maine, from June 19 to September 11. Laboratory work in pathology, optics, slitlamp, and refraction will be given. The enrollment will be limited to 100.

AEROMEDICAL RESEARCH POSITION

The Air University School of Aviation Medicine, Randolph Field, Texas, is in receipt of an announcement from headquarters, United States Air Force, that the school has been allotted one of the limited number of special research positions recently authorized by Congress to attract outstanding scientists to service laboratories. This action by the Air Force is the first of a series designed to create an Air Force Aeromedical Center capable of fulfilling the needs of that force which emerged from the war as the nation's first line of defense. It is the intention of the School of Aviation Medicine to utilize the new allocation, which carries with it a salary of $10,000 to $15,000 per anum, to establish a civilian position-vacancy for a director of research. Inquiries concerning this vacancy should be addressed to the Commandant, Air University School of Aviation Medicine (27th AF Base Unit), Randolph Field, Texas.

COURSE FOR ORTHOPTIC TECHNICIANS

The American Orthoptic Council and the Ophthalmological Study Council is offering a course for orthoptic technicians comprising: (1) Nine weeks of lectures, demonstrations, and laboratory work on the basic sciences and basic skills, to be given by six or more well-known ophthalmologists and six or more orthoptic technicians. This will be followed by: (2) Six to 12 months of practical work in clinics or private offices, learning the art of orthoptics under the most favorable conditions.

The first part of the course will be given at Nasson College in Springvale in the township of Sanford, Maine, June 28 to August 28, 1948. Tuition will be $100.00; board and room for nine weeks, $200.00.

The second or clinical part of the training will involve in some cases a fee, in some cases no fee, and in many cases a salary, especially when, after a few months' experience, the student becomes a valuable assistant.

The class in the basic subjects is not limited. The number of places available at once in offices and clinics for the second part is limited to 30 or a little more. The course, as a whole or in part, can be taken to great advantage by technicians who are not beginners but already have had experience and wish to improve their knowledge and their skill with a view to better work and a higher salary in a more desirable situation. The demand for competent orthoptic technicians far exceeds the supply.

For information or registration apply to the American Orthoptic Council, 520 Commonwealth Avenue, Boston 15, Massachusetts.

DELTA-GAMMA SCHOLARSHIPS

The Delta Gamma Fraternity has a $1,000 annual fund, from which smaller scholarship awards are available for preparation of those intending to become (1) orthoptic technicians, (2) teachers of partially seeing children, or (3) specialists for blind preschool children.

Anyone wishing to specialize in one of these fields may be eligible for assistance, the amount in each case to be determined by the particular need and costs involved. If you want to enroll for training in one of these fields, apply for a scholarship to Mrs. Richard P. Miller, 39 West Jefferson Road, Pittsford, New York.

Candidates are selected with the advice of a professional committee: Chairman, LeGrand H. Hardy, M.D., of the American Orthoptic Council; Mrs. Virginia Smith Boyce, administrative assistant, National Society for the Prevention of Blindness; Miss Ruth E. Lewis, professor of social work, George Warren Brown School of Social Work, Washington University; Dr. Berthold Lowenfeld, director of educational research, American Foundation for the Blind; Miss Ruth B. McCoy, assistant director, New York State Commission for the Blind; and Lillian Ray Titcomb, M.D., president of executive committee, Nursery School for Visually Handicapped, Los Angeles.

ORTHOPTIC EXAMINATIONS

The annual examination of orthoptic technicians by the American Orthoptic Council will be conducted in September and October, 1948.

The written examination will be nonassembled

and will take place on Thursday, September 9, 1948, in certain assigned cities and offices and will be proctored by designated ophthalmologists.

The oral and practical examinations will be held on Saturday, October 9, in Chicago just preceding the meeting of the American Academy of Ophthalmology and Otolaryngology.

Applications for examination will be received by the office of the secretary of the American Orthoptic Council, Dr. Frank D. Costenbader, 1605 22nd Street, N.W., Washington 8, D.C., and must be accompanied by the examination fee of $25.00.

Washington university course

The Department of Ophthalmology of Washington University School of Medicine, St. Louis, has announced that its annual refresher course will be given from June 7 through June 26, 1948.

The course is purely didactic, consisting of 98 hours of lectures. The subjects covered will include corneal diseases, ocular therapy, surgery, anatomy and pathology, optics, the oculorotary muscles, glaucoma, embryology, fever therapy, perimetry, neuro-ophthalmology, headache, allergy, office-laboratory procedures, industrial ophthalmology, ocular syphilis, radiology in ophthalmology, tuberculosis, dermatology in ophthalmology, and practical refraction.

The tuition is $150.00, and the only prerequisite for those taking the course is a minimum of one year's training in ophthalmology. The course is designed to refresh the busy ophthalmologist, to review candidates for the American Board of Ophthalmology, and to enable the returned physician-veteran to reacquaint himself with his specialty.

Further details may be obtained from Richard G. Scobee, M.D., director of graduate training in ophthalmology, Washington University School of Medicine, 640 South Kingshighway Boulevard, St. Louis 10, Missouri.

Miscellaneous

Eye-Bank report

At the end of its second year of operation, the Eye-Bank for Sight Restoration, Inc., New York, announced that there are now 150 hospital affiliations in the United States and that contributions through membership support have increased 50 percent. Affiliate eye banks have been established in Boston and New Orleans. It is reported that glaucoma clinics and other special types of clinics have increased in number.

Dr. R. Townley Paton, vice-president of the organization, reported that in two years the eye bank has accepted 600 eyes from the public and that 90 percent of these had been used for transplantation. Eyes that could not be certified as suitable for the operation were used for research.

Navy vision program

The U. S. Navy has adopted a comprehensive vision-improvement and eye-protection program which affects several hundred thousand civilian workers in shore establishments throughout the country, in the Pacific and Caribbean islands, and in Alaska and Panama. By direction of Under Secretary of the Navy W. John Kenney and under the supervision of Capt. E. E. Saunders (U.S.N.), contracts have been signed authorizing Ortho-Rater programs in 78 naval shore stations.

As is the case with regular vision testing programs in industrial companies, workers failing to meet visual standards of their jobs will be referred for professional eye care.

George Washington University Hospital

The eye department of the new George Washington University Hospital scheduled to open this spring will serve not only the hospital's eye patients but also those suffering from diabetes, psychiatric disturbances, high blood pressure, and other illnesses.

The new hospital building will permit the establishment of an eye department as a major department of the hospital. As such, its staff will cooperate closely with other divisions in the diagnosis of illnesses not commonly thought of in connection with the eye, according to Dr. E. A. W. Sheppard, who will head the department.

In addition to assisting in diagnosis, the department will make available for Washington eye patients the most modern equipment to test and treat eye disorders. Services will include: (1) A shop to grind lenses and fit and adjust glasses. (2) Facilities for examining and treating eye diseases. (3) A classroom where clinics will be held and undergraduate students will receive instruction. (4) An orthoptic laboratory. (5) An (eye) operating room. The opening of this operating room is expected to relieve present congestion in Washington hospitals. Time allotted for operations by eye specialists now is strictly rationed. (6) A glaucoma clinic.

N.S.P.B. test of children

Work has been started on the evaluation of methods and instruments used to test the vision of school children who may need eye care, in a study sponsored jointly by the National Society for the Prevention of Blindness, the U.S. Children's Bureau of the Federal Security Agency, and the Missouri Division of Public Health.

Six different types of tests will be used in checking the eyes of 1,200 children in 20 elementary schools in St. Louis. Teachers, nurses, and a technician will run the children through the various tests. After school personnel have completed their tests, all children will receive an eye examination by oculists at Washington University Eye Clinics. Because of the many tests and examinations to be given, it is expected that the research will take approximately a year.

Coöperating in this study, in addition to the Washington University School of Medicine, is the St. Louis City Board of Education.

Societies

Trachoma organization

The International Organization against Trachoma was founded officially by decision of the XIIIth Concilium Ophthalmologicum at its meeting at Amsterdam, in 1929, for the discussion of matters of scientific, therapeutic, and international interest connected with trachoma. The last general assembly of delegates and members was held in London on April 21, 1939. The proceedings were reported in *La Revue Internationale du Trachome* for July, 1939, and in the *British Medical Journal.*

A meeting of the executive committee of the I.O.A.T. was held in Paris on May 17, 1947. Present were Dr. MacCallan, president; Dr. Wibaut, secretary-general; Professor Nordenson, president of the Concilium Ophthalmologicum; Dr. Ehlers, secretary-general of the Concilium Ophthalmologicum; Dr. Bailliart, président de l'Association Internationale de Prophylaxie de la Cécité; Dr. Lavery, Eire; and Dr. Churchill, secretary-general, Adjoint de l'Association Internationale de Prophylaxie de la Cécité.

The quarterly journal *La Revue Internationale du Trachome,* which is published in French and in English, is the official organ of the I.O.A.T. Publication ceased during the war but is hoped to recommence shortly. Articles by members of the I.O.A.T. may be sent to: Dr. Jean Sédan, 94 Rue Sylvabelle, Marseille, secrétaire général, La Ligue contre le Trachome.

Membership of the I.O.A.T. is by an annual subscription of 25 shillings sterling; this may be paid to the account of the I.O.A.T. at the National Provincial Bank, 23 Wigmore St., London, W.I., or its equivalent to Dr. F. Wibaut, P.C. Hooftstraat, 145, Amsterdam, Nederland. Larger donations from ophthalmologic societies are invited for the purpose of meeting the general expenses of the organization.

Further information may be obtained from the president: Dr. A. F. MacCallan, Westminster Hospital Medical School, 17 Horseferry Road, London, S.W.I., or from the secretary-general: Dr. F. Wibaut, P.C. Hooftstraat 145, Amsterdam, Nederland.

Reading program

The 76th meeting of the Reading Eye, Ear, Nose, and Throat Society was held jointly with the Diplomates Association of Berks County Physicians. The speaker was Dr. Leandro M. Tocantins, associate professor of medicine at Jefferson Medical School. He spoke on "The Critical Appraisal of Available Methods for the Control of Hemorrhagic States."

Georgia annual meeting

The Georgia Society of Ophthalmology and Otolaryngology held its annual meeting at the Fulton County Academy of Medicine, Atlanta, March 5 and 6. The lecturers included: Dr. Bennett Y. Alvis, St. Louis; Dr. Arthur J. Bedell, Albany; Dr. Ramon Castroviejo, New York; Dr. J. Brown Farrior, New Orleans; Dr. French K. Hansel, St. Louis; Dr. J. Elliott Scarborough Jr., Atlanta.

Louisiana-Mississippi meeting

The Louisiana-Mississippi Ophthalmological and Otolaryngological Society will hold its annual meeting at the St. Charles Hotel in New Orleans on Saturday, April 17, 1948. The program will include: President's Address, Dr. Noel T. Simmonds, Alexandria, Louisiana; "Secretional Obstruction and Bulbar Poliomyelitis," Dr. Thomas C. Galloway, Evanston, Illinois; "The Preparation of Patients for Intraocular Surgery," Dr. Walter Stevenson, Quincy, Illinois; "The Management of Complications of Ocular Surgery," Dr. Watson Gailey, Bloomington, Illinois; The J. Raymond Hume Memorial Address—"Vertigo: Differential Diagnosis and Treatment," Dr. J. R. Lindsay, Chicago, Illinois.

Hungarian medical week

In commemoration of the Hungarian War of Liberty, the Hungarian Medical Trade Union will arrange a celebrating medical week from September 4 to 12, 1948. The Hungarian Medical Society cordially invites eminent medical personalities and practitioners of foreign countries to be present and would be greatly honored by their active participation.

Preliminary information will be sent to personal addresses, institutions, and so forth all over the world. In consequence of the war, a great part of the addresses of medical men in our possession was destroyed. For this reason it is desirable to draw the attention of the foreign medical community to the above mentioned Medical Week by means of publication in the medical press.

Program of Milwaukee meeting

The Milwaukee Oto-Ophthalmic Society held its regular meeting on February 24, 1948, at the Milwaukee Athletic Club. The Mount Sinai Hospital Departments of Ophthalmology, Otolaryngology, Radiology, Pathology, and Neurosurgery had charge of the program which included: "Introductory Remarks," Dr. M. S. Fox; "Indications for Fenestration Surgery: Case Report," Dr. Gerhard Strauss; "Encephalitis and Chiasmitis," Dr. E. E. Grossmann, Dr. Norbert Enzer, and Dr. J. Mufson; "Ocular and Nasal Findings in Lesions of the Optic Foramen: Case Reports."—Ophthalmology, Dr. S. S. Blankstein; Otolaryngology, Dr. M. S. Fox; Radiology, Dr. M. Moel; Pathology, Dr. Norbert Enzer; and Neurosurgery, Dr. J. Mufson.

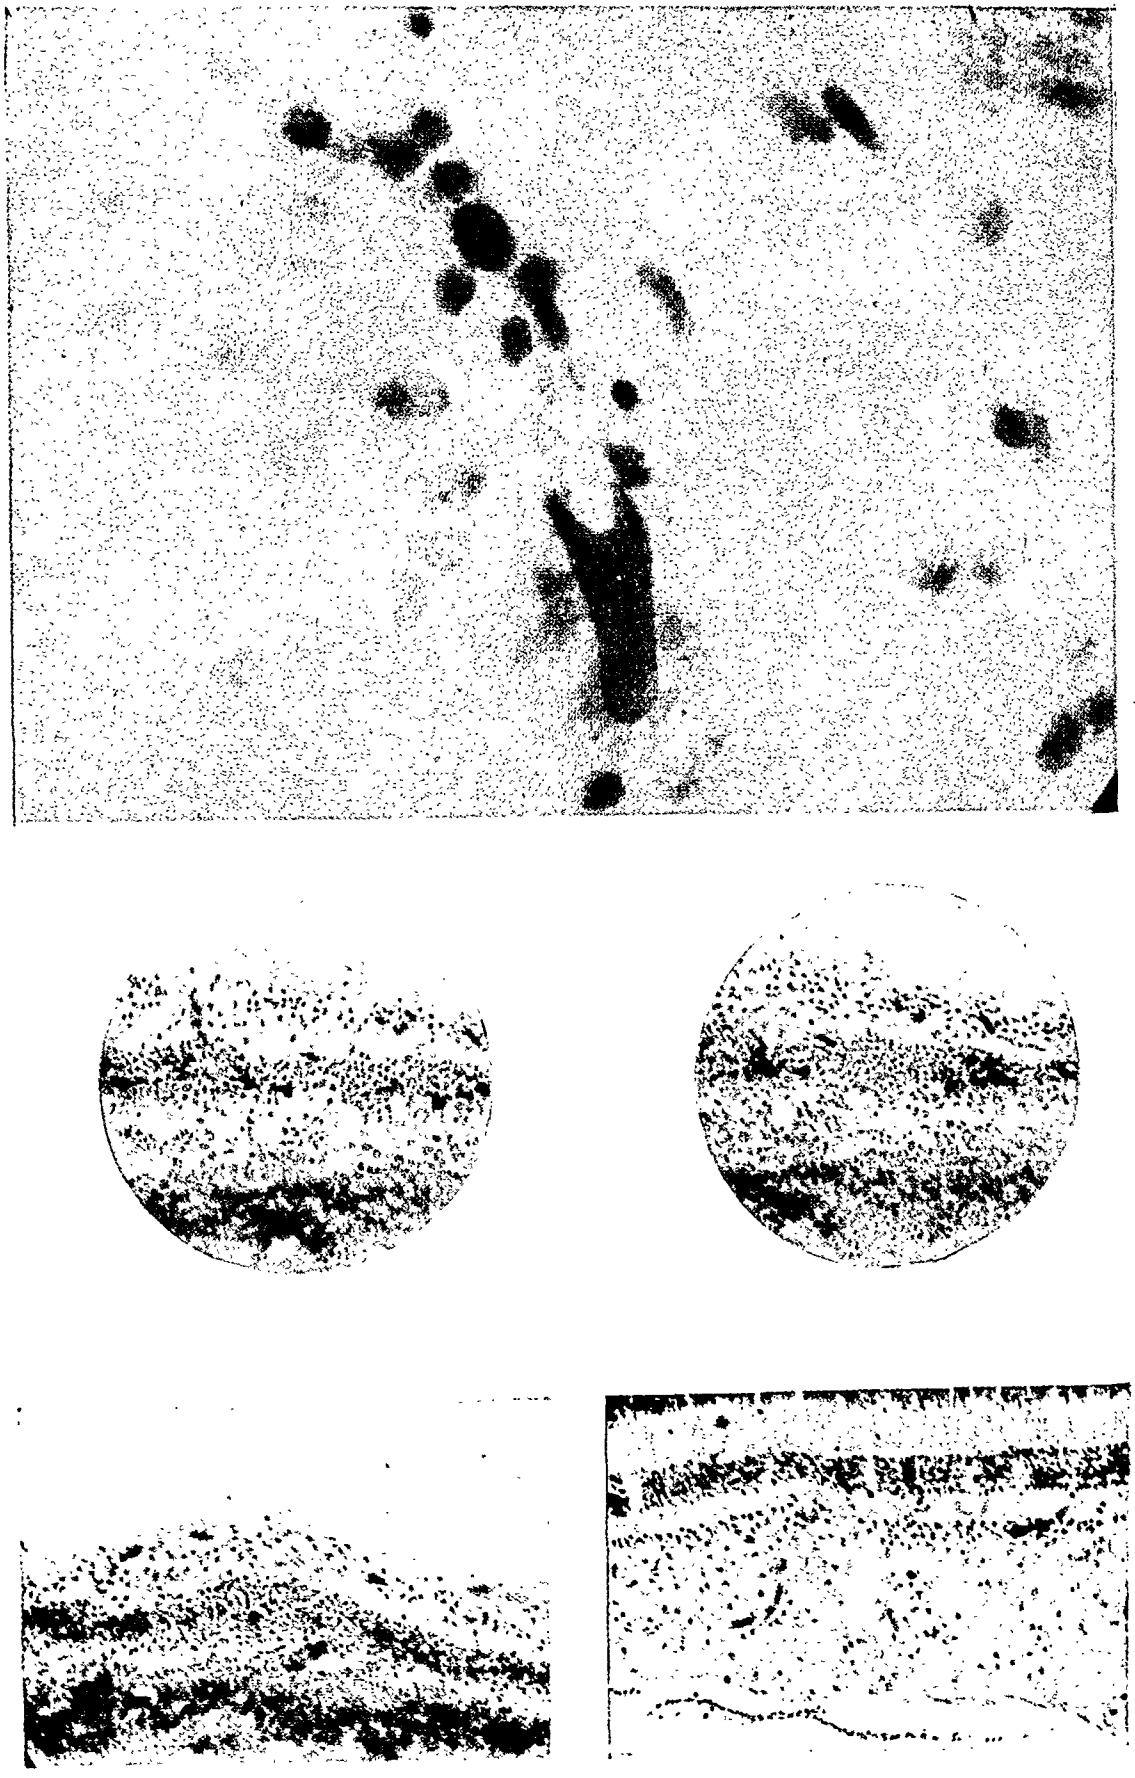

PLATE 1 (FRITZ AND HOGAN). FAT EMBOLI ARE SHOWN IN THE RETINAL VESSELS BY THE USE OF SUDAN-IV STAIN

AMERICAN JOURNAL OF OPHTHALMOLOGY

VOLUME 31 MAY, 1948 NUMBER 5

FAT EMBOLIZATION INVOLVING THE HUMAN EYE*

MILO H. FRITZ, M.D.†
New York
AND
MICHAEL J. HOGAN, M.D.‡
San Francisco, California

Prior to 1862 it had been surmised that fat embolism might follow injuries to the long bones or soft tissues. In that year, Zenker reported the first case of fat embolism in man. Since that time a fair number of case reports and studies of the condition have appeared in the literature.

ETIOLOGY OF FAT EMBOLISM

By far the greatest number of cases of fat embolism have followed injuries to the bones or soft parts of the body. Vance groups the factors causing this condition as follows:

1. Traumatic
   - A. To bones
     - (1) Fractures
     - (2) Jarring of bones
     - (3) Orthopedic operations
   - B. To soft parts
     - (1) Injury to subcutaneous fat
     - (2) Injury to fatty viscera
     - (3) Burns
2. Nontraumatic (dubious)
   - A. Diabetes
   - B. Childbirth
   - C. Injection of oily substances

The largest number of instances of this condition followed fractures of the long bones, particularly those of the lower extremities. Cases have been reported, however, following concussion of the bones, with liberation of fat into the circulation. Cases have been reported following manipulation of old contracted rheumatoid joints or other orthopedic operations such as osteotomies or excision of joints.

MECHANISM OF PRODUCTION OF EMBOLI

Depot fat is found in the subcutaneous tissues, omentum, viscera, and in the bone marrow. The fat in these various structures is stored within the confines of large cells. The marrow fat is the source of most emboli and may be liberated from the cells by direct rupture as in a fracture or by concussion from a blow. The vessels in the bones are held within the rigid Haversian canals and do not readily collapse following the injury. The liberated fat enters these torn vessels during or following the injury. This fat passes through the venous system to the right side of the heart and pulmonary circulation where fine emboli lodge in the capillaries of the lungs. Some of these capillaries may rupture, liberating fat into the alveoli, accounting for the fatty sputum which is occasionally noted. Some of the fat may pass through into the general circulation and result in systemic emboli. Fat may also be excreted by the kidneys, without the development of renal

* Part of the expenses connected with this research was met by the Florence Ellsworth Wilson Memorial Fund Fellowship in Ophthalmology.

† From the Eye-Bank Laboratory, New York, New York.

‡ From the Proctor Foundation for Ophthalmic Research and the Division of Ophthalmology, University of California Medical School.

damage. This accounts for the fat which is seen in the urine in many of these cases.

Symptoms and Signs

There are two main forms of the disease which may be encountered:

1. Pulmonary. The clinical symptoms in the pulmonary form may be of two types. The first develops soon after the injury and the symptoms are of acute and rapidly progressive pulmonary failure and are due to a massive flooding of the lungs with fat. The second type is more common and commences on the third or fourth day after the injury.

2. Systemic. The symptoms in this form depend on passage of fat to the various organs of the body after leaving the pulmonary system. In general the frequently involved portion of the body is the central nervous system. Restlessness, excitement, delirium, convulsions, and coma are frequently noted in this order. The skin may show petechiae; fat may pass into the urine through the renal glomeruli. Death may occur in from 2 to 6 days.

Ocular findings

A search of the literature shows only one case report which deals with the ocular findings (Evans). In this case a man, aged 23 years, was injured in a road accident. Twenty-four hours later the patient became drowsy. On examination he showed contusions, a fractured right tibia and fibula, right patella and right ulna. All fractures were set under ether anesthesia following admission to the hospital. Forty-eight hours after the injury, the patient was excited and developed incontinence of urine. He showed petechiae on the chest and neck, a slight squint of the left eye, and fat in the urine. Four days after the injury the fundi were examined and showed diffuse edema of the whole posterior pole, especially the macular regions. There were three crescentic areas of intensified pallor near the right macula. In the right eye there were two large subhyaloid hemorrhages, temporal and below the macula. In the left eye there was one smaller hemorrhage in the periphery. The ocular blood vessels appeared normal. Fifteen days after the injury the patient was much better and was able to read. The fundi showed less edema. Two months after the injury, the vision was 20/20 in each eye, and there was still a small remnant of the subhyaloid hemorrhage in the right eye but the left fundus appeared normal.

Because of the paucity of information in the literature concerning the ocular complications of generalized fat embolization and because the ophthalmoscopic and ocular histopathologic changes were so clearly and unequivocally observed in a typical case, it was deemed worthwhile to draw up a complete case report.

Case report

A 21-year-old soldier was admitted to the emergency room about 8:30 a.m. (Eastern war time), June 27, 1945, in shock.

History. At about 7:50 a.m., June 27, 1945, while the patient was on duty in the forward galley of a tug boat at the Boat Squadron Dock, a gasoline stove had exploded from an unknown cause and the concussion of the explosion had caused the following injuries:

1. Fracture, compound, complete, both tibias and fibulas, mid-third.
2. Fracture, simple, complete, medial malleolus, right tibia.
3. Fracture, simple, complete, posterior lip, left tibia.
4. Fracture, 9th rib posteriorly, right side, and 1st rib, left side.
5. Fracture, 1st sacral segment, simple, incomplete.
6. Wound, lacerated, parietal region of skull.
7. Hematuria, origin undetermined.
8. Shock traumatic; B.P. 40/15 mm. Hg.

Examination. At 8:40 a.m., the blood pressure was 120/80 mm. Hg. A 500-cc. transfusion of plasma was started immediately after admission. The pulse was in the range

of 84 to 88. Complete blood studies were ordered, including hematocrit, and the patient was immediately typed for blood transfusion. From 8:55 to 11:00 a.m., the blood pressure range was 115 to 130/75 mm. Hg. He was then given 500 cc. of whole blood.

After the patient's condition became stabilized, splints were applied to both legs. The patient was conscious and oriented at all times and discussed the accident quite freely.

X-ray films of the legs, pelvis, and chest were made, and the possibility of a head injury was kept constantly in mind. At no time were there any neurologic findings to indicate such an injury.

The patient was catheterized, for there was the possibility of a genito-urinary tract involvement, and bloody urine was obtained. A cystogram was obtained and showed no evidence of rupture of the bladder. The abdomen was soft. There was no pain nor tenderness over the kidney regions. The chest was clear, and at that time there was no evidence of a blast injury.

During observation and study, from 8:30 a.m. to 1 p.m., it was the opinion of the surgical department that this patient could be operated upon, the fractures reduced, and alignment maintained. At time of operation, red blood-cell count was 4,230,000; hematocrit, 40; and blood pressure, 108/80 mm. Hg.

Operation. Under ether and oxygen anesthesia, the legs were thoroughly scrubbed with soap and water, shaved, and alcohol and tincture of merthiolate applied. The wounds were debrided. The left tibia was united with transfixion screws, and the right tibia with transfixion screws and a 4-screw plate. During the operation, the patient received glucose, blood, and normal saline intravenously. He lost considerable fluid on the table. After fixation, casts were applied and the patient was returned to bed.

At 11 p.m., the patient was seen by the orthopedic department, and at that time he had recovered from anesthesia; the blood pressure was 116/80 mm. Hg; pulse, 116. He was talking about the accident, and his postoperative condition was good.

Course. He was next seen at 8 a.m., June 28, 1945. There was a very marked change in his condition. He was unconscious and reacted sluggishly to stimulation. There was very slight pupillary response to light, flaccid paralysis of the arms, and the temperature was 102.5°F.; blood pressure, 108/70 mm. Hg; respiration, 30; pulse, 130. Again the question came up as to the presence of head injury. The unconsciousness, the slight response to stimuli, and paralysis were all suggestive of a head injury. Acidosis, pulmonary edema, and secondary shock were considered.

Coma continued until time of death. Complete blood chemistry examination revealed no explanation for the coma. A spinal tap was done, and was grossly clear. Clinically there were no signs of increased intracranial pressure.

Eye examination. Ophthalmologic consultation on the same day revealed the pupils to be round and equal in size. They reacted briskly to light. Under homatropine mydriasis, the fundi showed round and oval, white, subretinal exudates completely surrounding both maculas and following the course of the main retinal vessels. There were no hemorrhages. The macula in the right eye appeared cherry red. Diagnosis was: (1) Multiple fat emboli of the retinal vessels. (2) Edema of the retina secondary to the embolism of the vessels.

Diagnosis. From the accumulated data, a diagnosis of fat embolism was based upon the following considerations: (1) Presence of fat in urine. (2) Coma in a man with multiple fractures. (3) Coma in a man without signs of increased intracranial pressure. (4) Eye-ground examination which showed embolic phenomena involving the retinal vessels. (5) Multiple petechial hemorrhages of skin and conjunctiva. (6) Chest films had a cotton ball appearance in the parenchyma of the lungs.

Later the same day the patient was seen

by Lieut. Col. Phillips Thygeson and Lieut. Col. S. Rodman Irvine, who wrote: "Media clear. Edema and exudates both fundi, more marked in right. Discs appear normal. No actual fat emboli seen but appearance of retinas suggest an embolic phenomenon involving central vessels."

On June 29th, the ophthalmologic note read: "There are multiple conjunctival petechiae in both eyes. Eyegrounds show no hemorrhages. Exudates increased in number in left eye. They are along vessels which appear quite normal."

The ophthalmologic note on July 3rd read as follows: "Cotton wool would best describe the exudates now. There are more of them along the vessels on the left and in one of them is a hemorrhagic area. On the right there are now many white exudates on both sides of the disc. The cherry red macula in the right eye persists."

About two days after admission, the patient had X-ray evidence of pneumonia in the right lower lobe. He was treated by oxygen, intravenous glucose and saline, multiple blood transfusions, intravenous vitamins, and concentrated albumen. He was also given penicillin intramuscularly in large doses, and from the 2nd to the 5th postoperative day, he was given 5 gm. of sodium sulfadiazine daily.

The patient at no time came out of his comatose state, and the course was gradually downhill. He developed an acute pulmonary edema, which disappeared on the sixth postoperative day after the administration of 100 cc. of concentrated albumen. Previous to this time, the man had been given concentrated glucose, atropine, and frequent tracheal aspirations. At times as much as 200 cc. of fluid would be obtained in one tracheal aspiration. Fat was never obtained in the sputum. Blood chemistry was relatively normal except for the blood chlorides, which were elevated on two successive days. This was taken care of by discontinuing the administration of intravenous saline. The red count ranged between three and four million.

The patient died on the 10th postoperative day, July 6, 1945, at 2:05 p.m.

General pathologic report

The following notes are all that have been found of the general pathology protocol. Scharlach-R stain was used.

Brain. Fat stain of the brain shows many capillaries plugged with fat emboli. Surrounding many of these emboli are seen focal areas of necrosis not associated with hemorrhage. There is seen in various portions of the section what appears to be free fat globules within the parenchyma and here and there early phagocytosis of the lipoid material is in progress.

Myocardium. Microscopic section of the myocardium shows nothing of note.

Lungs. Microscopic section of the lungs shows many of the alveolar spaces filled with polymorphonuclear leukocytes. The bronchioles are filled with purulent material. Many large phagocytes filled with brown-staining material are seen. Fat emboli can be demonstrated within the lung tissue. There is considerable hemorrhage within the alveolar spaces surrounding these emboli.

Liver. Microscopic section of the liver shows normal configuration of the liver lobules. The cytoplasm of hepatic cells is somewhat granular. Scharlach-R stain shows an occasional large droplet of fat within the sinusoids.

Spleen. Microscopic section of the spleen shows engorgement of the sinusoids.

Kidneys. Microscopic section of the kidneys shows many of the glomeruli in the H.-&-E. stain to contain what appears to be large clear spaces. Scharlach-R stain reveals that these areas are fat globules filling the capillaries.

Diagnosis. (1) Fat embolism (generalized fat embolization). (2) Pneumonia, terminal.

Ocular pathologic report

Gross examination

(Dr. Hogan, made this report.) Calottes had been removed from both eyes prior to

their reception at the laboratory. The specimens had been embedded in gelatin blocks and preserved in 10-percent formalin. It was not possible to identify the eyes as to whether they were right or left eyes or to render a gross description of the specimens.

Fig. 1 (Fritz and Hogan). Hemorrhage in the inner retinal layers (Sudan IV).

Fig. 2 (Fritz and Hogan). Focal area of retinitis. Note fat-filled capillaries at periphery of lesion (Sudan IV).

Technique

Frozen sections of the gelatin blocks of the embedded eyes were made with the freezing microtome. The cut sections were stored in distilled water containing a small amount of 10-percent formalin. The best sections were selected and stained with Sudan IV for fat. The stained sections were mounted on slides in a solution of either gum arabic or glycerin under glass cover slips. The cover slips were rimmed with paraffin or concentrated nitrocellulose to prevent drying.

Microscopic description

Cornea. The epithelium shows some atrophy and slight postmortem degeneration.

Limbus. Schlemm's canal is open and the

trabecular meshwork contains some clumps of dark uveal pigment.

Sclera. The sclera shows small, scattered globules of fat on the surface, but not in conjunction with any of the blood vessels.

Choroid. The posterior choroid, adjacent to the optic disc, shows several vessels just beneath the choriocapillaris which contain

Fig. 3 (Fritz and Hogan). Capillary fat emboli in inner retina (Sudan IV).

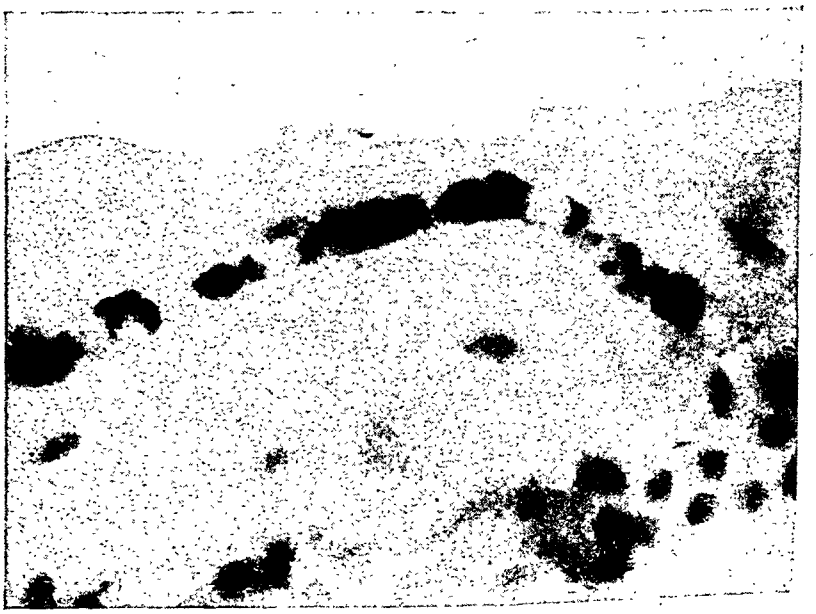

Fig. 4 (Fritz and Hogan). Embolus in retinal capillary (Sudan IV).

Anterior Chamber. There are several large dark clumps of uveal pigment in the angle.

Iris. The iris shows heavy pigmentation, but does not appear to be inflamed.

Ciliary Body. The stroma and processes show light diffuse edema and round-cell infiltration. Several small capillaries in the longitudinal portion of the ciliary muscle show fat emboli.

Choroid. The posterior choroid, adjacent to the optic disc, shows several vessels just beneath the choriocapillaris which contain fat emboli. The stroma around these vessels is chronically inflamed.

Retina. The principal changes in this eye have occurred in the retina, posterior to the equator. The temporal portion of the retina seems to be most affected, and there are extensive changes in the macula. The nerve-

fiber, ganglion-cell, and inner-plexiform layers are most severely affected. The following changes are noted in these areas: (1) Scattered, fine circumscribed hemorrhages in the nerve-fiber and ganglion-cell layers. (2) Focal areas of edema, hemorrhage, chronic inflammation, and secondary degeneration are seen in the inner portion of the retina (fig. 1). In and around these areas, the terminal retinal arterioles and capillaries are dilated and contain fat emboli which stain with Sudan IV (fig. 2). In some areas the capillaries have ruptured and fat lies loose in the retinal stroma. (3) Scattered capillaries in the nerve-fiber, ganglion-cell, and inner-plexiform layers throughout the retina show small fat emboli (figs. 3, 4, 5, and 6). Some of these vessels show perivascular round-cell infiltration. (4) In several areas, the inner limiting membrane shows interruptions and a fine fibrinous exudate fills the gap and lines the inner retinal surface.

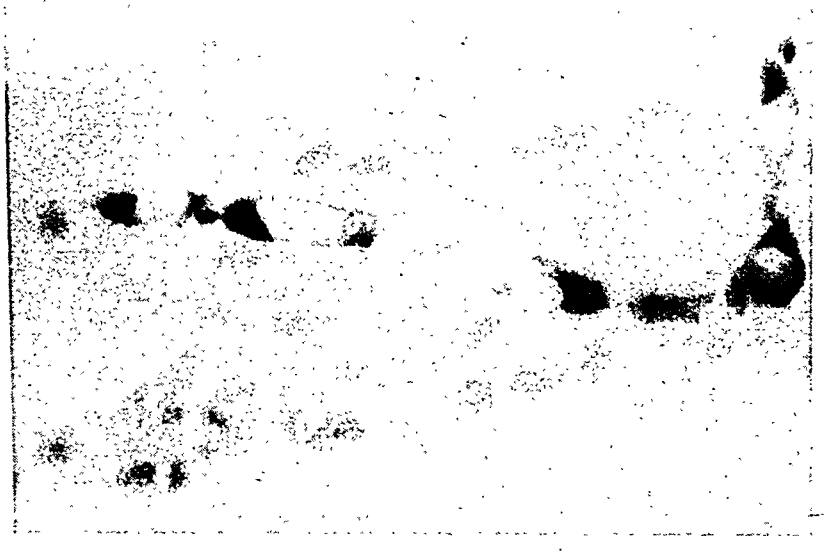

Fig. 5 (Fritz and Hogan). Fat embolus in retinal capillary (Sudan IV).

Fig. 6 (Fritz and Hogan). Embolus in retinal capillary (Sudan IV).

Optic Nerve. The disc appears somewhat

edematous, especially at the nasal and temporal borders. A number of capillaries in various sections show fat emboli. There are a number of small circumscribed hemorrhages on the disc, especially in the nerve-fiber layer on the nasal side. A few chronic inflammatory cells lie on the inner surface of the cup.

Vitreous. The vitreous details are obscured due to the necessity of embedding the specimen in gelatin.

Lens. The contents of the lens were lost in preparation of the specimen, but the capsule and epithelium appear normal.

Comment

The sections of this specimen show undoubted fat emboli in the terminal retinal arterioles and in the retinal capillaries. There are also a number of small retinal hemorrhages in the inner layers. The edema and degeneration of the retina seen in the areas of these emboli probably result from a lack of nutrition caused by blockage of the vessels. It is interesting that the larger retinal and optic-nerve vessels show no emboli.

The changes seen in the second specimen are identical with those reported in the above eye so it is not necessary to duplicate the description. In general the findings in the retina in this eye are not as severe as those seen in the fellow eye.

Diagnosis

1. Embolism, fat, retina, choroid, optic nerve, and ciliary body.
2. Retinitis, secondary to fat embolization.

210 East 64th Street (21).

University of California Medical Center (22).

The authors' thanks are due to the following individuals without whose coöperation the reporting of this case would not have been possible.

Lieut. Col. Coy S. Stone (MC), Chief of the Surgical Service, Station Hospital, MacDill Field, Tampa 8, Florida, gave the authors the opportunity of making the diagnosis and observing the eye grounds during the life of the patient.

Miss Madeline Banton, secretary to Colonel Stone, assembled records that seemed irretrievably lost in the confusion following the rapid changes of personnel after capitulation of the Japanese.

Capt. Millard B. White (MC), pathologist of the Station Hospital, contributed the protocols and made the sections of the thoracic organs, the abdominal organs, and the brain.

THE TEACHING OF OPHTHALMOLOGY*

The Harry S. Gradle Lecture

Derrick Vail, M.D.
Chicago, Illinois

We sincerely regret that Prof. Harry S. Gradle is not here with us, either to give this, the first Gradle Lecture, in person, or to hear its presentation. It is our great loss for Dr. Gradle, more than any other individual in the United States, thought more about and did more to stimulate the teaching of ophthalmology.

It was his genius that helped to develop the instruction courses that are so important in the life of the American Academy of Ophthalmology and Otolaryngology and its members, and it was he who conceived and executed the Home Study Courses in Ophthalmology that have guided and will continue to guide the early thinking and steadfast study habits of a neophyte ophthalmologist. He has written and talked much and thought deeply about all the phases of the teaching of our great specialty.

Shortly before his retirement, because of ill health, from the activities and the group of colleagues whom he loves, he was engaged in a plan to integrate all the ophthalmic facilities of Chicago and to form a continuous postgraduate course of ophthalmology, open the year around to any qualified physician, and covering every subject embracing the broad field of ophthalmology. It is the hope and ambition of the members of the Chicago Ophthalmological Society to carry out this plan to a successful conclusion. Alas, his genius and help are no longer available to us, and it will take much time and skill to come near to his expectations.

* Presented at the III Pan-American Congress of Ophthalmology, Havana, Cuba, January 7, 1948. From the Department of Ophthalmology, Northwestern University Medical School.

Teaching is responsibility

It is with considerable disquiet that I have accepted the invitation, and the great honor it imposes, to give the Harry S. Gradle Lecture, because until very recently my endeavors in the field of ophthalmic education have been limited and my outlook and experiences are just beginning to unfold. Yet the teaching of ophthalmology is a subject that is of the utmost importance to men and women everywhere and of the deepest significance to society. Eyesight is the greatest gift to mankind, and it is our chosen responsibility to endeavor to preserve, maintain, and restore, where necessary, the use of this priceless gift. The teaching of ophthalmology is a part of this grave responsibility and we will not have fulfilled our destiny until each one of us has added a bit to the pool of knowledge or has passed down parts of it to those who are to succeed us.

The teaching of ophthalmology entails a discipline similar to that of any other medical specialty, although the field that is covered is broader than most of them. Our material is the young physician, who has just completed his interneship, or the older physician, who wishes to take up the study and practice of ophthalmology either as a part of his practice or as the whole. But the seeds of our teaching should be planted earlier than this, in the minds of the undergraduate medical student and in some favorable cases by a postnatal approach, as those of us who have been lucky enough to have ophthalmologic fathers, and there are many such, can testify. Fortunate, indeed, are those individuals who have been exposed from the cradle on to the intellectual and

stimulating environment of ophthalmology and have grown up into the specialty as a natural birthright. Harry S. Gradle is one of these, and he is a great credit to a great father.

Qualifications of ophthalmologist

Our raw material must be of first rate quality. The individual seeking to make a success of the practice of ophthalmology must possess keen vision, excellent color discrimination, a steady hand, a courageous heart, sympathy and understanding and love for man. He must have a definite artistic temperament, a somewhat feminine quality of intuition, and he must be a perfectionist. He must have a high sense of duty, a conscience that pricks but does not stultify, and a masculine boldness that is at its best in emergency. He should be able to draw straight and curved lines with a pencil or knife. He should be interested in medicine and surgery, physics, optics, physiology, chemistry, and psychiatry. He should be a student of anatomy, embryology, and pathology.

The teacher should be an experienced clinician or laboratory worker, or both, with unquestioned intellectual integrity. He must be patient and sympathetic, logical, tireless, and efficient. But above all he must be interested in teaching, adaptable to new trends and situations, and eager to seize upon all tried methods of getting his subject across the barrier of his and his student's mind. Unfortunately, there are not enough of such individuals thus described, either teacher or student. But the ideal is there and it should ever be before us.

Facilities for teaching

On the whole, the physical plants and facilities for the teaching of ophthalmology throughout Pan America leave much to be desired. There are only a relatively few adequate places with ideal surroundings where ideal teaching to ideal students can be carried out. Yet if the instinct and urge, the wish and the ability are in the heart of a teacher, the student can learn even if there be nothing but a log for the two to sit upon, and sand upon which to draw the necessary diagrams. So, in the last analysis, it all comes down to the quality of the men, teacher and pupil.

Let us see how an individual, wishing to become one, develops into an ophthalmologist. These are the steps: (1) Undergraduate teaching, (2) graduate teaching, and (3) postgraduate teaching.

Undergraduate teaching

A recent study by a committee of the American Academy of Ophthalmology and Otolaryngology embraced an investigation of the curriculum of undergraduate ophthalmology in every medical school in the United States. Many interesting facts were disclosed upon which suitable recommendations to medical schools could be made.

There was a wide variation in the hours allotted, the subjects covered, and the methods of instruction. Some of the schools with great reputations were weak and others of lesser caliber were strong in this department. In some, the methods of instruction that were used were casual and haphazard, in others thoughtful and meticulous. The total number of hours varied from 24 to 118, the average being about 53 hours given to the undergraduate teaching of ophthalmology. The complete report of this committee is appended hereto. It rightly forms an essential part of this presentation.

*Report of the Committee on Undergraduate Instruction in Ophthalmology to the Council of the American Academy of Ophthalmology and Otolaryngology. October, 1947.**

The Committee on Undergraduate Instruction in Ophthalmology sent questionnaires to the ophthalmology department heads of 40 of the leading medical schools of the country. Replies were received from 37 regarding the amount and nature of the teaching given in their respective institutions. Appreciation is expressed by the committee for this coöperation since the ques-

* Published in the *Transactions of the American Academy of Ophthalmology and Otolaryngology*, Nov.-Dec., 1947, pp. 134-135.

tionnaire was somewhat long and involved. These replies were analyzed and carefully considered. Based on a study of them, the following outline is presented as a model for undergraduate teaching of ophthalmology. The committee realizes that modifications must be made by individual schools depending on available personnel and facilities and it is not their intention to present an exact outline, but rather to define in general terms certain goals that are considered desirable.

Outline for the Teaching of Ophthalmology to Undergraduate Medical Students. The anatomy and physiology of the eye may best be given as a part of the respective courses in the departments of anatomy and physiology. It is suggested that the services of the department of ophthalmology should be utilized in the presentation of these subjects.

The anatomy and physiology of the eye including physiologic optics might well occupy 20 to 24 hours, being approximately equally divided between the two subjects.

In the regular course of pathology one or two hours toward the end of the course should be devoted to the study of eye pathology. Here also the help of the department of ophthalomology might advantageously be utilized.

At the beginning of clinical instruction the student should be assigned to the department of ophthalmology for indoctrination in the use of ophthalmic diagnostic instruments for a period of from four to eight hours. This would include instruction in ophthalmoscopy, perimetry, external examination, the use of oblique illumination, the taking of vision, the gross examination of ocular motility, but no consideration given to the technique of refraction.

In the department of ophthalmology a minimum of 40 hours and a maximum of 60 hours should be required. Of this 20 percent to 40 percent may well be didactic and 60 percent to 80 percent clinical.

Didactic Instruction. The bulk of the didactic teaching should precede the clinical instruction in ophthalmology. The didactic teaching should be largely devoted to the relationship of ophthalmology and general medicine and to a study of the most important eye diseases met with in the general practice of medicine. To this end it is suggested that the first one or two lectures only be devoted to a review of the anatomy and physiology of the eye; a third lecture be on asthenopia and disturbances of ocular motility; a fourth on important eye diseases requiring differential diagnosis, such as conjunctivitis, keratitis, and uveitis, with special emphasis on glaucoma. All the remaining lectures, which therefore constitute a majority of the course, should be devoted to the various phases of medical ophthalmology. Under this head should be included such subjects as ocular manifestations of systemic diseases, syphilis, tuberculosis, diabetes, malignancies, blood dyscrasias, and vascular disease. Also the important subject of neuro-ophthalmology, including optic neuropathies and the ocular manifestations produced by intracranial lesions, should be considered. It is considered important that lectures should not slavishly follow textbooks, but should exceed the usual brief and relatively uninspiring textbook approach.

The use of visual aids to supplement teaching should be extensively employed.

Certain "don'ts" for the didactic course seem worthy of special mention, namely:

1. Do not discuss the technique of refraction.
2. Do not spend important time on the diagnosis of muscle anomalies.
3. Do not consider medical and ophthalmologic curiosities.

Clinical Instruction. Subjects in so far as possible should illustrate the material presented in the didactic lectures. Effective clinical teaching can be given only to small groups of students. Direct observation of surgery is of doubtful value. The salient points can be adequately covered with motion pictures. If surgical demonstrations are to be given, they should be confined to a few typical examples of common operations. The opportunity to observe operations may be offered as an elective.

History taking and actual examination of the patient by the student is an important feature and the student's work should be reviewed by the instructor. During this period of clinical instruction proper emphasis should be placed on the technique of the examination.

Since ophthalmology is a required course, an examination should be given at its termination.

Every student should be required to own his own ophthalmoscope and a suitable textbook.

It is urged that the departments of medicine, obstetrics, pediatrics, and neurosurgery require that an ophthalmoscopic record be made of each student on the patients assigned to him.

In so far as possible, elective courses in ophthalmology should be offered by the department. (Signed) Lawrence T. Post, M.D., *Chairman;* Edwin B. Dunphy, M.D., Derrick Vail, M.D., and Alan C. Woods, M.D.

Comment

The purpose of a good course in ophthalmology to the undergraduate medical student should be (1) to introduce him to an important and fascinating field of medicine, (2) to teach him ophthalmoscopy and the relationship between the eye and general diseases, (3) to teach him to recognize and diagnose the mutilating eye diseases that are likely to be encountered—such as glaucoma, iritis, conjunctivitis, and cataract—by any practicing physician, and (4) to teach him

the importance of consulting with the expert ophthalmologist who will be of great help to him and to his patient and who will gain his respect. The undergraduate course should not include refraction, ophthalmic surgery, and the various techniques of advanced study.

Graduate teaching

By graduate training I mean that obtained through residencies or preceptorship. It does not, nor should it, include short courses here and there. It is in this phase that the sincere, earnest, and talented young physician obtains his foundation of ophthalmic knowledge and practice, upon which his entire career rests and his integrity and intellectual honesty depend. There is a trend, and I think it is a wise one, for the development of special basic courses in ophthalmology to follow the interneship and to precede the residency.

Curriculum of training

This preresidential course embraces ophthalmic anatomy, histology, embryology, and pathology, optics, visual physiology, and principles of refraction. It includes the instrumentation and techniques of examination, such as inspection, observation, and notation, slitlamp biomicroscopy, tonometry, perimetry, gonioscopy, and especially ophthalmoscopy. The principles and care of the instruments are taught.

Emphasis is also given to biochemistry as it pertains to the eye, pharmacology and therapeutics, neuroanatomy, neurophysiology and neuro-ophthalmology, bacteriology, serology, and toxicology. Such miscellaneous topics as heredity, ophthalmic psychiatry, occupational or industrial ophthalmology, and so on, are essential parts.

A satisfactory basic course must cover, as far and as widely as possible, ophthalmology as it pertains to general medicine, for we are physicians first and ophthalmologists second.

Length of course

The length of such a course varies from place to place depending upon the talents and skills of the members of the faculty and on the physical facilities and equipment that are available.

A basic course without any clinical inclusion can be given adequately in four months. Clinical experience, enough at least to permit the graduate student to exercise the things that he has learned in the classroom, is desirable, but it prolongs the course six to nine months. This is not a misfortune for in the short course scarcely enough time is allowed for the student to digest and absorb the material that is presented to him.

The danger of a longer basic course is that the student considers, in some cases, that he has had enough training and will go out into practice without further to do.

At the moment this may be perplexing to the director of such a course, for as Prof. Alan C. Woods of Johns Hopkins has said, "There are a great number of poorly trained and educated men who have completed their military service, are dissatisfied with their former medical practice, and now take the opportunity offered by the G. I. Bill of Rights to enter a specialty which they correctly believe to be lucrative and erroneously believe to be easy. The great majority of this group are poor material and even under normal conditions would have great difficulty in obtaining hospital appointments. Under present conditions their chances of doing so are minimal."

Dr. Woods goes on to say, "I feel strongly that admittance to such basic courses should be limited to men who have either obtained their ophthalmological interneships or who have fair prospects of ultimately being properly placed."

Basic courses, therefore, no matter how long, should under no circumstances be considered as the final step in the training of an ophthalmologist.

When course should be given

There is too, at the moment, a controversy as to whether such a basic course should be given prior to or during the ophthalmic residency. There are excellent arguments to both sides, but I believe that, if some clinical work can be given along with the basic studies, the student is in a much better position to appreciate the residency training. It might be arranged, in addition, to give the resident about to graduate, a quick review in basic subjects.

Unfortunately, there are not enough residencies in the United States to take care of the demand and many a well-trained basic student has had to undertake a preceptorship of several years' duration. The final value of a preceptorship depends on the ability of the preceptor and the opportunity presented to the student to learn. Thus one can see that there is an enormous variation in the quality of the preceptorship between very bad conditions, even exploitation, on the one hand, to a glorious opportunity under a paternal, experienced, and loving hand of guidance on the other.

Residency training

Residency training has proved, in all fields of medicine, to be the best method of educating the physician, and it is especially so for the ophthalmologist. Whether it should be for two or three years' duration is a debatable point, but there comes a time when the young ophthalmologist must leave the nest and go on his own. The director of the department, jealous of his school or hospital, is usually pretty particular whom he chooses as resident and will see to it that the young man measures up to the highest principles and ideals. During the residency, the young ophthalmologist is expected to know his cases intimately; to read, study, and review the literature; and toward the end of his stay, he is usually encouraged to do a bit of research or to write a paper. He frequently takes some modest part in the teaching program, if there is one, of his hospital, and attends the local medical society meetings and staff conferences. His time is shared between hospital and outpatient work, and if he is fortunate and skillful and endowed by nature, he becomes a safe and even expert ophthalmic surgeon by the end of his term.

There are few hospitals in the United States that are equipped to offer residents educational opportunities of university standing. There is a need to tie together in some fashion these hospitals and the nearest university. The same thing applies to the study of the basic sciences, for it is in this important phase of his education that the young ophthalmologist needs guidance in his study schedule and in his study habits. The contact that he makes with the teachers in the basic sciences will lead to a closer union between the clinic and laboratory. It is no doubt difficult to find enough teachers for either the clinical or the basic-science studies. As time goes on, however, the number of residents who graduate will increase, and they should be able to assume much of this work.

Organization of residency

The residency should be organized as a real educational experience provided by qualified teachers who are willing to assume responsibility for adequate instruction. It should be a joint responsibility of medical schools and of those hospitals able to provide residencies of a satisfactory educational character.

A valuable residency should include careful supervision of the resident's work, particularly in his first few months of service. Organized regular ward rounds, with free discussion of the problems encountered and suggestions for their solution, are an essential part of any residency. Clinical conferences and staff meetings, not only those of the ophthalmic staff but also those of the entire hospital staff, must be attended by the ophthalmic resident.

The value of a journal club, with weekly meetings, has been well established. Under the direction of his chief, the senior resident should be given the responsibility for at least a portion of the conferences, seminars, and meetings. Reports, written by the resident, should be insisted upon, in order to develop his ability to organize his facts logically, to present them clearly, and to draw appropriate conclusions. He should be encouraged to speak from notes or memory, and thus develop his powers to speak effectively. It goes without saying that a good ophthalmologic library as part of a medical library should be easily available.

Experience in consultations

Consultations on his own, and particularly on other services, are of the utmost value, and every opportunity must be taken to foster and encourage them. The resident, who, as a future ophthalmologist, will be constantly called in consultation, should learn during his years in the hospital the value of such a consultation and how to conduct himself in meeting the patients and his colleagues. Therefore, he should be present as frequently as possible when his chief is called in consultation; and when he becomes the senior resident on his service, he can become a consultant to other services. When he is not satisfied with his findings, he should call upon his chief for assistance.

Living in a large hospital with other residents, he sleeps, eats, and lives medicine and ophthalmology. He shares in the experiences of the other services and he becomes acquainted with the different ways of doing things by different good men. To my way of thinking, there is no substitute for a good residency in the training of an ophthalmologist.

Postgraduate training

By postgraduate training, I mean that obtained upon completion of residency or preceptorship. It may follow the residency immediately and consist of, for example, a year or more as an assistant to a well-established and older ophthalmologist. Again, the postgraduate student may be a surgical fellow, traveling around from place to place, observing different techniques of different men with time to study, to experiment, to do literary or surgical research; or he may elect to spend some months in a physiological or biochemical laboratory learning methods and gaining experiences that may be useful later; or he may migrate for a space of time for special study in ophthalmic pathology in some great ophthalmic center.

Postgraduate training may come later and sporadically, through short refresher courses, or instructional courses, or through the special societies, such as this great body. Indeed, there is no end of opportunity and more and more of these courses are becoming available. They are of the utmost value to a man's life and career, refreshing his mind and lifting his spirit from the rut of daily practice and the making of money. All of us are here now, in spite of the expense and loss of time, because of that great hunger within us to learn and to experience more and new things that have to do with the work we love.

Technical aids to teaching

I have given much thought to a discussion of the technical helps for the education of an ophthalmologist. Scores of devices, such as moving pictures or films, animated drawings, slides, models—in short all of the contrivances now known as visual aids—are at hand. Sound film, technicolor, and television offer much promise for the future.

Our ophthalmic literature—books, journals, monographs, abstract journals, and so on—is becoming more valuable either directly or through microfilm. Language barriers unfortunately remain, and perhaps more thought should be given to a study of ways and means to overcome this difficulty more effectively. Home-study correspondence courses exercise considerable influence and may play a still more prominent part

not only in the education of the young ophthalmologist, but also as refresher courses for the practicing and older ophthalmologist. The true teacher is ever alert to methods and techniques whereby he can overcome the rather high threshold of resistance to new knowledge, a resistance that is so human in the student, in his colleague, and even in himself.

In the last analysis, however, the teaching of ophthalmology hinges on the character, the personality, the experience, the wisdom, the skill, the integrity, and, above all, the desire and love of teaching that is inherent in the teacher himself. Such teachers are few and far between. Such a teacher is our dear friend and colleague, Harry S. Gradle.

MONOCULAR OPERATION FOR HIGH DIVERGENT STRABISMUS*

L. WEEKERS, M.D.
Liége, Belgium

In high divergent strabismus, the deviating eye is often amblyopic. The patient readily consents to operation upon that eye but he objects to letting the sound eye be treated surgically. That is one of the reasons why a binocular operation, if suggested, is not always accepted. Another reason is that the doctor is sometimes not very encouraging as regards the complete correction of the squint after the operation.

There follows a description of a monocular operation which gives excellent and constant results. We have been using it successfully, with some minor improvements, for the last 20 years.†

The operation consists essentially in temporarily attaching the internal rectus to the external rectus of the same eye. Being maintained in this position for seven days, new adhesions occur between the internal rectus and the sclera. The internal rectus is considerably shortened, and its action greatly increased.

PROCEDURE

Anesthesia. Instill a few drops of cocaine. Inject 1-cc. scurocaine (4 percent) in the orbit, 1 cc. along the internal rectus, and 0.5 cc. behind the tendon of the external rectus. This anesthesia renders the manipulation practically painless.

Step 1. Without incising the conjunctiva, the tendon of the external rectus is seized with forceps. A double thread is passed against the sclera under the tendon, or under the muscle just behind the tendon (fig. 1). It is essential to the success of the operation that this hold be a strong one. The thread is double so that it can bear a strong pull without cutting the tissues (fig. 1).

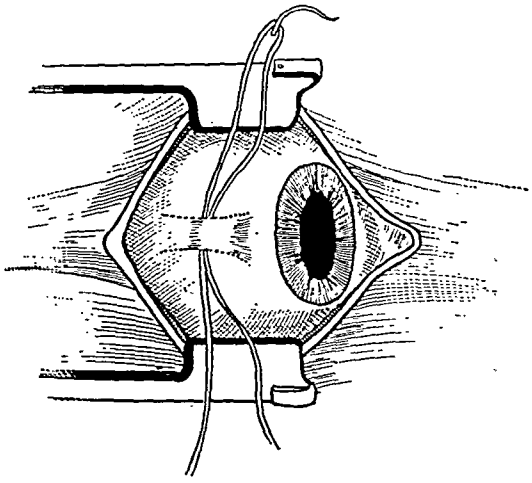

Fig. 1 (Weekers). A double thread is passed against the sclera under the tendon, or under the muscle just behind the tendon.

* From the Ophthalmological Clinic, University of Liége.

† Weekers, L.: Bull. Soc. belge d'Ophth., 78:43, 1939; Ophthalmologica, 96:210, 1939.

Step 2. The conjunctiva is dissected along the nasal half of the limbus from the 12- to the 6-o'clock positions. This dissection is carried far back; it must be sufficient to enable a complete covering of the cornea (fig. 2).

Step 3. This step consists in attaching the internal rectus to the dissected conjunctiva.

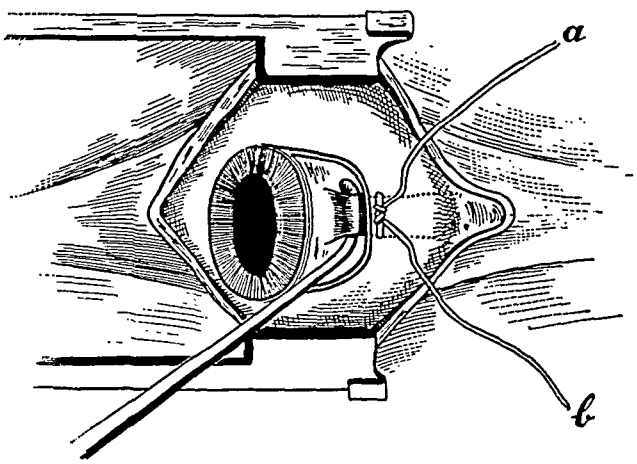

Fig. 2 (Weekers). The conjunctiva is dissected along the nasal half of the limbus from the 12- to the 6-o'clock positions. This dissection must be sufficient to enable a complete covering of the cornea.

A strabismus hook is placed under the tendon of the muscle. A strong silk thread is then passed as follows: (1) Through the conjunctiva, from outside inward, at about 1 mm. from the border, at a point corresponding to the lower edge of the internal rectus; (2) under the muscle; and (3) through the conjunctiva again, from inside outward, at a point corresponding to the upper edge of the muscle. The two ends of the thread are strongly tied. Both conjunctiva and muscle are included in the knot. This device insures a hold which does not risk letting go (fig. 2). The tendon of the muscle is cut with a cataract knife, close to the sclera.

The internal rectus and conjunctiva are severed from the globe and the adhesions which still attach the muscle and Tenon's capsule to the eyeball are cut backward with scissors.

Step 4. The double thread which passes under the external rectus is tied loosely. At that step of the operation, the knot remains unfinished.

Step 5. The thread on the internal rectus has two ends, a and b. One of them (a) is introduced into the loop made by the double thread of the external rectus (fig. 3).

Step 6. The double thread of the external rectus is now tightened further; the thread (a) of the internal rectus is caught but can still slide in the knot. All through this part of the operation, care is taken that the threads cause no trauma to the cornea.

Step 7. Everything is now ready for advancement of the internal rectus. The assistant by means of two forceps seizes the

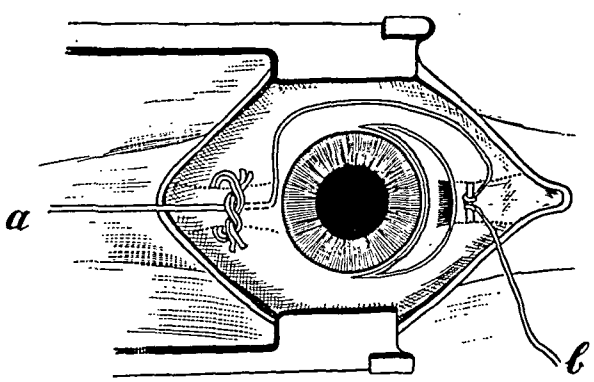

Fig. 3 (Weekers). The thread on the internal rectus has two ends, a and b. One of them (a) is introduced into the loop made by the double thread of the external rectus.

upper and the lower parts of the looped thread around the external rectus. He rotates the eye strongly inwards, carefully avoiding any deviation in height. The operator ties the two ends (a) and (b). The internal rectus and the conjunctiva slide over the cornea. The globe now is strongly convergent, with the cornea completely covered by conjunctiva.

Postoperative care

After the operation, astreptine (p. aminophenylsulfonamidum) in powder form is introduced into the fornix and a binocular

dressing is applied which is to be renewed after four days. It is preferable that the patient remain in bed. Seven days after the operation, the threads are removed on the operating table, under locally instilled anesthesia. The excess conjunctiva and muscle covering the cornea are excised with scissors.

Results

With the technique described above, the shortening of the internal rectus allows a correction of 35 to 40 degrees. Whatever one may fear, the ocular movements postoperatively are in no way limited.

Sometimes the strong tension of the internal rectus causes some enophthalmos, but ultimately this lessens or even disappears.

The cornea withstands the operation without any damage.

Fig. 4 (Weekers). (A) Divergent strabismus following a tenotomy on the internal rectus of the left eye during childhood. (B) Operation: shortening of the internal rectus of the left eye.

Fig. 5 (Weekers). (A) Divergent strabismus following a tenotomy on the internal rectus of the left eye during childhood. (B) Operation: shortening of the internal rectus of the left eye.

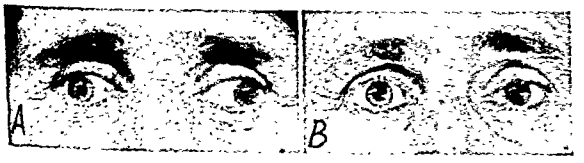

Fig. 6 (Weekers). (A) Divergent strabismus following bilateral tenotomy on the internal rectus during childhood. (B) Operation: shortening of the internal rectus and tenotomy on the external rectus of the left eye.

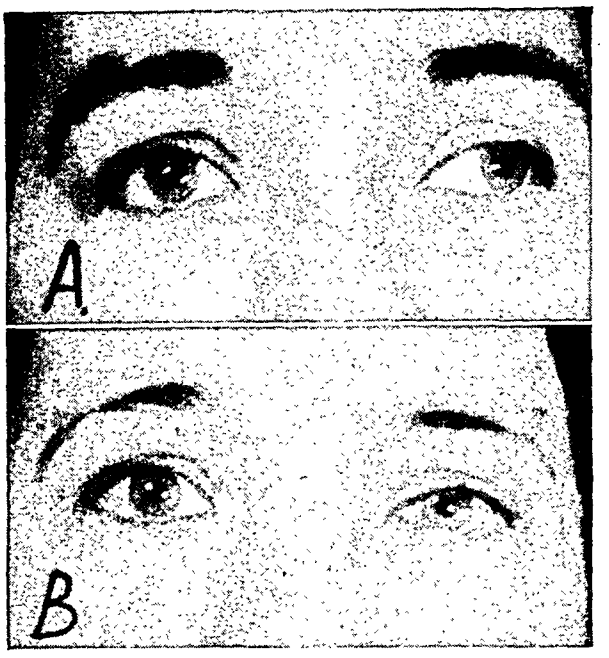

Fig. 7 (Weekers). (A) Weakness of both internal recti. (B) Operation: shortening of the internal rectus of the left eye.

The operation is indicated in all forms of divergent strabismus (concomitant, paralytic, or others).

The procedure has often given excellent results even in the divergent strabismus

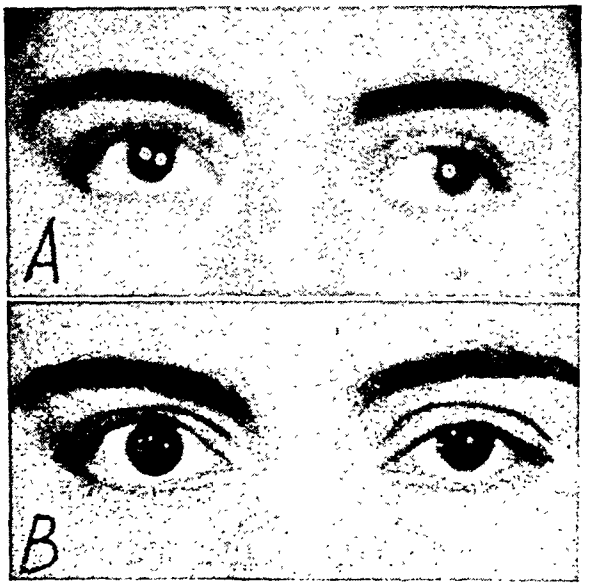

Fig. 8 (Weekers). (A) Weakness of both internal recti. (B) Operation: shortening of the internal rectus and tenotomy of the external rectus of the left eye.

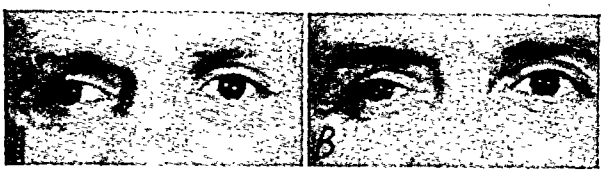

Fig. 9 (Weekers). (A) Divergent strabismus following trauma and loss of vision of the right eye during childhood. (B) Operation: shortening of the internal rectus and tenotomy of the external rectus of the right eye.

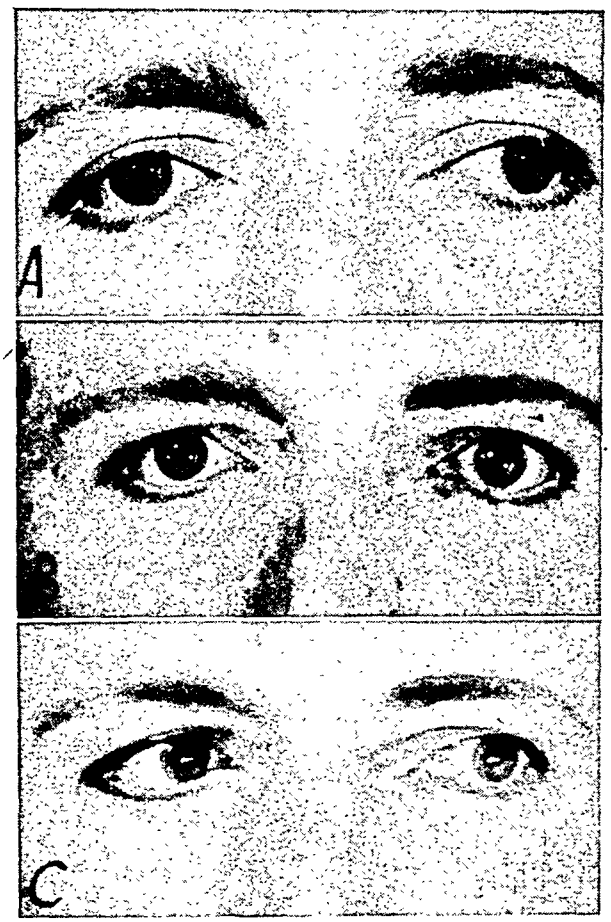

Fig. 10 (Weekers). (A) Weakness of both internal recti. (B) Operation: shortening of the internal rectus and tenotomy of the external rectus of the left eye. (C) The abduction of the operated left eye is very satisfactory.

which may follow tenotomy (unilateral or bilateral) of the internal rectus. When in such a case the tenotomized muscle cannot be found, the suture is attached to Tenon's capsule, and the results are as successful as when the muscle itself is sutured.

When the degree of divergence is considerable, and when surgical correction is incomplete, a partial or total tenotomy of the external rectus of the same eye is performed a month later. The tenotomy completes the correction, and it has the advantage of compensating the enophthalmos. Even in such cases, the mobility of the eye is not affected. Tenotomy is performed usually without hospitalizing the patient.

Photographs of patients with divergent strabismus, on whom this surgical procedure was used, are given herewith, showing their appearance before and after the operation.

Summary

The operation outlined consists essentially in provisionally attaching the internal rectus to the external rectus muscle of the same eye. The internal rectus thus forms new attachments to the sclera; it is considerably shortened; and its action is greatly reinforced. If necessary, the correction is completed a month later by a tenotomy of the external rectus.

This procedure is particularly suitable in high degrees of divergent strabismus. One of its great advantages is that it is monocular, and it avoids undependable scleral sutures. The results are excellent and constant.

66, Boulevard de la Constitution.

MILITARY OPHTHALMOLOGY IN THE EUROPEAN THEATER*

DON MARSHALL, M.D.
Kalamazoo, Michigan

WITH DISCUSSIONS BY F. PHINIZY CALHOUN, JR., M.D., AND TRYGVE GUNDERSEN, M.D.

The purpose of this paper is briefly to consider some of the problems of ophthalmology in the ETO, as they were met in a general hospital which was on the scene early and remained through the war in Europe. A comparison of the ophthalmic experience of the 298th General Hospital with that of other ETO medical units, and with those of other theaters, may bring out both generalities and variations of interest and future value.

This paper does not attempt to analyze surgical and therapeutic methods in detail, nor to make a study of the type of missile, location of injury, and resulting structural and visual damage. These problems are being thoroughly and well handled by a number of papers now appearing, based on more complete records than are available to me.[1-3]

Such studies require the time and data available best in an eye center in this country. No man has had opportunity to follow ocular patients from combat to final discharge. Those in the zone of the interior, at the end of the line where the patient and his medical record are before them, have probably had the best opportunity of assessing methods of care and results of injuries.

The 298th General Hospital began receiving patients at Bristol, England, in November, 1942, and continued active there until May, 1944, when it ceased professional work to prepare for the continental invasion. The first general hospital to open on the continent, it took charge of the Marine Hospital at Cherbourg, Normandy, in mid-July after D-Day, working there until the end of October. Late in November it opened a tented hospital on the outskirts of Liége, Belgium, and functioned on that site until the late summer of 1945. Total admissions on all services for the three sites were 35,702 up to June 25, 1945, and the total of all operations was 7,302.

TYPE OF WORK AND PROBLEMS MET

These facts are of importance in considering the type of work and problems met. In common with most general hospitals in England, we served troops who were training and staging for the cross-channel invasion.

WORK AT BRISTOL

Although we began functioning as a hospital at Bristol in November, 1942, no ophthalmology was done until December, when a total of 12 patients were admitted, and 10 outpatients were seen.

All the inpatients at the start were British, arriving by boat from the North African Theater. Nearly half of them were postoperative enucleations, for whom no treatment was necessary. Most of them were transferred on to British hospitals within 48 hours, and no operations were done during the month.

The number of inpatients dropped to a low of three and rose to a peak of 26 during January, due to the rather rapid inflow and transfer of British African casualties, whose ships docked at Bristol.

The outpatient or EENT Clinic Building was not completed and opened until February 20, 1943. It was not until then that refractions and the procurement of spectacles was started. During the next 14 months, work steadily increased as more troops arrived in Britain, despite the opening of additional station and general hospitals.

CHERBOURG HOSPITAL

In Cherbourg we were the only hospital serving that area for many weeks. We were

* Read before the Section on Ophthalmology, American Medical Association, Atlantic City, New Jersey, June 13, 1947.

50 miles from the line of combat, and soldiers injured at the front were evacuated almost invariably direct to England. We saw few of them but were hardly able to keep up with the rush of injured and ill from among the many thousands of troops and prisoners-of-war stationed on the peninsula.

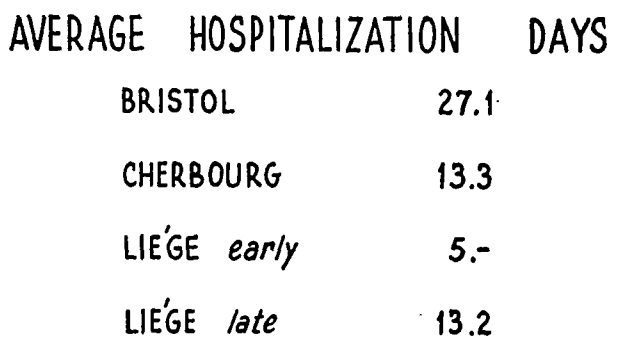

Fig. 1. (Marshall). Average hospitalization of ophthalmic inpatients.

This rush was particularly true of the outpatient clinic. Our appointments for refractions often ran a week in advance. There were many dispensaries in the area, but few medical officers would venture to handle even the simplest of ocular conditions, and they were not expected to carry out the special examinations for refractions and physicals.

Many a G. I. in that period wanted, and was even urged, to join the paratroopers. Such men came in by the dozen for the physical examination that was part of their application form. It bothered us a little to have to spend so much of our time on healthy men when we had come to France expecting to take care of the wounded. We functioned at Cherbourg as a station and general hospital for over three months.

Liége circumstances

In Liége circumstances differed again. With the five other general hospitals in the city we received combat injured from our section of the front, which was an hour away in November, 1944, and only 14 miles away in mid-December at the height of the Battle of the Bulge. At year's end we were averaging nearly 40 outpatient visits a day, including our ambulatory inpatients. Inpatients, injured in combat, poured in, many of them with other wounds, many of them remaining only until they could take the next jump to the rear. Those with minor injuries could often be healed and returned to duty direct. Our hospital, because of its location nearest to the airport, was designated a holding and evacuation unit for patients being sent by air from all other Liége hospitals. This last meant a tremendous flow of patients who stayed with us from a few minutes to several days, depending on how soon the next squadron of C47's came in to get them for transport to England or to western France.

Variations in work

During three years our work varied from that expected of a general hospital to that of an evacuation hospital. The treatment and handling of patients changed greatly with the current holding or evacuation policy.

At one extreme, at Bristol, nearly every case except progressive incurable conditions was made as fit for duty as he ever could be at our hospital, since we could keep him under treatment for as long as 180 days.

TOTAL IN-PATIENTS

	U.S.	BRITISH	CIVILIAN	GERMAN	TOTAL
BRISTOL (1 YEAR, 6 MONTHS)	127	36	1	1	165
CHERBOURG (3 MONTHS)	76	2	2	6	86
LIEGE (7 MONTHS)	358	1	1	8	368

Fig. 2 (Marshall). Total inpatients.

At the other extreme, during the winter in Liége, we were required to evacuate a man immediately if he could not be cured and returned to duty in a week. The necessity behind this was the demand for beds. Only

when transportation would itself be dangerous could a patient be kept.

This resulted in innumerable patients being evacuated without indicated treatment being undertaken. It was felt fairer to the patient and to the next hospital to evacuate the patient immediately to the UK, where the oculist could operate without rush and follow the convalescence through.

In Liége, most of the patients requiring extraction of a foreign body or linear cataract extraction, had already had preliminary surgery a few days previously, such as excision of prolapsed uvea and a conjunctival flap. Care was taken not to postpone surgery that was urgent, but many a patient, who often had additional wounds, was sent back to western France or to England, where there was less stress, better equipment, and fewer buzz bombs, all conducive to better ophthalmic results. The average stay of an ocular patient in our hospital is shown in Figure 1.

Figure 2 shows the total number of ophthalmic inpatients admitted, an average of 9.2 per month at Bristol, 28.7 at Cherbourg,

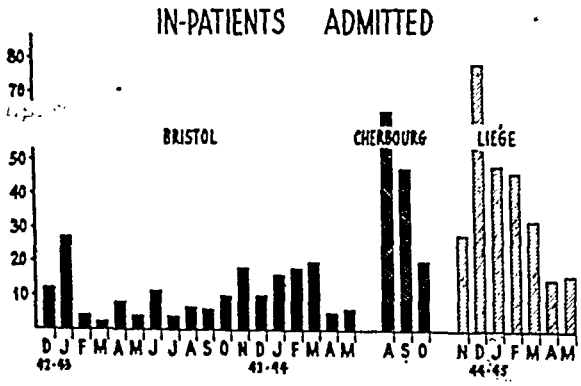

Fig. 3 (Marshall). Ophthalmic inpatient admissions per month.

and 52 at Liége. The graph in Figure 3 shows admissions monthly. The high number in December and January, 1942-43, was due to receipt of boatloads of casualties from Africa. Later such arrivals were entrained immediately for other hospitals that had opened inland. A general rise is noted through 1943 until two months before D-Day, due to a steady increase in the number of troops. The drop before D-Day was due to the freezing of units in southern England.

The high load at Cherbourg dropped as the combat line moved away to the east, and as other hospitals arrived and opened. We

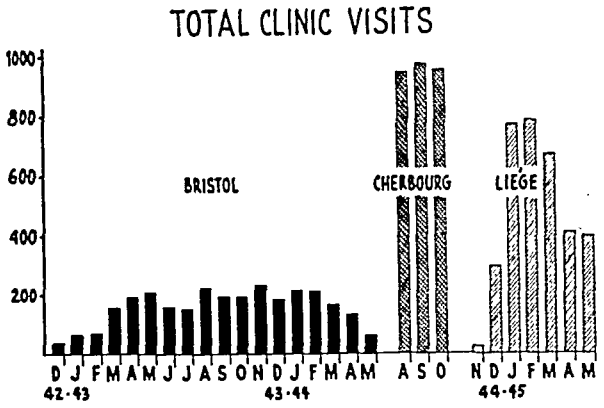

Fig. 4 (Marshall). Ophthalmic outpatient visits per month.

handled relatively few combat injuries at this site.

The peak at Liége in December, 1944, and January, 1945, was due partly to an active front near us, and still more to the Battle of the Bulge, which was close enough to force all Liége hospitals to make plans for retreating to the rear. Wounded arrived the same day as injury. We were acting additionally as a holding unit. With the spring pushes to the Rhine, the flow of casualties remained heavy, and remained so to the end, for forward hospitals kept emptying their beds in order to advance.

In general, the outpatient load (fig. 4) ran parallel with the general hospital load and with admission of inpatients. It was exceptionally heavy in Cherbourg, increased partly by required ocular examination of candidates for paratroop service. The number of refractions there was also heavy, a large portion due to arrivals of troops from the States who had been shipped out before being supplied with spectacles. The combat front had to make up the deficiencies of the home front. Again there was a peak in refractions in January and February, 1945

(fig. 5), when the scores of men came in who had lost everything in escaping before the German counterattack at Christmas time.

Among these a large percentage had no copy of their prescription for lenses. A complete examination had to be made again.

The amount of ophthalmic surgery was perhaps surprisingly small, as shown in Figures 6 and 7. It was highest at Liége, because of the flow of combat casualties, and does not represent the total amount of surgery indicated on inpatients. Many foreign bodies, many traumatic cataracts, and some enucleations were deliberately sent on to the rear or to England. Attention is directed to the fact that no surgery was undertaken at any time for strabismus. This was in line with theater policy.

Of the purely ophthalmic surgery seen near the front two conditions were impressive. One was the great number of men with

Fig. 8 (Marshall). Disposition of patients.

multiple corneal foreign bodies, usually bits of sand imbedded at all depths, and, of course, often perforating. Such foreign bodies should not all be removed at once, but a judicious balance should be kept between removing the more irritating ones and not stirring up reaction to remove others. The other condition met, mentioned also by Culler,[4] was the relative difficulty in enucleating eyes that were literally exploded and shredded by a missile going through. The third impressive lesson of war was the vast amount of intraocular damage that may result from contusion injuries, whether direct or remote, for which there is little therapy. But it has been truly said my many authors that the professional care and scientific problems of military ophthalmology are the same as those in civil life.

Disposition of inpatients is shown in Figure 8. Well over half the patients at Bristol

and Cherbourg were returned to full or limited duty. When dealing mostly with combat casualties at Liége, this figure dropped to 40 percent, while evacuation of patients to the rear increased to 54 percent. Of course, many patients were evacuated because of other wounds, such as fractures. The evacuation figure was lowest, 16.3 percent, at Bristol, where we could hold a patient up to 180 days to effect a cure. Even then many of the patients shipped back home went because of congenital or preservice defects, rather than failure of therapy.

Figures 9 and 10 give a condensation of principal ocular diagnoses. Most patients had more than one, or several, diagnoses.

A comparison of the causes of ocular conditions, Figure 11, is revealing. Combat injuries were naturally highest at Liége. Yet that figure was exceeded at Cherbourg proportionately by noncombat injuries. Preëxisting disease and injuries were highest at Bristol, where all troops were carefully screened and classified physically in preparation for the invasion. The proportion of noncombat disease, of which uveitis is an example, remained fairly constant, while the incidence of severe hysterical amblyopia, listed as combat disease, happened to be perfectly constant.

Of practical interest is an analysis of the causes of blindness in one or both eyes, newly acquired during service.[5] About three fourths of the instances in which both eyes were blinded were due to combat injuries.

The noncombat injuries causing bilateral blindness were usually explosions, sometimes accidental, sometimes due to negligence, as when a cartridge was swept into a fire unknowingly and exploded. One accident was due to high-tension current causing third-degree burns and electric cataracts. The single instance of bilateral blindness due to disease was optic atrophy following ingestion of methyl alcohol.

Figure 12 reveals also that, particularly at Cherbourg, the frequency of loss of vision of one eye due to noncombat injury was distressingly frequent.

Figure 13 lists in partial condensation the

causes of noncombat injuries. One concludes that war is a dangerous game even out of combat. At Bristol the greatest single cause in this group was a flying fist in personal assault, or a knee in football. In Cherbourg, by far the greatest number were caused by

explosions in the hand, or equally close. Perhaps because they were new to war and typical, souvenir-minded Americans, many a soldier in Normandy attempted to keep, deactivate, or alter into cigarette lighters various German shells and cartridges, particularly the attractive German 20-mm. ack-ack shell. This shell had a double and highly

sensitive firing mechanism, which went off too easily and too often.

Some explorers of forts were caught and injured by accidental explosions, over-inquisitiveness, or booby traps. Almost invariably the eyes were involved, either by superficial foreign bodies or by perforating wounds.

The 20-mm. shell injury became a clinical picture that could be diagnosed down the hall on admission—a man brought in with both hands heavily bandaged, face and neck covered with bleeding points, and one or both eyes padded. Three times I removed cancellous bone from around or even within the eyeball, in each instance a piece of bone from the patient's own finger, which had been blown off by the shell in his hand, or in a vise while he worked on it.

Considering total figures, the largest number of noncombat injuries were caused by explosions nearby, as by shells, grenades, and detonators. Nearly an equal number were caused by something thrown or swung at the eye, as boards, branches, a bayonet, stone, rifle barrel, nail, and so forth. The last eye I enucleated in service was that of a nurse, the globe ruptured by a swinging golf club. Many men accidentally bumped or fell onto objects in the confusion and darkness, and many an eye was lost in personnel fights.

In 1942, Col. Derrick Vail, before becoming European Theater Consultant, proposed that means be found to protect eyes in war. Visors, made of metal, were studied in this country and in England.[6] They would interfere with the field of vision but if used at the right time would save scores of eyes. Rycroft[7] suggested using the antigas shield, a simple goggle of plastic, in various noncombat activities where particles of metal or chemical may fly toward the eye. Unquestionably, better protection would save many eyes in combat, while goggles and more care would reduce greatly the devastating number of eye injuries from accidents and carelessness behind the lines.

Ophthalmic problems of wartime

Now, I venture to comment on several ophthalmic problems of wartime, realizing full well that others have had more experience and are better informed to discuss them than I. Let me preface these remarks with an expression of gratitude to Col. Derrick Vail, who, as Senior Consultant in Ophthalmology, was the first to foresee these administrative problems and was constantly and successfully striving to effect their solution. His planning and energetic work

made a tremendous difference in the entire picture.

The problem of how to keep busy, up-to-date, and dexterous is a universal difficulty of the doctor at war. In England, many ophthalmic officers were allowed to attend lectures and meetings of British ophthalmic groups; some fortunate ones spent a two-weeks period observing work at Moorfields in London. An ophthalmic club was formed, which held several worthwhile meetings. And after hostilities, a group under the leadership of Maj. F. P. Calhoun took a series of lectures at Oxford, then toured the island visiting prominent clinics. It is impossible to be prepared for large-scale combat without idle troops and officers, if sufficient medical personnel is present to carry the combat load later. But that medical personnel must be kept active in their work and constantly stimulated.

At least in general hospitals, it was early agreed that the Sections of Ophthalmology and Otolaryngology should be separate in personnel and management. This is proper, avoids friction, is logical. The head of each section, if adequately trained, should be entitled to the rank of major.

Ophthalmology seemed to have no special problems in finding a place to work that did not apply to most of the hospital. Whether it be in a tent, a hut, or a building, a little imagination easily arranged an adequate outpatient clinic in the available space, even to a dark room. In England, a few hospitals had a special EENT major operating room. In the 298th General Hospital, all major surgery was done in the general operating rooms.

Electric current varied

Electric current was at times a problem for all. At Bristol American equipment took 115 volts, and American connecting plugs would not fit the British receptacles. The British current supplied was 220 volts. The search for transformers and plugs was long and trying, and it took months before all was smoothed out. At Cherbourg and Liége electric current was undependable, so that, in the clinic, battery current was used almost entirely for examining instruments. Water supply was fitful at Cherbourg, and was cut by a single bomb at Liége, which almost closed the operating room for a few days. An army general hospital in that theater was not set up to be completely self contained and independent. In our specialty it must be remembered that correct current is essential for use of the diathermy, the electric magnet, and the Projecto-chart.

Equipment problems

Surgical and diagnostic equipment for ophthalmology is an important problem now being reviewed by the Subcommittee on Ophthalmology of the National Research Council. Colonel Vail spent his early months in Britain seeking adequate ophthalmic equipment for his officers. Table of Equipment (TE) was not bad, but allowed for much improvement.

Getting the items allowed was still another problem. Strabismus hooks and cilia forceps were a dime a dozen, but tenotomy scissors were scarce, and a Schiøtz tonometer was almost never seen at all. It is not easy to make one list that will suit all surgeons. Yet such an analysis as is now under way should find room for worthwhile changes.

We were supplied with a Lancaster hand magnet and a retinal detachment outfit that attached to the Bovie unit and both did well. Perimeters were not supplied, but were obtained for a few by luck. Another instrument, not supplied by the army to the European Theater but found to be essential, was a slitlamp. Most of us in England eventually acquired a British-made simplified slitlamp that was adequate, and a few found their way to the continent before VE-Day. In the future, a slitlamp should be standard for any general hospital, although it may be necessary to develop a simplified, more portable model for this purpose.

In late 1942 and early 1943, the African

Theater seemed to have priority over Britain in American supplies. Therefore the six general hospitals first to arrive required and received through lend-lease much British ophthalmic equipment. Some of this was excellent, well above usual military quality. Without it we could hardly have functioned. The ophthalmic equipment eventually assembled at the 298th General Hospital by D-Day was more than ample, perhaps more complete than any other U. S. hospital in England. This was due to the continued efforts of Colonel Vail, and our honest search over a period of a year and a half. Having thus prepared for the rush anticipated after the invasion, it was particularly painful to be ordered to leave all this in place, turning the entire hospital and its equipment over to another unit in May, 1944.

Optical problems

One major problem was the optical one. Unquestionably this will always be with us, and will almost certainly increase in another war.[8] A poignant example of the importance of the problem is that at one time the British had 7,000 men at camp near Cairo who had been evacuated from the front for replacement of glasses.[9] A man who cannot see adequately is a casualty and as noneffective as a wounded man.

Today in war, good vision is required for flying, for aiming, and for driving a vast mechanized army on wheels; and behind the lines, many a farmer boy becomes a clerk or a radar operator and discovers his eyes need help. In addition, many men with special ability and training are so valuable that they are needed despite glasses. Unquestionably, from the viewpoint of manpower and man hours, the whole field of refractions and spectacles is one of the biggest that needs careful study and solution for the future.

Like others, I ran into this problem from several angles. During a brief training period in Arkansas, I had seen a capable ophthalmologist and his willing but untrained assisting officer attempt the impossible of refracting up to 100 inductees a day. In England, there was more leisure, and many a hurried refraction was repeated and the lenses perforce changed, a waste of time and lenses.

Refraction needs

Another minor problem at Bristol was the number of men, especially Negroes, working as stevedores at Bristol channel ports, who legally acquired a day of rest by arranging for the long trip by ambulance from their station to the 298th General Hospital for refraction. They had ample symptoms, and poor visual acuity, but the vision improved miraculously as soon as a trial frame was put on, whether it contained any lenses or not.[10] There is no sure way of determining whether or not a soldier needs glasses, if he has symptoms, without refracting him. Scores of refractions proved unnecessary except for making that decision.

In England, everyone was checked physically, which disclosed many cases of amblyopia and disqualified men who never had met induction standards. This caused many to be sent home, another waste of time and effort. It also proved to be a waste of manpower, for the return flow became so heavy that it was stopped, the new policy being to keep men in Britain who had only one good eye, or a high refractive error. We put them on limited or noncombat duty. The British, harder pressed, sent their one-eyed men almost up to the front line.

Delivery of glasses

In Cherbourg, troops were arriving by shiploads. Many had not received their glasses before leaving home. Delivery of spectacles in the States at that time seemed to take about four weeks or more. In Britain, we got delivery in from 3 to 7 days for ordinary strengths. In Cherbourg, delivery took three days or more, depending on the quality of the courier service at the moment.

In Liége, we had delivery in 24 hours most of the time. The story of supplying spectacles and gas-mask lenses in the European Theater is an interesting one that could be told by Colonel Vail or one of his optician officers.

Breakdown in record system

The Battle of the Bulge brought home the realization that despite repeated directives there was an actual breakdown in the system of keeping records of the individual prescription for glasses. Men swarmed in for new replacement spectacles. They had lost everything, their personal records, their headquarters records sometimes, and often their "dog" tags.

To supply new glasses they had to be examined from the beginning again, and this despite regulations requiring that their prescriptions be in two places in their records and a third independent copy on their person. As Sir Stewart Duke-Elder has remarked for the British, in the early days provision for glasses was inadequate because their importance was not foreseen and because their enormous wastage was not anticipated. He was forced to change the whole set-up for the British Army. It is probably not practical to put the prescription on the dog tags, but every effort should be made to devise a more certain means of always having it on the person of the soldier.

Optometrists did excellent work in the ETO, and without them the number of refractions done would have been only a portion of the actual accomplishment. They varied of course in their aggressiveness and personality, their self confidence and ingenuity. They were always responsible to a medical officer in their professional work. Effort was made to put them where they could give the most help. I believe most ophthalmologists were grateful for the help they received from them. Placing optometrists in a medical service corps is a logical step, and will allow them a rank more commensurate with their technical ability.

Gas-mask frames were not satisfactory. The gas-mask insert lens, hurriedly supplied to all who seriously needed them before the Normandy invasion, seemed to work very well. Not as important, nor as well solved, was the need for a simple, reliable test for night vision.

Diseases encountered

A few diseases encountered, although not differing from those found in civilian ophthalmology, had peculiar aspects in the service. One was pterygium, which was something every eye man not too busy was eager to tackle, for it afforded an opportunity to "keep his hand in" with little serious risk. The problem was that of recurrence. One soldier at Valley Forge Hospital in this country had had 13 recurrences and 12 operations. Toward the end of the war in Europe some pressure was made from higher levels to avoid surgery for pterygium except in the most severe degrees.

A similar situation was found with strabismus. Many a surgeon with little surgery to do did muscle cases to benefit both the patient and himself. Such correction of a severe cosmetic defect has been advocated[11] in order to improve personality and to enable reclassification to full military duty.

On the other hand, I have watched over Prof. Ida Mann's shoulder at Moorfield's while she interviewed a British soldier dropped from his army because of diplopia following surgery for squint, with excellent cosmetic results. And I have seen an American G. I. evacuated back from the front with the same story, and with the ophthalmologist's name typed plainly on the first section of the field medical record.

Both surgeons were good and did good work. Neither soldier seemed to be a malingerer or quitter. Nevertheless, diplopia of a disqualifying degree seemed surprisingly prevalent following surgery for strabismus in service, and it, therefore, became a service-connected disability. Such surgery was

officially frowned upon in the ETO.

Uveitis in all its forms was a problem because it incapacitated a man for so long. A total of 34 cases of endogenous or nontraumatic uveitis were seen, the larger number at Bristol. Phlyctenular keratitis for some reason was much more frequent in England than on the continent.

What to do with the one-eyed man in an army is a question that should be given a studied and clear answer before another war. He lacks stereopsis, yet many a one-eyed man drives well. Wiley Post flew around the world successfully with only one eye. Amblyopia is frequent; enucleations increase as the war progresses. Need the lifelong amblyope be restricted in ordinary duties? The newly blinded must of course go through a period of readjustment.

The newly developed plastic prostheses, made by staff dental officers, proved relatively simple, very satisfactory when done by a capable man, and a happy solution to a difficult shortage. That story has been told elsewhere.

Several authors during and since the war have emphasized the importance of discovering early the presence of ocular injuries, which may so easily be overlooked in the presence of additional, often more severe wounds. The answer is training of forward medical officers to examine the eyes routinely, at least superficially, for signs or symptoms of ocular injury or defective vision.

Sulfonamides and penicillin, which were given to all wounded almost without exception, reduced the incidence of serious ocular infection almost to the zero point. Gross infections were few, and I saw no case of sympathetic ophthalmia in three years' service.[12]

Management of ophthalmic patient

The management in service of an ophthalmic patient varies with many factors. The actual medical care differs little or none from civilian methods. That point has been repeatedly made by many authors. Intervening conditions pose many problems, however.

A patient may arrive who was injured 10 minutes before in his company area, or 10 hours before at the front with no previous treatment, or 3 days before, with prolapse excised and a conjunctival flap in place, or 30 days before with a month's treatment in a station hospital intervening.

He may or may not have other injuries which take precedence. You may be allowed to keep him six months, or be urged to evacuate him the next day. You may have all needed equipment for his required surgery, or you may be without electricity and water.

In these respects military ophthalmology differs greatly from civilian. Although a few general rules could be laid down, each patient needed an individual decision. The need for beds and current directives, his general condition or other wounds, the amount of preliminary surgery already done, and the period required for convalescence all were factors that made up the picture. Occasionally equipment was decisive. Another factor that undoubtedly altered management was the training and confidence of the ophthalmologist, a factor that probably weighed in both directions depending upon the man.

As patients and their records came back from the front, it was possible soon to assess the capability and conscientiousness of those ahead who were doing ophthalmic surgery. Such an evaluation became of importance when the patient arrived with his wounds or eye hidden by a partial or total conjunctival flap. Important and useful as they may be, and perhaps essential, conjunctival flaps, like a plaster cast, hinder revaluation of the patient's condition as he travels back through the chain of evacuation.

How close behind the lines should a capable ophthalmologist be? This would seem to depend on the stability of the line, the speed of evacuation, and the capability of the general surgeons at the front. It would

seem highly desirable that an ophthalmic casualty be able to reach a trained ophthalmologist within 24 hours following injury. Barring that, he should reach the hands of a general surgeon well versed in ophthalmic first-aid procedures. Some of the surgical auxiliary teams had such men, who in a pinch could and did do an excellent excision of prolapse with conjunctival flap. After preliminary study and surgery by a trained ophthalmologist, the patient, if seriously injured, should be flown to an ophthalmic center, where good equipment, adequate help, and some peace of mind for both patient and surgeon are available. As noted by Duke-Elder, the proportion of injured eyes lost in World War II was only half that of the previous war, the reduction being due not only to advances in surgery, but also to the increased speed with which the injured patient was placed under trained care.

Discussion

Dr. F. Phinizy Calhoun, Jr., (Atlanta, Georgia): The basis for my comments on this paper is my service as ophthalmologist for the 2nd General Hospital from February, 1942, until October, 1945, of which 40 months were spent in the ETO.

Like Dr. Marshall's unit, my hospital functioned in three main sites, the first in Oxford, the second near St. Lo, and the third in Nancy, France. I have read with interest Dr. Marshall's full-length detailed report and I would like to compliment him on the careful records he has kept and on his splendid analysis of his cases. His tables show distinctly how the type of work and method of handling of eye cases varied with the military situation, and, in general, the tables are representative of the type and volume of work done in other outstanding general hospitals in the ETO.

Probably the most important single factor in the effectiveness of eye care in England and in France was the fine work of the Senior Consultant in Ophthalmology, Colonel Vail, and of his successor, Colonel Greear. The presence of these men to correlate all eye care, to prod the chiefs of supply and personnel, to put ophthalmology in the limelight, and to forward international relations, was very essential and effective. I

am proud of the splendid way in which they met and overcame almost unbelievable difficulties in policy, and in men and equipment, elevating ophthalmology from a relatively obscure position in military medical care to a very secure one.

I would like to say a word about the ETOUSA Ophthalmological Society formed in early 1943 at the suggestion of Colonel Vail. In the beginning, composed of the handful of eye men in the ETO who were doing eye work, this little organization was paramount in bringing us together so that we managed to have three large meetings before the preparations for D-Day scattered us.

The distinguished honorary members of the society were Colonel Vail, Brig. Sir Stewart Duke-Elder, Lieut. Com. Edwin B. Dunphy, Sir Ian Fraser of St. Dunstans, and Air-Commodore V. C. Livingston.

Dr. Eugene Anthony did a splendid job as editor of the "Journal," and three issues were published. This little journal was very important in the dissemination of eye information to all of us. Besides containing short biographies of the members, the "Journal" gave case reports, abstracts, short original articles of topical interest; summarized military eye directives which changed frequently and often never reached us in any other way; and gave us the latest information about services for glasses, diathermy, magnet, prostheses, and pathologic specimens.

Most important of all, I believe, the "Journal" had a helpful-hints section, which proved a great aid to us in our improvisations. We very quickly learned that we had to improvise to be of any use ophthalmologically, and this section in the "Journal" helped us along those lines. There were set forth simple methods of sterilizing solutions and instruments; of making our own sulfa ointments; measurements for the construction and marking out of a home-made Bjerrum screen; methods for the construction of perimeters, irrigating tips, depth-perception apparatus, and so forth. A good replaceable eye dressing in use at the 5th General Hospital was publicized. I know of one man who constructed from odds and ends a satisfactory slitlamp, and of several who made effective magnets from radar equipment.

I wonder if any of you have thought enough of your three issues of the *ETOUSA Journal of Ophthalmology* to have them bound. They have already become collectors' items, and your medical library would be glad to get them.

Another factor that contributed greatly to the success of eye care in England was the close coöperation of the British, not only as civilian and military groups, but as individuals. Prior to the landings in North Africa in November, 1942, no American equipment was made available to us, and for the next year only a little was available. We, therefore, had to depend almost entirely on British facilities and equipment, which, incidentally, was always of high quality. The British helped greatly in the spectacle program, began the training of some of our blind at St. Dunstan's, furnished us prostheses, a magnet and diathermy service, individually loaned us instruments and equipment, and were always willing to aid us with our problems.

This coöperation was further brought home to me after V-E Day when, in July and August, 1945, I was asked to help Lieut. Colonel Greear, the senior consultant in ophthalmology, organize a posthostilities training course in ophthalmology to be given at Oxford, England, under the direction of Prof. Ida Mann. Eminent British ophthalmologists throughout the United Kingdom were interviewed and worked into a time table. I found that the lecturers, all prominent in British ophthalmology, were most eager and willing to do all they could and on one refused the invitation to participate. This spirit was a great tribute to the friendly and coöperative relationship between American and British ophthalmologists established

during the war by the successive senior consultants in ophthalmology.

Although allocations were made for 40 men to attend the course, which lasted four weeks, the base commands, due to redeployment responsibilities, unfortunately could only incompletely fill their respective quotas, and only 22 men were released to attend the course.

The course was successful in providing a taste of academic ophthalmology to men who had been doing military ophthalmology for varying periods of time. These men were uniformly eager and appreciative of the opportunity offered them by the U.S. Army, and were repeatedly impressed by the education, poise, and ability of the British lecturers, many of whom were internationally known.

Amid the historic and scholarly surroundings of Oxford, to sit at the feet of Ida Mann, H. M. Traquair, Foster Moore, Eugene Wolff, Charles Goulden, McCallan, R. E. Wright, John Foster, Greeves, and others, was indeed an impressive and memorable experience for each American student of ophthalmology.

Dr. Marshall has asked me to say something about air casualties, since my unit treated a large number of all types in 1942 and 1943. Excluding the many cases of accidental injury and the few cases of solar retinitis and of eye changes due to frostbite, there were 33 crew members of the heavy bombers of that period who received eye wounds due to enemy shell fire.

Since most of the injuries were due to the 20-mm. cannon shell which exploded at a fairly constant distance from the airman upon striking the duraluminum skin or plexiglass, most of the wounds were combined with concussion and were due, at least in part, to flying particles of aluminum or plexiglass. The fragments of the brass percussion fuse and the steel casing of these projectiles, together with the large steel fragments of anti-aircraft fire from the ground, were additional sources of eye injury.

All but four of these 33 men had other severe wounds, usually of the head. I cannot fully explain why the right eye was injured more severely and exactly twice as often as the left. It was miraculous that only 8 of the 33 had even a slight injury to the opposite eye, and only one case was permanently blinded in both eyes. Seventeen, or about one half, of the 33 had a penetrating wound of the eye, and 9 of these required early or subsequent enucleation.

One half the cases of penetrating wounds were due to metallic fragments and one half to plexiglass fragments. Only 2 of the 8 cases with metallic intraocular foreign bodies proved to be magnetic, and in one of these cases the foreign body was magnetic in both eyes. Magnetic foreign bodies were frequently found in other parts of the body, and every effort had to be made to exclude them in the eye.

In the 16 cases in which a nonpenetrating injury was the principal diagnosis, a rupture of the choroid, manifest as an indirect concussion injury, was present in 7 cases. Most of the remaining cases were multiple plexiglass foreign bodies of the cornea. Although the airman's eye wound resembled most closely the land-mine wound of the foot soldier, I believe the air injury was more often unilateral and showed less tendency to reaction and infection. Unlike the sand and gravel and powder particles in the land-mine injuries, the eye tolerated small particles of aluminum and plexiglass without continued reaction.

I would like to mention several impressions with which I returned after service in the ETO. First, the extreme importance of the careful rehabilitation of otherwise healthy soldiers who have very suddenly and irrevocably lost one eye due to severe injury. We learned that if they were allowed to sit around and were not immediately taught confidence in themselves and helped

in learning a new way to judge depth, they would quickly grow psychologically past any useful military service in the ETO or elsewhere. Early and persistent efforts at ping-pong was one of the most useful things in this rehabilitation.

Secondly, the complete conjunctival flap with a pursestring suture not only made further evaluation and treatment by the next ophthalmologist difficult, but in several cases provided a shortened postenucleation socket due to a too firm and too abundant inclusion of conjunctiva.

Thirdly, I believe that the many cases of uveitis, particularly exudative choroiditis, resulted in a longer incapacity and a longer combined loss of time from duty, than almost all other conditions.

Fourthly, I believe that in the future some modification of the Berman locator will be a most useful instrument in the early management of foreign-body cases, and that such an instrument will be basic equipment. I might also add that in my experience in the ETO I was never successful with either the Mellinger or Solus giant magnets in cases where the Lancaster hand magnet had failed.

DR. TRYGVE GUNDERSEN (Boston, Massachusetts): I have been asked to add the experiences and resulting points of view of those of us who were in the North African and later the Mediterranean Theaters where our forces were engaged in a war without interruption from November, 1942, to May, 1945. The action involved long campaigns through enemy country which varied from deserts to snow-capped mountains. It involved seven widely separated amphibian landings, one of which was relatively ill-fated.

It is to be remembered that at Anzio the entire beachhead was under daily enemy shell fire for more than five months. Furthermore, long holding operations at times made the warfare in this theater similar to that of World War I. It was a theater which involved almost every phase of modern warfare.

Besides being the most enduring fighting battlefield of World War II, the North African and Mediterranean areas offered an interesting battlefield from a point of view of sanitation and health. It is of everlasting credit to the medical department of the United States Army that over 500,000 Americans could be kept in that disease-infested country and remain as healthy as if they were at home.

I shall only mention the almost complete absence of such scourges as typhoid, smallpox, typhus, plague, and leprosy. Malaria was certainly uncommon, too. Duke-Elder states that practically the entire French Army of 32,000, and to a less extent the British, fell a victim to trachoma during the Napoleonic campaign in Egypt in 1798-99, and immense numbers of them were sent home blind.

During my service in these theaters, 26,223 patients were admitted to our hospital, of whom 1,936 were eye patients. In addition, I saw 3,075 for refraction, and 1,090 for other conditions in the outpatient department. This comprises a total of 6,101 patients seen by me.

The diagnosis of trachoma was made only seven times. In six, the infection was obviously old. Only one soldier contracted the disease overseas. Other ophthalmologists had comparable experience.

Dr. Marshall has mentioned how to utilize ophthalmologists in the theater. Everyone will grant that early operation is ideal and that the first operation should be the definitive one. Therefore, one's first thought is, "Place the eye surgeon forward as far as possible." But competent eye surgeons are rare. In my visits to each of our 84 hospitals, I found only seven doctors who had been certified by the American Board of Ophthalmology. There were perhaps an equal number of qualified, though noncertified, men.

The flow of casualties from a military

front may be compared to the flow of a river, for instance, the Mississippi, with casualties trickling or often flooding down from every rivulet, feeding the whole stream, through the Ohio, the Missouri, the Arkansas, and so forth. Every drop of water must be treated, preferably as soon as it falls from the sky, but remembering not to miss a single drop. It would be folly to waste good men by placing them along the Teche of Louisiana, the Fox of Wisconsin, or even the Chicago River of Illinois.

The problem of distributing ophthalmologists can be met by the creation of mobile ophthalmic teams, who might be hurried in to cope with flooding areas. This was part of the British plan. The disadvantages were the handicaps involved in doing major eye surgery under field conditions and the necessity of early or often immediate evacuation of patients postoperatively. Since eye casualties are transportable as litter patients with binocular bandages, and since they can no longer be considered emergencies—thanks to sulfonamides and antibiotics—it is my opinion that patients fare better when promptly evacuated to a first-class eye surgeon in a first-class hospital (eye center), be it several hours further behind the lines.

A different problem arises in regard to refraction. Equipment for refraction was not authorized for evacuation hospitals at the onset of World War II. Until this serious defect was rectified, combat men had to be

	No. of Cases	% of Total Hospital Admissions	% of Patients Seen Including O.P.	% of Patients with Eye Diagnosis

evacuated to general hospitals or station hospitals in the communication zone for an ordinary refraction. During the Anzio engagement, the problem became serious because of the large numbers of soldiers applying for evacuation and the difficulties involved in evacuating them.

The general hospitals in the Naples area were unnecessarily cluttered with these otherwise healthy men. Not until Maj. William H. Droegemueller and Maj. Edmund B. Alvis, each with an assistant, volunteered to establish a refraction clinic on the Anzio beachhead was this problem solved. These two ophthalmologists performed over 1,200 refractions on this dangerous beachhead. Their service has never been fully recognized, and I wish to commend them before their colleagues assembled here.

For those of us who joined the Army after our 40th birthday, and for many others, Army life was technically a voluntary project. Those who were by nature provident and farsighted did everything possible to anticipate their wants and increase their efficiency. Some studied the Officers' Guide Book; others took correspondence courses in everything from the detailed organization of a pack artillery regiment to just how to pile manure in the accepted Army manner. The benefits derived therefrom were somewhat questionable.

Of greatest benefit to me were the tools of my trade, which I carried with me. My ophthalmic surgical kit was small, but carried my favored instruments. The contents which I found most useful included my own needle holder, speculum, assorted forceps, chalazion clamp, six packages of Kalt corneal needles, several spools of 0.0025 fine silk, a set of Walker pins, several good Stille scissors, and a magnetic probe. In addition, a complete set of instruments for corneal transplantation happened to give me great pleasure.

While in Morocco, where human life is cheap and animal life is cheaper, our hospital established an animal farm with an excellent Arab diener who nursed our animals for fifty cents a day, plus three meals of good army food. There was an abundant supply of rabbits, other rodents, and some monkeys. It gave great opportunity for experimentation during the quiet periods.

The diagnostic equipment that I carried

with me included two ophthalmoscopes (fortunately, these had large handles which accepted the standard Army dry-cell battery), a retinoscope, my own trial frame, and cross cylinders. These items were used daily, and obviously suited me better than anything the Army offered.

There was little hope of carrying heavy books until the hospital library became organized. When this happy day was announced, the librarian accepted my three volumes of Duke-Elder's textbook and several other classics from my own shelves.

Dr. Marshall has given us an interesting account of his long and splendid service for the American soldier. It is a pleasure to add my own statistics and those of the Mediterranean theater to his (figs. 1 and 2).

DR. DON MARSHALL (closing): I wish to thank Dr. Calhoun and Dr. Gundersen for their valuable and most interesting additions to my paper. Their experience was far wider than mine.

CANCER AND THE LENS

ERICH SACHS,* M.D.
Chicago, Illinois

AND

REUBEN L. LARSEN,* M.D.
Evanston, Illinois

Cancer of the lens has never been observed. What are the anticarcinogenic factors which render the lens immune to cancerous invasion?

The lens is composed of epithelial cells which continue to multiply throughout life, and constitutes a complete, metabolically active organ in itself. It is, however, characterized by certain special features which distinguish it from all other organs. Hence it appears logical to focus attention on those features which make the lens a unique structure. Some of these cannot at present be related to the biology of cancer; for others the underlying mechanism is unknown. The discussion of these possibilites is presented in the hope that it may stimulate experimental research.

ACCESS TO THE LENS

Assuming that cancerogenic substances are introduced into the organism or originate within the body outside the lens, what are the chances for the carcinogen to reach the lens proper?

Passage. The lens is suspended by means of the zonule fibers like a spider in its cobweb. An agent can reach the lens only through the aqueous; it must be able to pass through the ciliary processes and be soluble in the aqueous.

The ciliary processes present a formidable barrier against transmission to the lens from without. Larger molecules, such as protein or bilirubin (even in severe jaundice†), do not pass into the aqueous. Two possible deterrents, therefore, may prevent a carcinogen from acting upon the lens. The agent, because of its chemical structure, may not pass into the aqueous at all; or it may enter the aqueous only in such insignificant amounts that the threshold concentration for carcinogenic actions is never reached.

Diffusion. If it be assumed, however, that a carcinogen should penetrate the barrier of the ciliary processes and concentrate in suf-

* Associate editors, *The Illinois Cancer Bulletin.*

† Unpublished experiments.

ficient strength in the aqueous, it would still have to penetrate the lens capsule in order to reach the lens proper. The capsule provides another barrier because it permits diffusion only at a very slow rate.

If the permeability of the capsule decreases with advancing years (as assumed by several authors[1]), age, generally promoting development of cancer, would exert an adverse influence in the lens.

Solubility. The aqueous is a true watery solvent and is practically devoid of colloids, protein, and fat.[2] The majority of carcinogens studied so far are water-insoluble. Hence a carcinogen belonging to the group of water-insoluble agents could not reach the lens.

Secondary aqueous. The physiologic properties of the aqueous change radically after tapping the anterior chamber. The secondary aqueous, formed after draining off the primary, resembles blood plasma in many respects. By applying this technique, it should be experimentally feasible to expose the lens to known carcinogens in adequate concentrations, and thus learn how the lens reacts to a carcinogen when contact is actually made.

Biologic considerations

General nutritional factors. The lens, unlike other organs, does not depend upon the blood for nutrition; its nutrition is derived from the aqueous. The chemical and physical differences between these two media are associated with another difference of equal significance. Other organs possess means for controlling the influx of nutrients through regulating the blood supply; the intensity of normal-lens metabolism is dependent upon the composition of the aqueous. No mechanism is known through which the lens could induce the aqueous to furnish nutrients at an increased rate if higher requirements than the normal should arise, as would be the case if cancer should develop.

The lens may then be considered as an organ under permanent and rigid caloric restriction throughout life. To a certain extent its low metabolic activity is indicated by the rate of oxygen consumption. Even in youth oxygen consumption is only a fraction of that of other body tissues. Increasing age further reduces the respiratory activity. The lens with a cataract takes up even less oxygen than a normal one.[1]

Caloric restriction is known to have an anticarcinogenic effect on cancer incidence and development. The conclusion may therefore be drawn that the lens, an organ with a minimum of metabolic activity, cannot be very susceptible to cancer. Age and cataract formation (in which glycolysis also drops far below normal) create conditions even less favorable for cancer. If, however, cancer should get a foothold in the lens, the first few malignant cells would find a paucity of nutrients and would be unable to induce more ample nutrition by stimulating ingrowth of vessels. Rather, in the initial state when most vulnerable, they would be compelled to compete with the normal lens cells for the scarce available nutrients.

Special nutritional factors. The energy requirement of the lens is supplied by carbohydrates, probably in the form of glucose alone. Of the two mechanisms for glucose utilization in the body—aerobic oxidation to CO_2 and H_2O, or anaerobic glycolysis to lactic acid—the anaerobic process is much more important.

The normal energy metabolism of the lens is thus keyed to a type of glucose utilization which cancer in the lens—most likely of epithelial origin—must adopt due to the lack of oxygen. Thus the first few cancer cells would have to begin life in competition with a group of normal cells which are dependent upon the same type of glucose metabolism. The advantage of cancer cells over normal cells would not exist in the lens.

In contrast to other normal tissues (which utilize both mechanisms) the lens alone possesses a complete glycolytic enzyme system, but a vastly inferior respiratory enzyme system. Neither cytochrome nor cytochrome oxidase are present in the lens cells.[1]

A highly developed capacity for anaerobic glycolysis does not suffice in itself, however,

to render tissues cancer resistant, as evidenced by the retina. The retina exhibits the highest glycolytic activity of any tissue studied so far, and it also has a significant oxidative capacity; yet cancer develops in the retina (retinoblastoma).

Other biologic considerations. The suggestion has been made that cancer cells originate and begin to proliferate in response and as an adaptation to conditions which interfere with the growth and proliferation of normal cells.[3] On the basis of this hypothesis, the increase of cancer incidence with advancing age has been referred to the retardation of growth, associated with senescence, promoting discontinuous growth or proliferation.

In the lens, cellular growth and proliferation are extremely well controlled. If it were different, the value of the lens as a refracting medium would be jeopardized.[4] The beautiful rhythmicality of the anatomic pattern, the increasing index of refraction from the cortex toward the nucleus, the high regularity of the intralental refracting surfaces, all these features are incompatible with major irregularities in growth or proliferation of the lens cells. Age, although inducing many changes, does not impair these properties. The lens cells continue to grow and proliferate until death.

If the aforementioned hypothesis be true, the lens gives cancer little chance to exist in its domain.

Physical factors

Pressure. Cancer cells, when proliferating, infiltrate and push aside adjoining tissues, and the total volume of an affected organ tends to increase. The intralental pressure in the nonaccommodating eye is probably high, a conclusion drawn from the strength of contraction of the ciliary muscle required to overcome the pressure exerted by the capsule on the lens substance.[5, 6]

Although one cell may fail to correspond exactly to adjacent cells—due to slight irregularities in arrangement—it must not be assumed that the resulting, easily demonstrable spaces are empty. These spaces are certainly filled with fluid to insure homogeneous distribution of pressure throughout the lens. Other spaces, such as blood and lymph vessels, do not exist in the lens. It would seem that "wedging in" of cancer cells between normal cells would meet with considerable mechanical resistance from the pressure within the lens.

Light. The retina is protected by the refracting media against damage from ultraviolet radiation.[7] The cornea, because of its thinness, absorbs very little; the aqueous, being noncellular, is biologically inactive; the lens, because of its thickness, absorbs a considerable amount. It is known that ultraviolet radiation promotes conditions which are favorable to cancerous growth.

It may not be too farfetched to conclude that the lens cells are thus naturally adapted to a relatively high dose of ultraviolet radiation, another characteristic held in common with cancer cells. As in anaerobic glycolysis, the lens cell thus meets the cancer cell on the same competitive level, while other body cells, under similar conditions, would be at a distinct disadvantage.

Lens constituents

Minerals. The sodium content of the lens is extremely low. In tumors, generally, the sodium content is increased, but nothing definite is known about the influence of sodium on the growth of cancer.[8]

The potassium content of the lens, on the other hand, is extremely high, but decreases rapidly when cataract develops. Potassium promotes glycolysis. Its presence in large amounts, in both the lens and in tumors generally (where it corresponds with their metabolic rate), may thus be referred to the peculiar energy metabolism of the lens and of cancer respectively.

Protein. There is a questionable decrease of glutathione in the protein found in cancerous growths. In the lens, glutathione is present in significant amounts.

Lenticular protein is unique in that it lacks species specificity, possessing organ specificity only, with an amazing degree of similarity, at least in mammals. This feature

may point to a lower grade of specificity (common to both lens and cancerous tissue), another similarity to cancer.

Enzymes. As mentioned before, the lens cells contain neither cytochrome nor cytochrome oxidase. When cytochrome-c activity of normal human tissues and human neoplasms was compared, cytochrome activity was highest in certain normal tissues and lowest in the tumors of greatest malignancy.[9]

In this study cytochrome-c activity was found to be highest in those tissues in which cancer incidence is least frequent. The lens does not seem to fit into this pattern. In our opinon, however, the absence of cytochrome in the lens and the low cytochrome activity in cancer is one more similarity between lens and cancer, all of which taken together make lens tissue the most direct competitor of malignant tissue.

Other factors

Hydrogen-ion concentration. The pH of the lens is approximately 7.4. At this pH the alpha and beta proteases present in the lens are inactive. If the proteins of the lens break down, the resultant increase in acidity activates the proteolytic enzymes, and the way is opened for large scale hydrolysis of these proteins.[10]

Proteolysis induced by cancer is promoted by reduced oxygen pressure. The oxygen pressure in the aqueous corresponds to only 0.8 to 0.12 volume percent. (The actual volume of oxygen in the arterial blood is approximately 19 cc. percent.) Hence, should tumor cells succeed in becoming established in the lens, it can be assumed that they would exhibit considerable proteolytic activity because of the favorable milieu. The released amino acids would quickly render the reaction within the lens more acid, the mechanism for autolytic decomposition of lens proteins would be released, and swelling and destruction of the lens would result.

Another intereting possibility may be assumed. The lens may not be immune to cancer, but cancer, in its beginnings, may create conditions which tend to destroy the lens before the new growth has advanced to a point where it is demonstrable.

This hypothesis may also be applied to the competition between lens and cancer cells for glycose. If the cells of the lens were deprived of sufficient quantities of glycose for any length of time, the impairment of energy metabolism would soon bring about destruction of the lens.

Summary

Factors of biologic, metabolic, physical, and chemical nature—any or all of which may be responsible for the nonexistence of cancer in the lens—are considered and discussed.

RECORDING OF VISUAL FIELDS*

MAX CHAMLIN, M.D.
New York

To the busy clinical ophthalmologist, the detailed study of visual fields is frequently an undesirable chore. Too often it turns out to be time consuming and taxes the doctor's patience excessively. Some men even ignore it and others relegate it to the nurse, secretary, or technician. To one who devotes much of his time to this work, it is apparent that the science of perimetry is not to be relegated to a technician. Duggan[1] goes so far as to say that he would condemn such practice as much as that of allowing one's secretary to do the ophthalmoscopic examination.

Some ophthalmologists believe that a very elaborate machine for the study of visual fields does away with the need for the doctor. We must remember, however, that the technique is far more important than the machine. To quote Traquair,[2] "Perimetry is not done by the perimeter, but by the perimetrist, and simple tools properly used are much less productive of wrong conclusions than undue reliance on the dicta of an elaborate instrument." Since the technique of perimetry should be guided by the clinical aspects of the case, one can understand that it would require a clinician to study the visual fields satisfactorily.

TIME-SAVING METHODS

However, since the clinical ophthalmologist may find it too time consuming, it seems pertinent to discuss some of the methods available for time saving and efficiency in recording visual fields.

DICTATE THE FINDINGS

In examining the patient's visual fields on the perimeter, it is best for the examiner to study the successive meridians and dictate the findings to his secretary as he makes them.[3] In this way, the examiner does not waste time looking for the proper place on the field chart, getting a good light to read by in the darkened room, readjusting his own position in relation to the test-object holder, and so forth.

All these distractions are time consuming and tax the subject's patience as well as that of the doctor. Furthermore, taking out time to record interferes with the routine, the patient grows restless and may change his position, and the examiner has to readjust the patient's position for each setting of the perimeter. It is advantageous, therefore, to dictate the findings to the secretary who can insert them on a card previously prepared for this purpose. This card (fig. 1) has the various meridians listed one under the other in the order in which they are examined, and the secretary records the data as the doctor calls them off. There is also provision for object size, distance, and color—all of which are dictated by the perimetrist as he examines.

ROUTINE OF EXAMINATION

For accuracy and uniformity, it is best to start with the 0-degree meridian representing the patient's right horizontal meridian in either eye, and to go up and to the patient's left (that is, clockwise for the examiner as he faces the patient) and, in this order, all the way around the field at 30-degree intervals.

Each meridian is recorded in order, the opposite meridian not being explored at the same time. One finds it less confusing and faster to record each meridian in order, for example 0 degree, 30 degree, 60 degree, and so forth; *not* 0 degree, 180 degree, 30 degree, 210 degree, and so forth.

By following one meridian after the other, the examiner can more easily appreciate the field as it unfolds itself, and thereby adjust

* This work was done under a grant from the William L. Hernstadt Fund. From the Ophthalmological Service of Dr. Samuel Gartner and the Neurosurgical Service of Dr. Leo M. Davidoff, Montefiore Hospital, New York City.

his technique to the conditions found. Single aberrent readings which differ appreciably from the adjacent readings will attract the examiner's attention and will suggest that the same meridian be explored and that the 15-degree readings on either side be explored as well. If the examiner alternates readings between one side of the field and the other while he dictates to the secretary, he may lose track of the general contours of the field and cannot, therefore, guide his technique as accurately.

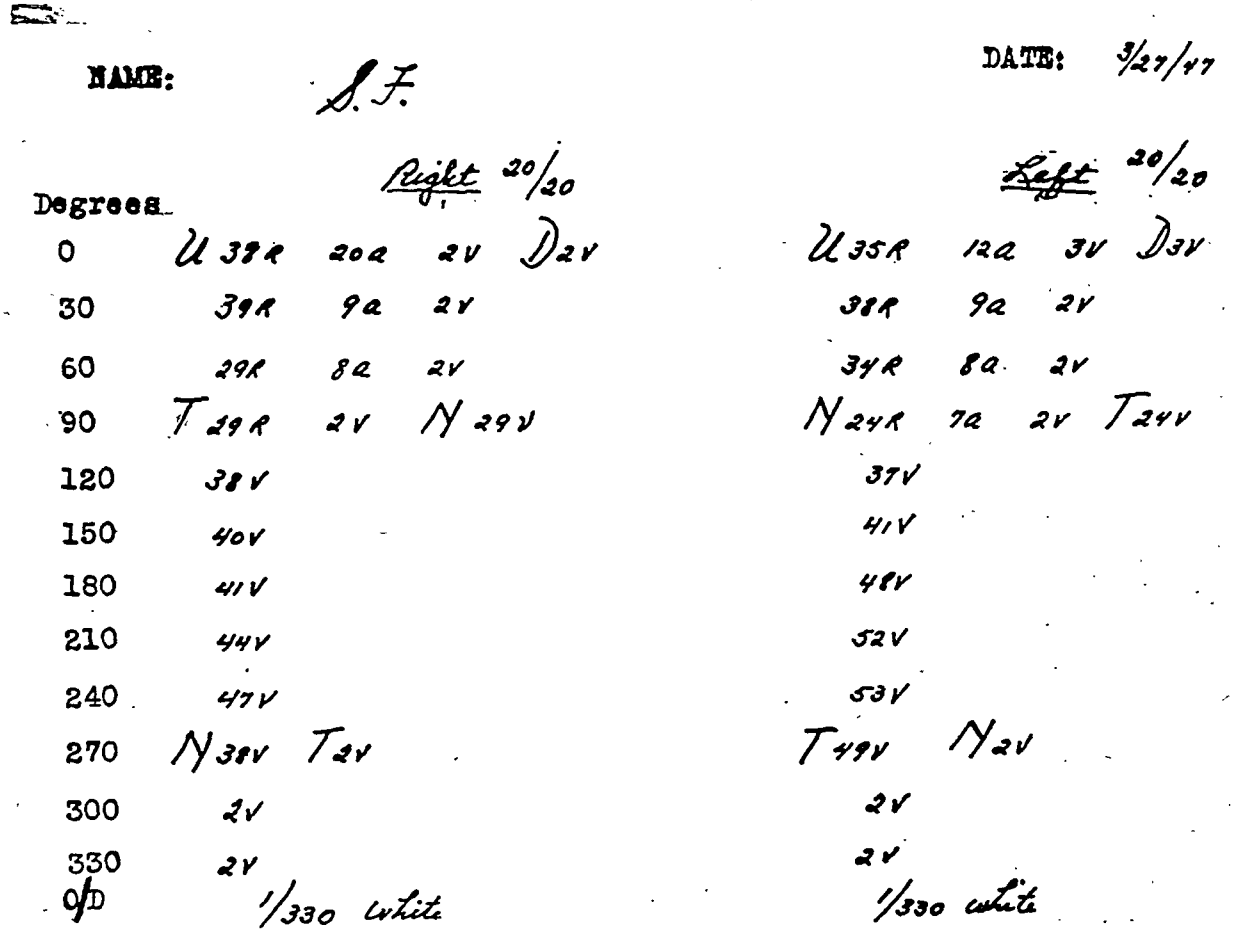

Fig. 1 (Chamlin). Card for recording data for peripheral fields. (The fields in Figure 2 were plotted from the data on this card.)

If all visual findings are definite and the patient is quite sure of his responses, no qualifying remarks are made in the dictation. On the other hand, if the patient gives a definite description of seeing the test object very blurred in certain areas, such as one would see in an area of relative scotoma, the dictation is given so as to indicate that there is some relative defect in this area.

To illustrate this. If we are exploring the 30-degree meridian in the right field of Figure 2 and the patient sees the test object blurred at 39 degrees and continues to see it blurred until it reaches the 9-degree arc, where it suddenly disappears completely and reappears clearly at the 2-degree arc, this 30-degree meridian would be dictated as "39r,9a,3v"—the small letters "r," "a," and "v" standing for "relative," "absolute," and "vision." The last symbol, "v," indicates clear vision for that portion of the field.

Checking relative defects

Of course, in evaluating relative defects, one must be quite sure that it is really a defect and not the normal amount of blurring due to the physiologic diminution in visual acuity in the periphery, corresponding to the

normal "sloping edge" of Traquair. One way of checking the area of relative defect is to use the method of "rapid comparisons"[4] and compare this area with one in another meridian about the same number of arc degrees distant from fixation.

For example, if the patient thinks that the test object is blurred between 10 and 20 degrees in the 60-degree meridian, one should move the test object rapidly to the 120-degree meridian between the 10 and 20 degree arcs, and ask the patient to compare the appearance of the test object in the two different places.

The same test object should be seen approximately equally well in these two areas, unless the defect crosses the vertical meridian. In such a case we may use a point equidistant from fixation in the 240-degree or 300-degree meridians.

It is well to make these comparisons rapidly, holding the test object in each of the comparable areas for only a brief second at a time. One should keep asking the patient "is it clearer here or there" and should accept only very definite and consistent answers.

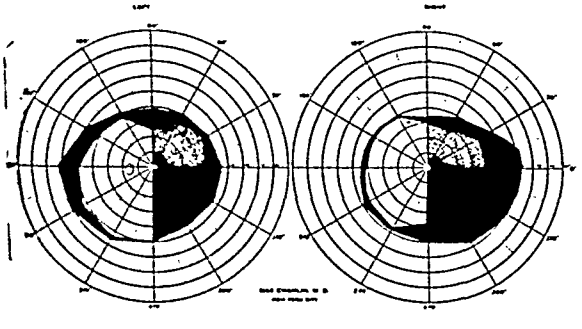

Fig. 2 (Chamlin). These visual fields were filled in from the data recorded on the card shown in Figure 1.

In order to avoid the necessity for moving the arc of the perimeter with each of these rapid changes, it is well to use a paddle type of carrier.[5] With this carrier, which furnishes a large dark background for the test object and simulates the perimeter surface, the examiner merely changes the position of the paddle carrier rapidly from one area to the other, approximating the meridian and arc position rather than actually measuring it on the perimeter. Once the quality of the defect is evaluated in this way, accurate measurements with the perimeter arc in position can be made. In asking the patient to evaluate the test object against the paddle carrier without the perimeter background, it is well for the examiner in his black gown to provide a substitute background.

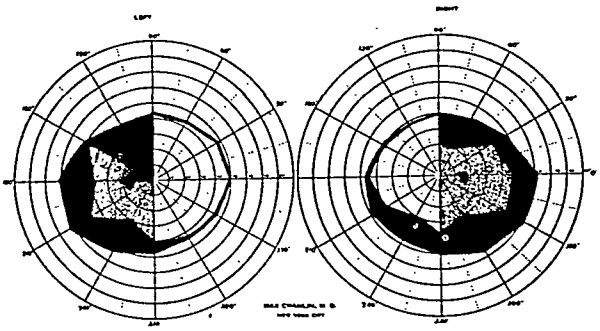

Fig. 3 (Chamlin). Peripheral fields for 1/330 white, showing bitemporal hemianopic defects with varying density.

In the same meridian, one must be careful about labelling a more peripheral arc as relative compared to a more central arc. A pathologic defect is more definite if the test object becomes blurred more centrally after having been seen more clearly peripherally in the same meridian.

Recording of Readings

This method of recording vision, relative defect, and absolute defect, as "v," "r," and "a" may seem a little complicated at first, but actually resolves itself into a very simple method of dictation. As another example, in Figure 2, in the 60-degree meridian of the left eye, if the test object was seen blurred at 34 degrees, disappeared at 8 degrees and returned clearly at 2 degrees, the dictation for the 60-degree meridian of the left eye would be "34r, 8a, 2v." These readings are dictated at the time the patient calls them, as the test object is carried along the meridian being explored.

In those cases in which one suspects a

sharp line of demarcation, such as in the temporal hemianopias of chiasmal lesions where the 90-degree meridian may divide a relative or absolute defect temporally from a zone of good vision nasally, the 90-degree meridian is dictated as "T" and "N," standing for "temporal" and "nasal." The readings are taken separately along the temporal and nasal side of the vertical meridian.

Thus, in Figure 3, the 90-degree meridian in the left eye would be dictated as N43, T0. The same designation of "T" and "N" is used for the 270-degree meridian.

Furthermore, if a sharp horizontal division is found between a zone of good and poor vision in any but the vertical meridians, I use "U" and "D," standing for "up" when reading above the meridian and "down" when reading directly below it. These readings, of course, are made directly above and below the line along the middle of the perimeter surface in the meridian being explored. Thus, in the left field of Figure 3, the sharp change from absolute to relative scotoma in the 150-degree meridian is recorded as U0, D48r, 13a. "T," "N," "U," and "D" are inserted as capitals, while the "v," "r," and "a" are inserted as small letters.

Areas of diminished vision

In those areas where the test object is sighted by the patient, but the patient tells the examiner that it is very blurred, one may indicate the area as being relatively scotomatous. Of course, we are not really giving that portion of the field a definite value in terms of visual angle, color, and illumination. We merely describe it as an area of diminished visual acuity as compared to other areas for the same visual angle and illumination.

These areas of diminished vision can be further analyzed with lesser stimuli into absolute scotomas. However, for most practical purposes, merely indicating a definite blurring as a relative defect is highly satisfactory.

Some patients are very keen in their observations and correspondingly expressive in their descriptions of how they see the test object and thereby give us good data for recording various degrees of density of scotomatous areas. However, one should not attempt to record such gradations on the basis of the patient's evaluation of a single visual-angle stimulus. This would lead to too many complicated factors.

It is safer to accept only one degree of vision as being that of a relative scotoma—that area in which the patient definitely sees the object but where it is definitely not as clear as it is in other areas equidistant from the fixation point.

Recording tangent-screen findings

A similar procedure of dictation may be used in recording findings on the tangent screen. Here the markings are in 22.5-degree meridians and corresponding record cards are used when recording fields such as the 1/2,000 white or the 5/2,000 red.

Here again, one can use the symbols, "U," "D," "T," and "N" to indicate sharp dividing lines as well as the letters, "v," "r," and "a" for indicating varying degrees of density of scotoma or vision. By dictating the findings, we can avoid putting pins into the screen, thus saving time, wear and tear, and the distracting influence of the pins on the tangent screen.

Against this method, one might say that, without the pins, the examiner does not visualize the field as it unfolds itself and thereby fails to take extra readings in areas suggesting a defect. However, if one uses the tangent screen fairly frequently, one will easily learn to visualize and interpret the field as he dictates it.

Verbal dictation and recording by the secretary is not particularly useful in mapping out small scotomas. Here, the usual method of inserting black headed pins or a light dab of chalk is preferable.

Advantages of these methods

There are several advantages to this method of recording perimetric and tangent-screen findings.

1. It gives an accurate, numerical record of the patient's field, not affected by the error in recording hastily and interpolating distance for the various arc degrees on a perimetric chart in a darkened room. For future reference and comparison, these original records are most accurate.

2. The patience of the subject is not taxed with boring delays between readings, and consequently he maintains more constant fixation.

3. The entire procedure becomes much more rapid, thus doing away with one of the reasons that some men do not study visual fields more often. The secretary can be taught to plot the fields from these charts within 3 to 5 minutes after recording all data; or she can plot them after the doctor is through with his work, if the findings are not of an urgent nature. It is preferable to see the plotted field before the patient leaves the office, so that any suspicious recordings which might bear checking can be verified.

Visual field charts

There are many types of charts in use for recording of visual fields. Many of them use some shading of the periphery, leaving unshaded that portion usually subtended by a 5/330-white test. If all perimetry were done with this visual angle, the shading would be adequate as indicating the normal. However, with modern methods of quantitative perimetry, using different visual angles, this shading loses much of its value, and to the inexperienced eye, may often be misleading. While the 5/330-white test is satisfactory for marked peripheral defects, it is not quite sensitive enough for minimal types of peripheral defects. For such minimal types of interference, one should use a minimal stimulus, such as the 3/330 white, or better still, the 1/330 white. The last one mentioned, while not reaching out as far in the periphery of the field as the 3/330 white, is a much more delicate test and more apt to show minimal interference in the field, even when quite peripheral.

Chart for peripheral-field study

Therefore, since 5/330, 3/330, and 1/330 all have their uses, I have devised a chart for use at Montefiore Hospital for peripheral-field study with all these three isopters indicated on it in a light contrasting color (fig. 4).

In order to avoid confusion, the meridional- and arc-degree markings are of an orange color, and the normal isopters are indicated in a very light green—so light, that on casual inspection, the examiner will not notice these isopter lines. However, the recorder has no difficulty in seeing and using the line for the particular test employed. The outermost green line represents the 5/330-white field, the next one the 3/330, and the innermost one the 1/330 field. The visual field tracings are done in the usual black ink.

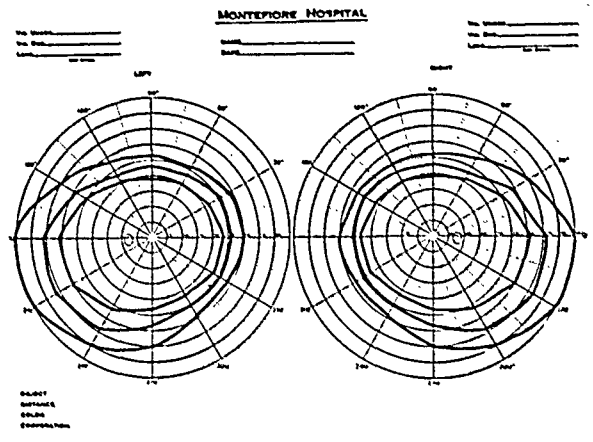

Fig. 4 (Chamlin). Photograph of author's chart for recording peripheral fields. The chart is white and the meridional and arc markings are of a light orange color. All the printing on the chart is also light orange in color. The median normal isopters for the 5/300, 3/330, and 1/300 white are marked off in very light green, hardly perceptible on casual inspection. These isopter lines have been accentuated with heavy black ink so as to show up well in this photograph. The light orange lines have also been changed to black for the purpose of this photograph.

After recording the visual fields, the secretary goes over the isopters for the particular visual angle used in the same black ink. Thus, if we use a 3/330 test, the secretary blackens the middle isopter line, then outlines the field as found for the patient, and

blackens the space between these two lines. Thus, all blackened space indicates lost field.

This method of blackening all the lost field up to the normal isopter is used by many workers for the 5/330 field by blackening up to the shaded area. For smaller visual angles; that is, for the slightly inner isopters, some workers have used the corresponding normals to indicate lost field. Most examiners, however, merely draw the line on the field and do not indicate the normal.

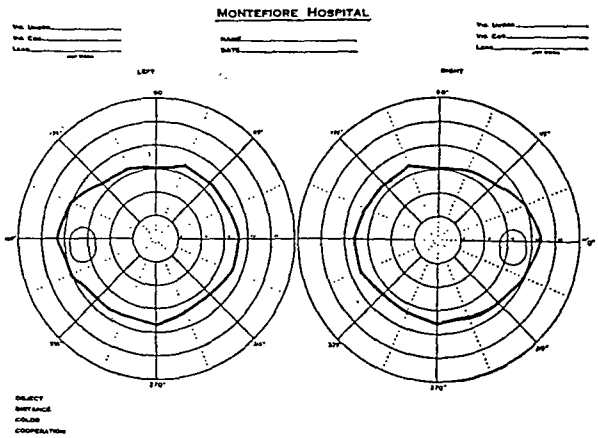

Fig. 5 (Chamlin). Author's chart for central fields. As in Figure 4, all the printing, arc, and meridional markings are in a light orange color. The isopter used for 1/2,000 white, normally a very light green, has been marked with black ink for the purpose of this photograph.

In reading these charts, all the observer has to know is that the outermost blackened line is the normal extent of field for the particular test used. Of course, if the plotted field is larger than the normal one, there is no space to fill in and the normal need not be blackened.

Minimum normal field

To one who has had experience with the various isopters for the various visual angles, this filling in of lost field may not be very important. However, many of the physicians to whom these charts are presented are not acquainted with these normals, and a normal 1/330 field may appear like a generalized peripheral contraction when plotted on a chart whose periphery is shaded for a 5/330 field.

The 5/330 isopter is represented pretty much the same on most perimetry charts and is almost the same as the averages found by Ferree, Rand, and Monroe.[6]

In this same article, the authors studied a large series of normals and worked out what would be a minimum normal field for the 5.8/330 (1-degree stimulus). They conclude with reasonable assurance that a field smaller than this is probably a pathologic contraction.[7]

This minimal normal field takes into consideration even the smaller fields of presbyopes. When considering only myopes and presbyopes, the average field was found to be not more than 10 to 12 degrees narrower than the normal used on the Montefiore chart. Therefore, any contraction beyond 12 degrees on this chart should be considered as probably induced by a pathologic condition.

The 1/330 isopter used on the Montefiore chart is practically the same as the median value given by Ferree, Rand, and Monroe for 150 nonpathologic cases. These authors worked out the lowest normal field for this visual angle (0.17 degrees) including the fields of presbyopes.[8] The greatest difference between the 1/330 isopter on the Montefiore chart and the smallest field for presbyopes is about 10 degrees nasally and 17 degrees temporally. Therefore, any contraction beyond 12 degrees on the 5/330 isopter and beyond 10 degrees nasally and 17 degrees temporally on the 1/330 isopter should be considered suggestive of pathologic conditions.

Interpretation of fields

In general, if the field is uniformly constricted, it is unlikely that one is dealing with a true pathologic contraction. On the other hand, localized indentations and sector defects are much more common in truly contracted fields. Of course, in any doubtful cases, one should expect the emmetropes and hyperopes to have larger fields, and the myopes and presbyopes, smaller ones. A truly technical normal could be established by

working out a long series of fields depending on the refractive error as well as the age. However, if one wants to feel very safe before considering a field contracted, he may do so by using these low normals as worked out by Ferree and Rand.

One may assume other normals than those assumed normals as fairly reliable, especially, as in this case, when the smaller halves of each field are homonymous and the clinical picture warrants a homonymous field defect. However, if the findings do not give a clue, one could well use the median normals on these charts as a guide.

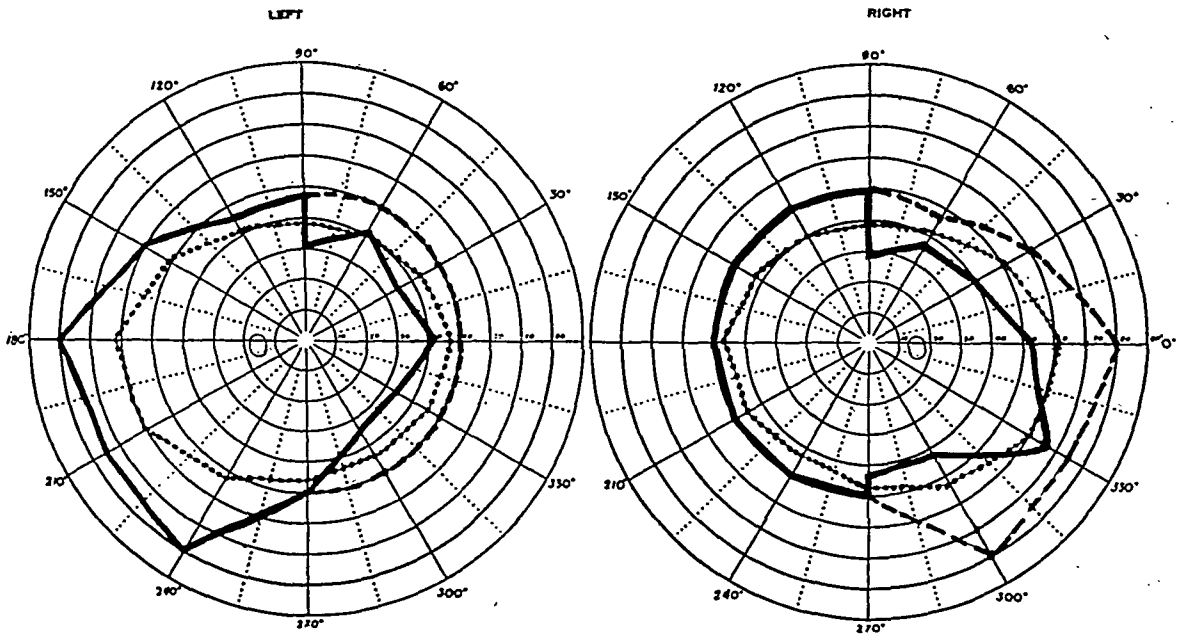

Fig. 6 (Chamlin). The solid heavy black line is the field plotted for A. R. with 1/330 white. The dotted line represents the median normal for this visual angle as used on the author's chart.

In this case, the extent of the normal field in the homonymous defective area of the right eye may be assumed by the broken line which is filled in from the corresponding normal field in the left eye.

That is, the normal for the right temporal field is plotted by a broken line by using the corresponding fuller temporal recordings in the left field. The normal for the left nasal field is plotted by a broken line using the corresponding fuller nasal recordings in the right field.

It is reasonable to assume that the right and left normal fields are equal in size and shape, since both eyes had equal visual acuity and equal refractive error. It will be seen that these assumed right homonymous normals follow the general contour of the fuller, normal, left homonymous recordings.

This is the field study in a case of left temporal lobe lesion with beginning right homonymous field defect.

reported on the charts by the findings in a particular case. For example, in Figure 6 we see that the left half of each field, being unaffected by the interference of the visual pathways, shows an extent of field well beyond the 1/330 isopter shown on my chart. In such cases, we may assume the normal field to be represented by the less affected temporal and nasal halves. One could, in such cases, gauge the normal or the general contour of the fuller size of the field with reasonable accuracy. One may consider such

In similar fashion, the Montefiore chart for central fields has a normal isopter for 1/2000 white indicated on it (fig. 5). Here again, the arc and meridian markings are colored a light orange and the 1/2,000 isopter is a very faint green. The values for this 1/2,000 isopter were made after Hefftner and discussed by me in a previous article.[5]

According to some observers, the normal 1/2,000 field extends for an average of about 19 degrees while, according to others, it may extend to about 26 degrees.[9] The author has

found many patients who do not perceive the 1-mm. test object at two meters beyond the 10- to 12-degree meridian. This is in accordance with the findings of McLean.[10]

If a patient's 1/2,000 field reaches uniformly about 10 degrees all around fixation and no other peripheral or central defect can be found, it is quite likely that this is the

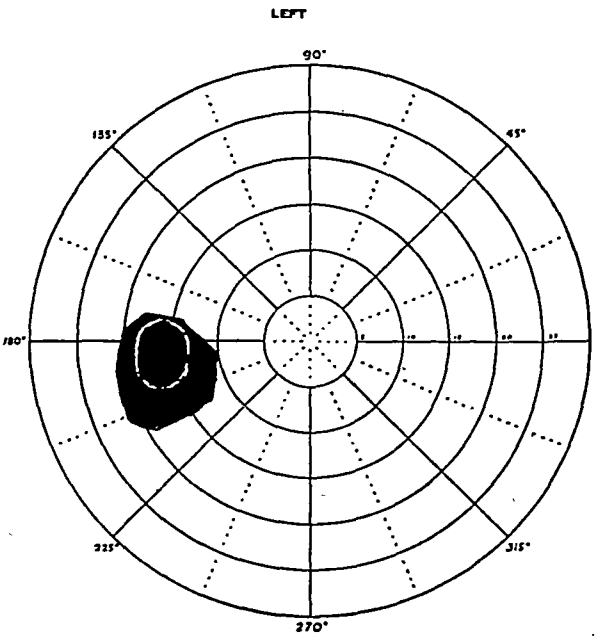

Fig. 7 (Chamlin). Black and white reproduction of an enlarged blind spot. An orange line outlining the normal blind spot on the chart is left unblackened and stands out against the black of the enlarged blind spot to show the normal area.

normal for him. Thus, we must make allowances for a wide range of normals as in the peripheral field. Here, again, localized contractions such as homonymous or bitemporal defects are much more significant than generalized regular contractions.

Show up normal blindspot

The 45-degree meridians are marked off by solid lines to the 5-degree arc and then by dotted lines. The 22.5-degree markings are represented by dotted lines and stop at the 5-degree arc. This allows more space centrally for detailed recordings. The unmarked meridians within the 5-degree arc can be gauged with reasonable accuracy. The blind spots are calculated according to the average of Evans' report on five workers.[11] When filling in the blind spot demonstrated by perimetry, it is well to show up the normal blind spot within it so that the physician can easily gauge the amount of enlargement, if any. This can easily be done by not blacking the outline of the normal blind spot (fig. 7). Here, the orange color outline of the normal blind spot is left intact to stand out, as normal, against the blackened area.

Recommended charts

The charts are printed on white thin paper so that the black ink shows up well and can easily be traced from another field record if necessary. The light orange and green markings become inconspicuous next to the black recordings and the latter stand out well. These charts are useful for hospital and office records, and especially for demonstrations to large groups at clinical conferences. However, for reproducing field studies in medical publications, it is better to use black meridional markings and to trace the normal isopters used from another chart before filling in the space representing lost field. I have used such charts in this article.

Summary

1. A rapid method of recording visual fields is described. This method allows the examiner to work rapidly, uninterruptedly, and accurately while he dictates his findings to his secretary.

2. This method gives a permanent, accurate, numerical record of the visual-field studies, together with a simple method for recording differences in scotometric densities.

3. The Montefiore charts for central and peripheral fields are described. These charts carry the commonly used normal isopters in light colors so the proper ones can be utilized in indicating lost field, thus making the finished chart a schematic picture of the subject's visual field and its deviation from the normal.

THE STEREOPHOTOGRAMMETRIC STUDY OF THE ANTERIOR SEGMENT OF THE EYE*

ENRIQUE V. BERTOTTO
Rosario de Santa Fé, Argentina

An historical study of contact lenses and their development from the time of Fick, that is about 1888, to the present, leads to the conclusion that in order to make a perfectly fitting contact lens, a faithful reproduction of the curves of the anterior segment of the eye must be obtained.

The drawbacks to the standard lens, that is, with fixed curves, have been partially solved by using a cast of the eye but this procedure does not fulfill all the necessary requirements and presents unsolved difficulties which will not be discussed in this paper since they are well known to all those who have made a particular study of contact lenses.

The ideal lens is that which would rest on a large surface of the ocular conjunctiva. For this, it is necessary to try to obtain with the maximum exactitude a pattern of all the curves of the anterior segment of the eyeball, covered by the conjunctiva so as to avoid compression of the vessels and subconjunctival capillaries which feed the cornea and perilimbic region.

Dallos, to whom the first results of this study were communicated, is entirely in agreement as to the necessity of obtaining these curves; he maintains these curves should be of such exactitude that the margin of error would not exceed 0.05 mm. (personal communication).

Stereophotogrammetry consists in the calculation of the form, dimensions, and position of a given object from photographs of the same. It is a highly specialized subject in engineering which can only be practiced by skilled technicians. The author is indebted to the collaboration of A. Saralegui, an engineer, whose knowledge has given the solution of many of the problems arising in the course of this work.

It has already been stated that the curves to be obtained are those which form the anterior segment of the eye, covered by the

* Read before the II Pan-American Congress of Ophthalmology, Montevideo, Uruguay, November, 1945.

ocular conjunctiva. The transparency of the conjunctiva, which makes it invisible on a photographic plate, is a great drawback. This was the first difficulty to be solved. Several methods tried gave negative results until the eye was powdered with lamp black. This method gave a satisfactory result; that is a perfect stereoscopic view of the conjunctival and corneal surfaces. The fine film which covers the anterior segment of the eye, the vessels which run under it, and even the sclerotic could all be seen.

The fundamental problem thus solved, it was possible to chart the points of observation necessary for the stereophotogrammetric measurements which enable one to plot the curves made by the conjunctival surface of the anterior segment of the eye millimeter by millimeter throughout the whole of its extent.

The technique was as follows. After the administration of akinesia and local anesthesia, the eye was powdered with lamp black, by means of a strainer; the lids were then separated and a snapshot was taken with a Zeiss stereoscopic camera of the anterior segment of the eye. This camera has orthoscopic objectives, its own illumination, and a focusing eyepiece. The photographic plates gave negatives which permitted the eyeball to be measured within the preëstablished limits of error.

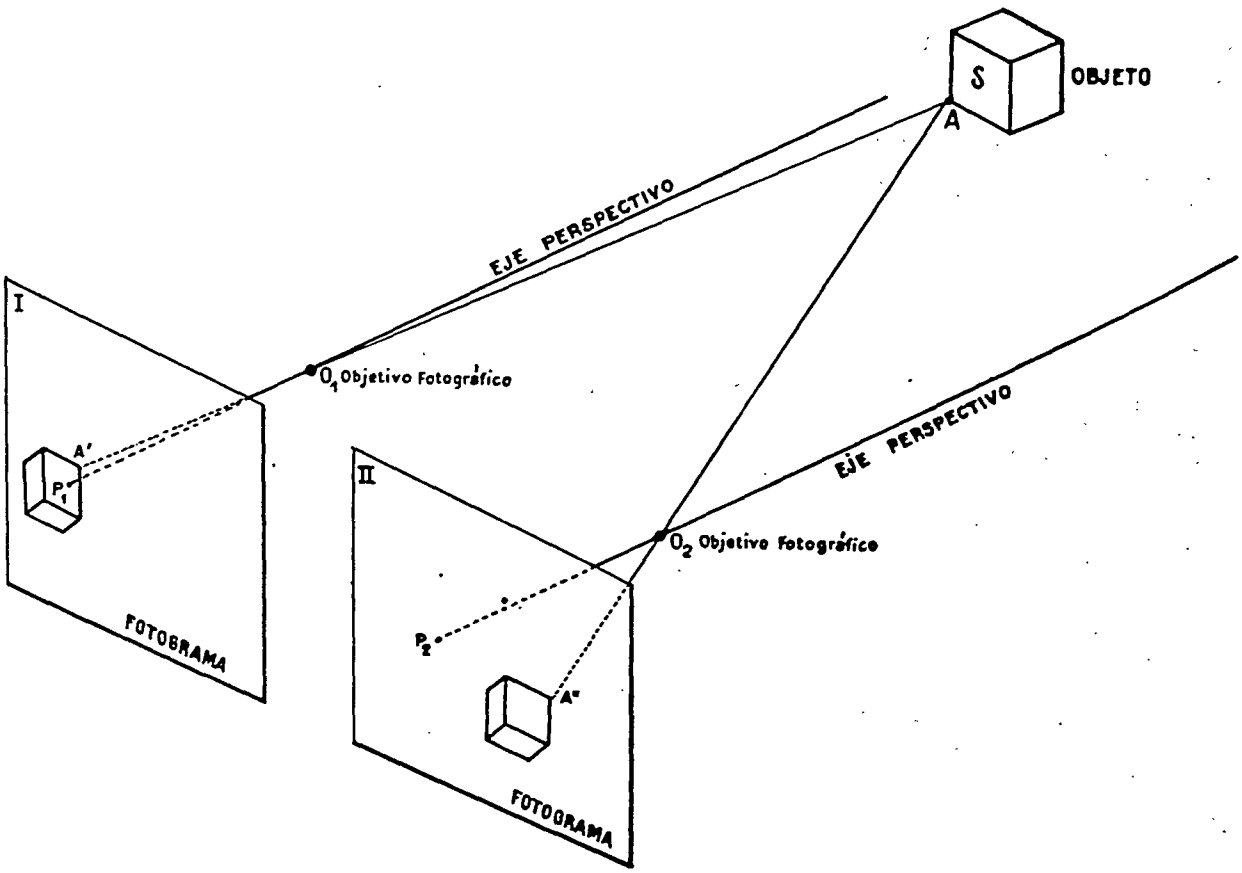

Fig. 1 (Bertotto). A diagram of the simplest way in which two photograms can be taken.

These stereoscopic photographs, from now on referred to as photograms, provide exact and different views of an object. In stereophotogrammetry, two photograms of an object are needed to reconstruct the object in three dimensions. It should be noted that the two photograms must be different; that is, taken from two different points in space, of which the relative position as well as that of the main axes of the perspectives must be accurately known; the greater this accuracy the more exact will be the reconstruction.

Figure 1 is a diagram of the simplest

way in which two photograms can be taken. These have been marked I and II. Their principal points are P_1 and P_2. The positions in space from which they are taken are O_1 and O_2 and the main axes of the perspectives are $O_1 P_1$ and $O_2 P_2$.

Figure 2 illustrates how any point, A, of the object, S, is reconstructed in space A_1, by placing the two photograms, I and II, exactly in the relative position they held at the moment of being taken, and materializing in any way (either optically or mechanically) the beams AO_1 and AO_2, which produce A_1 at their intersection.

It is obvious that in solving the problem by mechanicoptical method or by calculation, the accuracy of the reconstruction of A_1 corresponding to A will depend on the delicacy with which $A'O_1$ and $A''O_2$ have been materialized or in what way the segments P_1A' and P_2A'' have been measured. This last also necessitates the knowledge with the utmost precision of the distances of d_1 and d_2 of the photographic objectives as well as the separation of their posterior nodal points.

Having obtained the foregoing data, the numerical solution of the problem is obtained by a simple equation of proportion. The figures which are known in order to find the unknown; that is, the reconstruction of point A in space (D_A) are the following:

$$d_1 = d_2 = d$$
$$O_1 O_2 = b$$
$$P_1 A' - P_2 A'' = P_A$$

with these data, the following equation can be made:

$$\frac{D_A}{b} = \frac{d}{P_A} \text{ which gives } D_A = \frac{b \times d}{P_A}$$

Dispensing with the numerical calculation, these photograms were later made by the most perfect stereophotogrammetric instrument known up to the present—the Wild A5 Autograph. The exceptional scope of this instrument has made it possible to draw with extraordinary rapidity transverse and frontal (annular) sections of the anterior segment of the eyeball traced automatically millimeter by millimeter.

The mathematical study of the condition under which the photograms were made and the automatic reconstruction as well as the measured proofs made by the automatic counters of the wild A5 Autograph, make it possible to be certain that the alteration

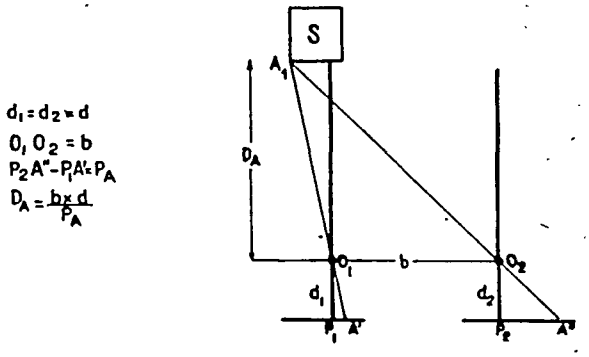

Fig. 2 (Bertotto). This illustrates how any point, A, of the object, S, is reconstructed in space at A_1, by placing the two photograms, I and II, exactly in the relative position they held at the moment of being taken.

in the reconstructed points is less than 0.02 mm. or to be even more exact 0.017 mm. This degree of accuracy will certainly be improved upon in further studies.

Study of the curves obtained by stereophotogrammetry

The camera used takes a stereoscopic photograph with an approximate ratio of 2 to 1, or double the natural size of the eye. Figure 3 is a photograph showing the conjunctiva and cornea powdered with lamp black. The position where the section must be made by the Wild A5 Autograph has been marked by a white line. Underneath the stereoscopic photograph there is a drawing showing the natural size and another three times larger (3 : 1).

In Figure 4, the distance of the different points which make up a curve are related to a plane parallel to the photograms. The measurements can be obtained in thousandths of a millimeter and at any point desired on the curve. Only a few measure-

ments taken at haphazard were established in this diagram.

Figure 5 shows an annular graph; that is, the sections were made in the frontal plane. The circular curves correspond to a center. At the side in the same figure is a diagram of its projection on a plane, with the object of making the explanation simpler. The curve obtained by joining the several projected points will correspond to

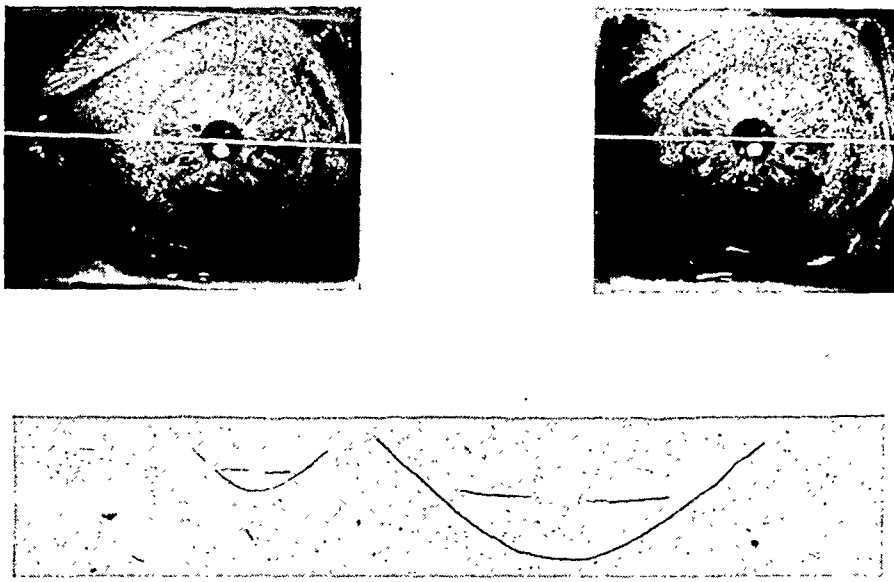

Fig. 3 (Bertotto). This shows the conjunctiva and cornea powdered with lamp black. The position where the section must be made by the Wild A5 Autograph has been marked by a white line. Underneath the stereoscopic photograph there is a drawing showing the natural size and another three times larger (3:1).

section made at a determined distance from a plane similar to that which was referred to in the previous figure, and each line corresponds to a millimeter of the photographed object going from the periphery to the

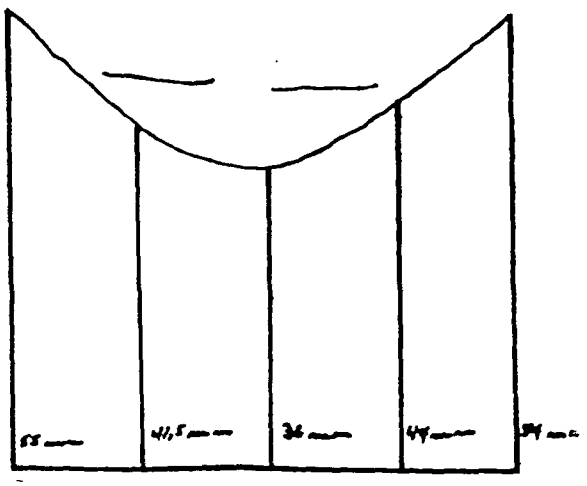

Fig. 4 (Bertotto). The distance of the different points which make up a curve are related to a plane parallel to the photograms.

a section of the eye which passes through the center of the pupil.

Figures 6 and 7 are important as they emphasize the number of serial sections of an eye, which can be made and which can be increased if necessary; they also demonstrate the need of powdering the eye. This series of curves corresponds to transverse sections through the eye from the upper part; namely, that which covers the superior segment of the eye, to the lower part of the same, passing through the center of the pupillary area; the distance between each line corresponds to one millimeter in height.

In Figure 6, the eye had been well powdered, so the necessary points for the stereophotogrammetry were obtained both in the conjunctiva and the cornea. A study of the graph shows that the curve passes from the conjunctival surface to the cornea without apparent signs of transition. In Figure 7, the cornea had not been powdered

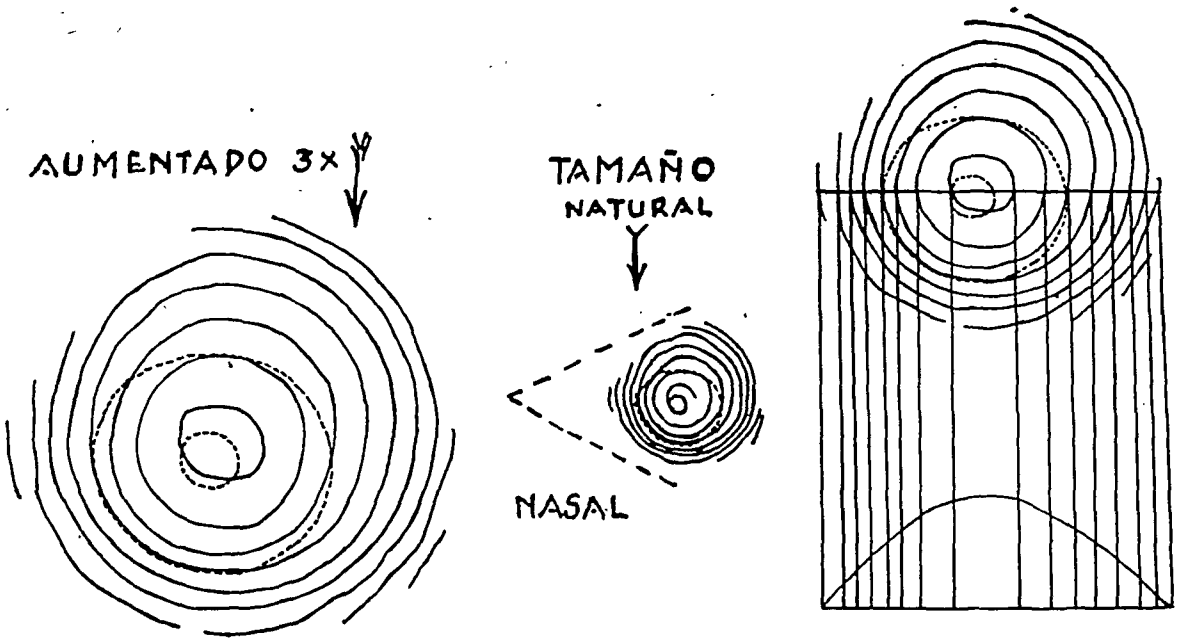

Fig. 5 (Bertotto). An annular graph with the sections made in the frontal plane.

and, therefore, since it is transparent, it has not appeared in the autographic examination. Since the distance between each section is 1 mm., it is easy to deduce that the vertical diameter of the cornea is 12 mm.

The object of Figure 8, is to demonstrate the various planes which can be obtained from a section with the Wild A5 Autograph. It represents three sections of the eye, amplified six times, and with a difference of 3 mm. in height between each section. The middle section is the one which passes approximately through the center of the pupillary area.

Examining this figure, one sees in the first place the bulbar conjunctiva and the anterior aspect of the cornea as obtained by the method under discussion. Immediately behind the curve made by the conjunctiva, there is a second curve which corresponds to the surface of the sclera; its central part, well separated from the curve of the cornea, represents the surface of the iris. In the central section, the posterior line is interrupted in its middle part where it corresponds to the pupil.

At this point attention must be drawn to the fact that the values given to the scleral

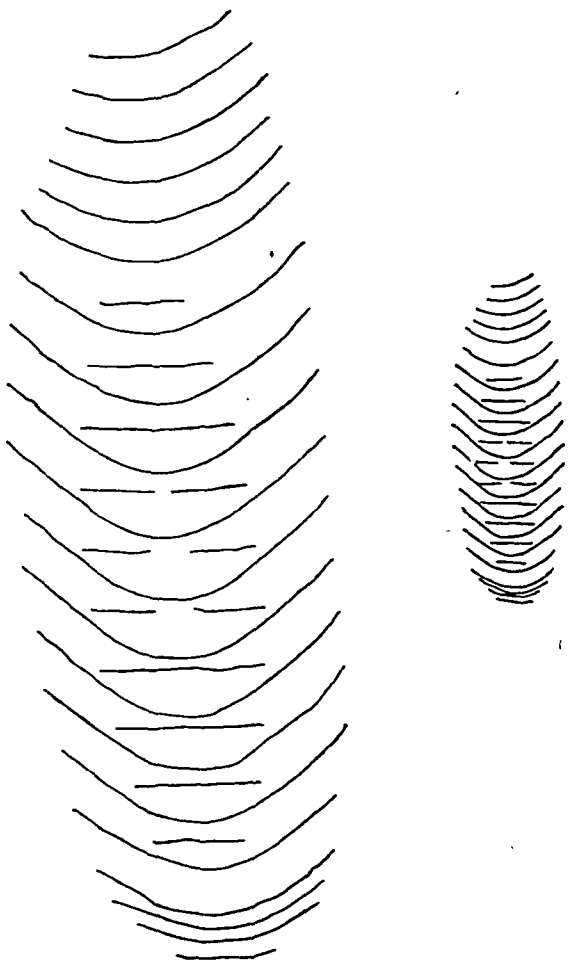

Fig. 6 (Bertotto). A study of the graph shows that the curve passes from the conjunctival surface to the cornea without apparent signs of transition.

curve and those of the surface of the iris are not accurate as no study has been made of the parallex or corneal refraction.

Figure 8 corroborates the importance of powdering the eye with lamp black, since

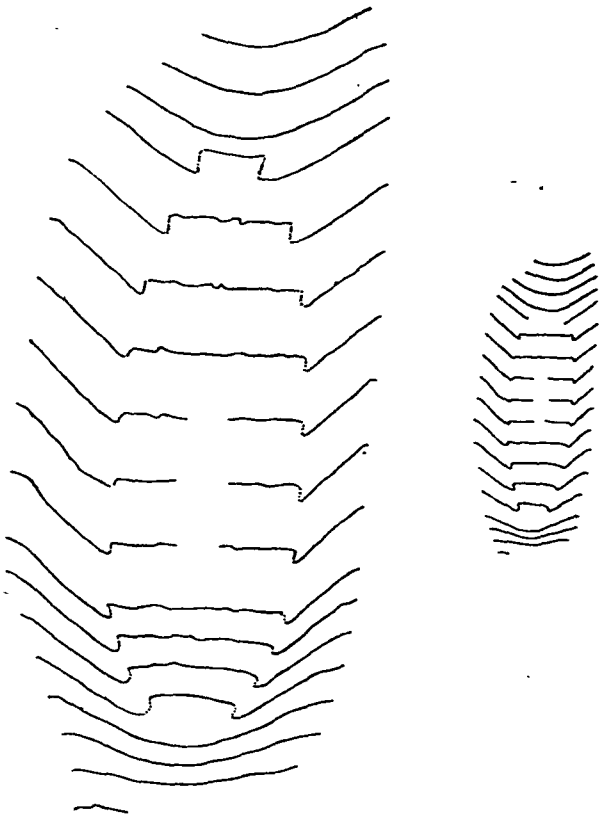

Fig. 7 (Bertotto). Since the distance between each section is 1 mm., it is easy to deduce that the vertical diameter of the cornea is 12 mm.

it demonstrates the separation between the surfaces of the conjunctiva and sclera. It also shows the importance of the surface taken as the base in making a contact lens because, if the sclera is taken, there will certainly be pressure on the vessels and subconjunctival capillaries with subsequent disturbances due to the resulting anemia.

Discussion

The majority of ophthalmologists specializing in contact lenses have abandoned the use of standard lenses, having found that a lens made on a cast of the eye affords greater probabilities of success. There is no doubt, however, that the problem is far from being solved owing to the difficulty of obtaining a perfect pattern or negative of the eyeball which if successful makes the manufacture of the contact lens relatively easy.

Without lessening the importance that casts of the eye have had in the development of the study of contact lenses, Town's opinion on their value can still be fully endorsed: "In the best of cases it is only possible to obtain a defective approximation of the eye." (*Archives of Ophthalmology,* 1940, volume 22, page 822.)

The truth is that a cast of the eye presents certain difficulties among which can be

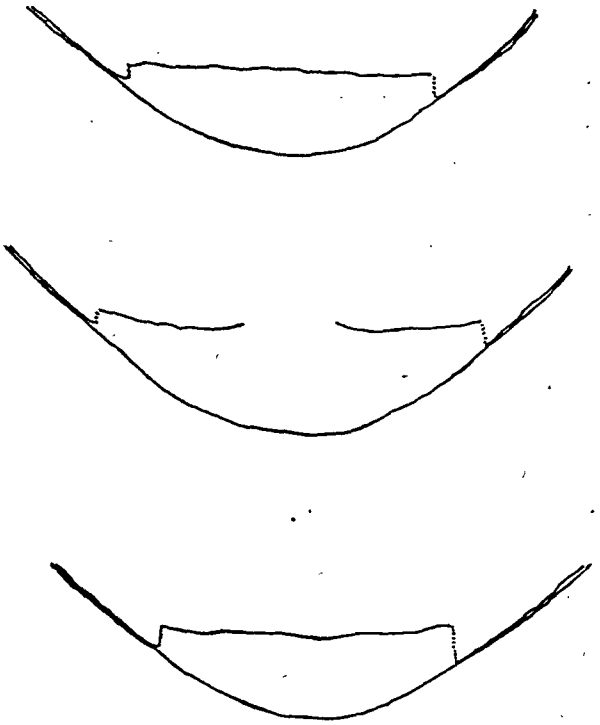

Fig. 8 (Bertotto). The object of this illustration is to demonstrate the various planes which can be obtained from a section with the Wild A5 Autograph.

mentioned: (1) Movements of the eyeball during the taking of the impression; and (2) conjunctival folds and pressure exerted on the ocular tissues.

These inconveniences are eliminated by stereophotogrammetry because there are no movements of the eyeball since the photograph is taken instantaneously, the time employed being 1/25 to 1/50 of a second. It is believed that even more rapid snapshots might be obtained if fresher plates of

greater sensitivity than those used in this study could be employed.

The conjunctival folds and pressure on the eyeball are also eliminated by this method as the only direct manipulation of the eye is the separation of the lids, the facial nerve having been previously paralyzed so as to avoid the defensive contraction of the orbicular muscle of the lids.

Apart from the great advantages which have been mentioned, the method assures that the resulting measurements will have a maximum error of only 0.02 mm. which will be improved upon as the technique is perfected, and which it is believed can be considered negligible in the manufacture of the lens, as it must rest completely on the whole surface in a uniform manner. When the contact lens follows the curves of the eyeball in their slightest detail, it will not easily become laterally displaced or rotate on its interoposterior axis. Also by this method the diameter and exact height of the cornea can be faithfully determined in any meridian desired. With all these exact data, it should be possible to obtain in all contact lenses uniform application over the perilimbic area and a perfect adaptation between the posterior surface of the lens and the vertex of the cornea.

The small number of experiments it has been possible to perform do not allow more definite conclusions as to the advantages of stereophotogrammetry applied to the anterior segment of the eyeball. When the plan of study was sketched out, it was divided into three parts as follows:

1. The obtaining of the curves which made up the anterior segment of the eye—a problem which can be considered as solved, even though it is necessary to perfect the photographic technique.

2. The transference of the curves into three dimensions; that is, the making of the cast of the eye is still being studied. The practical problem has been solved, the photocast having been obtained, but the optic part must be confirmed.

3. Having obtained the cast of the eye, a perfect fitting contact lens must be made. This last phase of the problem has not yet been approached but it should be the easiest, because of the advances which have been made both in plastics and in the manufacture of lenses.

Conclusions

1. A new method of obtaining all the curves which make up the anterior segment of the eye based on the application of stereophotogrammetry to ophthalmology is presented.

2. It is absolutely necessary to powder the eye with a contrasting medium because of the transparency of the conjunctiva and cornea.

3. The results obtained have been better than were expected since the margin of error is only 0.017 mm.

4. This method should be of great value in the manufacture of contact lenses.

THE OCULAR SYNDROME OF CATARACT AND PAPILLEDEMA IN THE MANIFEST FORM OF PARATHYROID DEFICIENCY*

DONALD J. LYLE, M.D.
Cincinnati, Ohio

A white woman, aged 53 years, was referred because of failing vision. Her medical history previous to her 49th year was irrelevant. At that time she had undergone a thyroidectomy. Since the operation she had lost her hair, her skin was dry, and her nails were brittle. Her chief concern was her dimming vision. She said that she had been given calcium following the operation but she had not taken any for the past year.

Eye examination revealed vision to be: R.E., 20/200, corrected to 20/100; L.E., 20/50, corrected to 20/40. Diffuse posterior subcortical opacities were found in both lenses. The fundi were still discernible and appeared normal. The pupils were equal and reacted normally to light and accommodation. The extraocular muscle balance was normal. The visual fields were normal. There was a slight elevation of the intraocular pressure above the upper limit of normal.

Diagnosis. Because of the history and the presence of a cortical type of cataract, a tentative diagnosis of postoperative parathyroid deficiency was made. A calcium test showed 8.1 mg. per 100 cc. of blood. Miotics were prescribed, and the patient was returned to her physician, who was asked to make further tests to substantiate the diagnosis. In addition to the low calcium, positive Chvostek and Trousseau signs established the diagnosis of latent parathyroid deficiency.

During the three-year interval between the first examination and the cataract extraction, the lens opacities increased to maturity with loss of useful vision. The intraocular pressure fluctuated, apparently rising with the reduction of calcium and falling when the calcium returned to a normal level. At first, the impression was that the increased intraocular pressure was induced by a primary noninflammatory glaucoma. Later, a secondary type of glaucoma, the result of disturbances from the same causes which led to the development of the lenticular opacities, was thought most likely, due to the fact that the pressure fluctuated with the calcium-blood balance.

Cataract operations. The cataract was removed from the right eye by an intracapsular operation with no complications. The immediate convalescence was uneventful and a corrected vision of 20/30 was obtained within six weeks. After this time, the intraocular pressure began to cause steaming of the cornea. The tension was controlled by a cyclodialysis operation. Later, a keratoconjunctivitis produced a permanent opacity in the center of the cornea. This may have been a type of parathyroid lesion described by Leonard[9] or may have been the result of the corneal damage from the glaucoma or from the frequent tonometric instrumentation. The corrected vision was reduced to about 20/70 as a result of the complications. Throughout the postoperative period, the fundus appeared normal.

Four months later, the cataract was removed from the left eye. Just prior to this operation, the calcium level was determined and found at 8.6 mg. and raised to between 9 and 10 mg. per 100 cc. of blood. Again the operation, as with the right eye, was uncomplicated, and the hospital convalescence was uneventful until the ninth day, when the following episode occurred.

Complications. The patient, lying in bed, was heard to emit a loud, piercing scream and was found in a generalized convulsion lasting approximately four minutes. Dyspnea and cyanosis followed but disappeared within the hour, leaving the patient in a
